### Independent Learning Activities 894

The joints, ligaments, and muscles of the ankle and foot provide stability and mobility in the terminal structures of the lower extremity. During standing, the foot bears the weight of the body with minimum muscle energy expenditure. The foot must also be both pliable and relatively rigid depending on various functional demands. This versatility allows the foot

to absorb forces, accommodate to uneven surfaces, and serve as a structural lever to propel the body forward during walking and running.

A clear understanding of the complex anatomy and kinematics of the ankle and foot is important when treating impairment in this region of the body. The first section of this

chapter reviews highlights of these areas the reader should know and understand. The second section contains guidelines for the management of disorders and surgeries in the foot and ankle region, and the third section describes exercise interventions for this region. Chapters 10 through 13 present general information on principles of management; the reader should be familiar with the material in these chapters and should have a background in examination and evaluation in order to effectively design a therapeutic exercise program to improve ankle and foot function in patients with impairments from injury, pathology, or recovery following surgery.

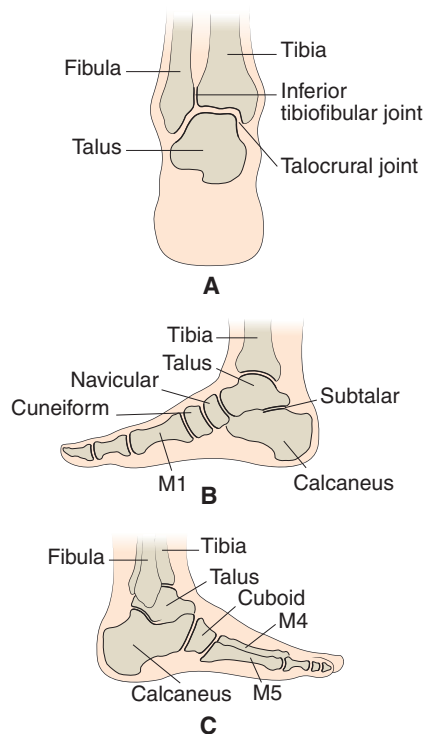

## Structure and Function of the Ankle and Foot

The bones of the ankle and foot consist of the distal tibia and fibula, 7 tarsals, 5 metatarsals, and 14 phalanges (Fig. 22.1).

## Structural Relationships and Motions

### Anatomical Characteristics

The leg is structurally adapted to transmit ground reaction forces from the foot upward to the knee joint and femur during upright activities. Depending on the activity, the foot and

**FIGURE 22.1** Bones of the ankle and foot. (A) Anterior view of the lower leg and ankle, (B) medial and (C) lateral views of the ankle and foot.

ankle provide a foundation of either stability or motion to the distal extremity that assists the leg in managing forces and demands. The motions in the ankle and foot are defined using primary plane and triplanar descriptors.

### Leg

The tibia and fibula make up the leg. These two bones are bound together by an interosseous membrane between the bones, strong anterior and posterior inferior tibiofibular ligaments that hold the distal tibiofibular articulation together, and a strong capsule that encloses the proximal tibiofibular articulation. Unlike the radius and ulna in the upper extremity, the tibia and fibula do not rotate around each other, but there is slight movement between the two bones that allows greater ankle joint motion.

### Foot

The foot is divided into three segments: hindfoot, midfoot, and forefoot.

**Hindfoot.** The talus and calcaneus make up the posterior foot segment.

**Midfoot.** The navicular, cuboid, and three cuneiforms make up the middle foot segment.

**Forefoot.** Five metatarsals and 14 phalanges make up the anterior foot segment. Each toe has 3 phalanges except for the large toe, which has 2.

## Motions of the Foot and Ankle Defined

### Primary Plane Motions

Although motions in the foot and ankle do not occur purely in the cardinal planes, they are still defined as follows:<sup>71,211,293</sup>

**Sagittal plane motion around a frontal (coronal axis).** *Dorsiflexion* is movement in a dorsal direction, which decreases the angle between the leg and dorsum of the foot, and *plantarflexion* is movement in a plantar direction. Motion occurring at the toes may also be called dorsiflexion, or extension, and plantarflexion, or flexion.

**Frontal plane motion around a sagittal (anteroposterior) axis.** *Inversion* is inward turning of the foot, and *eversion* is outward turning. Normally, an inward and outward motion is described by the terms abduction and adduction, but because the foot is at a right angle to the leg, the terms abduction and adduction are not used for this frontal plane motion.

**Transverse plane motion around a vertical axis.** *Abduction* is movement away from the midline, and *adduction* is movement toward the midline.

### Triplanar Motion

Triplanar motion occurs around an oblique axis at each articulation of the ankle and foot. The definitions are descriptive of the movement of the distal bone on the proximal bone. When the proximal bone moves on the stabilized distal bone, as occurs

in weight bearing, the motion of the proximal bone is opposite, although the relative joint motion is the same as defined.

**Pronation.** Pronation is a combination of dorsiflexion, eversion, and abduction. During weight bearing, pronation of the subtalar and transverse tarsal joints causes the arch of the foot to lower, and there is a relative supination of the forefoot with dorsiflexion of the first metatarsal and plantarflexion of the fifth metatarsal. This is the loose-packed or mobile position of the foot and is assumed when the foot absorbs the impact of weight bearing and rotational forces of the rest of the lower extremity and when the foot conforms to the ground.<sup>71</sup>

**Supination.** Supination is a combination of plantarflexion, inversion, and adduction. In the closed-chain, weight-bearing foot, supination of the subtalar and transverse tarsal joints with a pronation twist of the forefoot (plantarflexion of the first metatarsal and dorsiflexion of the fifth metatarsal) increases the arch of the foot and is the close-packed or stable position of the joints of the foot. This is the position the foot assumes when a rigid lever is needed to propel the body forward during the push-off phase of ambulation.<sup>211,293</sup>

**NOTE:** The terms *inversion* and *supination*, as well as *eversion* and *pronation*, are often used interchangeably.<sup>252</sup> This text uses the discrete terms defined above.

## Joint Characteristics and Arthrokinematics: Leg, Ankle, and Foot

The characteristics of each joint in the leg, ankle, and foot dictate how they contribute to the function of the ankle and foot complex.<sup>211,293</sup>

### Tibiofibular Joints

Anatomically, the superior and inferior tibiofibular joints are separate from the ankle, but they provide accessory motions that allow greater movement at the ankle. Fusion or immobility

in these joints impairs ankle function. The strong mortise formed by the distal ends of the tibia and fibula makes up the proximal surface of the ankle (talocrural) joint.

**Superior tibiofibular joint characteristics.** The superior tibiofibular joint is a plane synovial joint made up of the fibular head and a facet on the posterolateral aspect of the rim of the tibial condyle. The facet faces posteriorly, inferiorly, and laterally. Although near the knee joint, it has its own capsule that is reinforced by the anterior and posterior tibiofibular ligaments.

**Inferior tibiofibular joint characteristics.** The inferior tibiofibular joint is a syndesmosis with fibroadipose tissue between the two bony surfaces. This strong articulation is supported by the crural tibiofibular interosseous ligament and the anterior and posterior tibiofibular ligaments.

**Accessory motions.** With dorsiflexion and plantarflexion of the ankle, there are slight accessory movements of the fibula. The direction of movement is variable depending on facet orientation of the proximal tibiofibular joint and elasticity in the tibiofibular ligaments. However, movement is necessary to allow full range of the talus in the mortise during ankle dorsiflexion.

### Ankle (Talocrural) Joint

**Characteristics.** The ankle (talocrural) joint is a synovial hinge joint formed by the mortise (distal end of the tibia and the tibial and fibular malleoli) and trochlea (dome) of the talus. It is enclosed by a relatively thin and weak capsule. It, along with the subtalar joint, is supported medially by the medial collateral (deltoid) ligament and laterally by the lateral collateral (anterior and posterior talofibular and calcaneofibular) ligaments (Fig. 22.2).

The fibular malleolus extends farther distally and posteriorly than the tibial malleolus, so the mortise angles outward and downward. This causes the axis of motion to be rotated laterally 20° to 30° and inclined downward 10°. The surface of the mortise is congruent with the articulating surface of the body of the talus.

**FIGURE 22.2** Ligaments of the ankle and foot. (A) Medial view, (B) lateral view, and (C) posterior (cross-sectional) view. (From Martin, RL, and Kivlan, B: *The ankle and foot complex*. In Levangie, PK, and Norkin, CC (eds): *Joint Structure and Function*, ed. 5. Philadelphia: F.A. Davis, A and B, p 445; C, p 449, with permission.)

The surface of the talus is wedge-shaped, wider anteriorly, and also cone-shaped, with the apex pointing medially. As a result of the orientation of the axis and the shape of the talus when the foot dorsiflexes, the talus also abducts and slightly everts (pronation). When the foot plantarflexes, the talus also adducts and slightly inverts (supination). Dorsiflexion is the close-packed, stable position of the talocrural joint; plantarflexion is the loose-packed position.

### CLINICAL TIP

It is important to recognize that the stable positions of the ankle and the foot do not always coincide. For example, when a person walks in high heels, the ankle joint is more vulnerable to injury, because the talocrural joint is in a less stable, plantarflexed position while the subtalar and transverse tarsal joints are in a close-packed (rigid) position.

**Arthrokinematics.** The concave articulating surface is the mortise; the convex articulating surface is the body of the talus. With physiological motions of the foot, the articulating surface of the talus slides in the opposite direction. The arthrokinematics are summarized in ONLINE Box 22.1 and available on the FA Davis web site related to this textbook.

### Subtalar (Talocalcaneal) Joint

**Characteristics.** The subtalar (talocalcaneal) joint is a complex joint with three articulations between the talus and calcaneus. It has an oblique axis of motion that lies approximately 42° from the transverse plane and 16° from the sagittal plane, allowing the calcaneus to pronate and supinate in a triplanar motion on the talus.

Frontal plane inversion (turning heel inward) and eversion (turning heel outward) can be isolated only with passive motion. The subtalar joint is supported by the medial and lateral collateral ligaments, which also support the talocrural joint; the interosseous talocalcaneal ligament in the tarsal canal; and the posterior and lateral talocalcaneal ligaments (see Fig. 22.2). In closed-chain activities, the joint attenuates the rotatory forces between the leg and foot so that, normally, excessive inward or outward turning of the foot does not occur as the foot maintains contact with the supporting surface.

Of the three articulations between the talus and calcaneus, the posterior is separated from the anterior and middle by the tarsal canal. The canal divides the subtalar joint into two joint cavities. The posterior articulation has its own capsule. The anterior articulations are enclosed in the same capsule as the talonavicular articulation, forming the talocalcaneonavicular joint. Functionally, these articulations work together.

**Arthrokinematics.** The facet on the bottom of the talus in the posterior compartment is concave, and the opposing facet on the calcaneus is convex. The facets of the anterior

and middle articulations on the talus are convex, whereas the opposing facets on the calcaneus are concave. With open-chain physiological motions of the subtalar joint, the convex posterior portion of the calcaneus slides opposite to the motion; the concave anterior and middle facets on the calcaneus slide in the same direction, similar to turning a doorknob. With the component motion of eversion, as the calcaneus swings laterally, the posterior articulating surface slides medially, and with inversion, the posterior articulating surface slides laterally.

### Talonavicular Joint

**Characteristics.** Anatomically and functionally, the talonavicular joint is part of a complex articulation between the talus and navicular as well as the anterior and medial facets of the subtalar joint. It is supported by the spring, the deltoid, the bifurcate, and the dorsal talonavicular ligaments. The triplanar motions of the navicular on the talus function with the subtalar joint, resulting in pronation and supination.

During pronation, in the weight-bearing foot, the head of the talus drops plantarward and medially, resulting in a pliable foot and decreased medial longitudinal arch. In essence, as the calcaneus everts, it cannot also dorsiflex and abduct with the foot on the ground, so the talus plantarflexes and inverts on the calcaneus. This downward and inward motion of the talar head results in an upward and outward motion of the navicular and a flattening of the arch. During supination, the opposite occurs, resulting in a structurally stable foot and an increased medial longitudinal arch. The calcaneus inverts, and the talus dorsiflexes and everts, resulting in the navicular plantarflexing, inverting, and adducting.

**Arthrokinematics.** The head of the talus is convex; the proximal articulating surface of the navicular is concave. With physiological motions of the foot, the navicular slides in the same direction as the motion of the forefoot. In the open-chain motion of pronation, the navicular slides dorsally and laterally (abduction and eversion), resulting in a flattening of the medial longitudinal arch. With supination, the navicular slides in a plantar and medial direction (adduction and inversion) (see ONLINE Box 22.1).

### Transverse Tarsal Joint

**Characteristics.** The transverse tarsal joint is a functionally compound joint between the hindfoot and midfoot that includes the anatomically separate talonavicular and calcaneocuboid joints. The talonavicular joint is described in the previous section. The calcaneocuboid joint is saddle-shaped. The transverse tarsal joint participates in the triplanar pronation/supination motions of the foot and makes compensatory movements to accommodate variations in the ground. Passive accessory motions include abduction/adduction, inversion/eversion, and dorsal/plantar gliding.

**Arthrokinematics.** The articulating surface of the calcaneus is convex in a dorsal-to-plantar direction and concave in a

medial-to-lateral direction. The articulating surface of the cuboid is reciprocally concave and convex.

### Remaining Intertarsal and Tarsometatarsal Joints

The remaining intertarsal and tarsometatarsal joints are plane joints that reinforce the function of transverse tarsal joints and, during weight bearing, help regulate the position of the forefoot on the ground.

### Metatarsophalangeal and Interphalangeal Joints of the Toes

The metatarsophalangeal (MTP) and interphalangeal (IP) joints of the toes are the same as the metacarpophalangeal and IP joints of the hand except that, in the toes, extension range of motion (ROM) is more important than flexion. Extension of the MTP joints is necessary for normal walking. Also, unlike the thumb, the large toe does not function separately from the other digits.

## Function of the Ankle and Foot

### Structural Relationships

**Interdependence of leg and foot motions.** In the weight-bearing foot, subtalar motion and tibial rotation are interdependent. Supination of the subtalar joint results in or is caused by lateral rotation of the tibia, and conversely, pronation of the subtalar joint results in or is caused by medial rotation of the tibia.<sup>211,293</sup>

**Arches.** The arches of the foot are visualized as a twisted osteoligamentous plate, with the metatarsal heads being the horizontally placed anterior edge of the plate, and the calcaneus being the vertically placed posterior edge. The twist causes the longitudinal and transverse arches. When the foot is bearing weight, the plate tends to untwist and flatten the arches slightly.<sup>211</sup>

- Primary support of the arches comes from the spring ligament, with additional support from the long plantar ligament, the plantar aponeurosis, and short plantar ligament (see Fig. 22.2). During push-off in gait, as the foot plantarflexes and supinates and the MTP joints go into extension, increased tension is placed on the plantar aponeurosis, which helps increase the arch. This is called the windlass effect.
- In the normal static foot, muscles do little to support the arches, yet without muscle tension, the passive supports stretch and foot pronation increases under weight-bearing loads. In this respect, muscles contribute to arch support during ambulation.

**Effect on posture.** During standing with weight equally distributed in both lower extremities, if one foot/ankle complex

is more pronated than the other, the overall effect is a frontal plane asymmetry with a “short leg” on that side. All typical landmarks (crest of the ilium, greater trochanter, popliteal crease, head of the fibula, and medial malleolus) on the side of the pronated foot are slightly lower.

**Abnormal foot postures.** A person with a varus deformity of the calcaneus (observed nonweight bearing) may compensate by standing with a pronated (or everted) calcaneus posture.<sup>72</sup> Internal rotation of the leg, valgus at the knee, and internal rotation of the femur may also be seen with the pronated foot posture. The terms *pes planus*, *pronated foot*, and *flat foot* are often used interchangeably to mean a pronated posture of the hindfoot and decreased medial longitudinal arch. *Pes cavus* and *supinated foot* describe a high-arched foot.<sup>252</sup>

### Muscle Function in the Ankle and Foot

**Plantarflexors.** Plantarflexion is caused primarily by the two-joint gastrocnemius muscle and the one-joint soleus muscle; these muscles attach to the calcaneus via the Achilles tendon.

**Secondary plantarflexors.** Other muscles passing posteriorly to the axis of motion of plantarflexion contribute minimally to that motion, but they have other functions.

- Tibialis posterior is a strong *supinator* and *invertor* that supports the medial longitudinal arch during weight bearing<sup>247</sup> and controls and reverses pronation during the loading response of gait.
- The flexor hallucis longus and flexor digitorum longus muscles flex the toes and help support the medial longitudinal arch. To prevent clawing of the toes (MTP extension with IP flexion), intrinsic muscles must also function at the MTP joints.
- The fibularis longus and brevis muscles primarily *pronate* the foot at the subtalar joint, and the longus gives support to the transverse and lateral longitudinal arches during weight-bearing activities.

**Dorsiflexors.** Dorsiflexion of the ankle is caused by the tibialis anterior muscle (which also inverts the ankle), the extensor hallucis longus and extensor digitorum longus (which also extend the toes), and the fibularis tertius muscles.

**Intrinsic muscles.** Intrinsic muscles of the foot function similarly to those of the hand (except there is no thumb-like function in the foot). In addition, they provide support to the arches during gait.

**Stability in standing.** During normal standing, the gravitational line is anterior to the axis of the ankle joint, creating a dorsiflexion moment. The soleus muscle contracts to counter the gravitational moment through its pull on the tibia. Other extrinsic foot muscles help stabilize the foot during postural sway.

## The Ankle/Foot Complex and Gait

During the normal gait cycle, the ankle goes through a ROM of 32° to 35°. Approximately 7° of dorsiflexion occurs at the end of midstance, as the heel begins to rise, and 25° of plantarflexion occurs at the end of stance (toe off).<sup>254</sup>

### Function of the Ankle and Foot Joints During Gait

The shock-absorbing, terrain-conforming, and propulsion functions of the ankle and foot include the following:<sup>211,254,267</sup>

- During the *loading response* (heel strike to foot flat), the heel strikes the ground in neutral or slight supination. As the foot lowers to the ground, it begins to pronate to its loose-packed position. The entire lower extremity rotates inward, reinforcing the loose-packed position of the foot. With the foot in a lax position, it can conform to variations in the ground contour and absorb some of the impact forces as the foot is lowered.
- Once the foot is fixed on the ground, dorsiflexion begins as the tibia advances over the foot. The tibia also rotates internally, which reinforces pronation of the subtalar joint and loose-packed position of the foot.
- During *midstance* and continuing through *terminal stance*, the tibia begins to rotate externally, initiating supination of the hindfoot and locking of the transverse tarsal joint. This brings the foot into its close-packed position, which is reinforced as the heel rises and the foot rocks up onto the toes, causing toe extension and tightening of the plantar aponeurosis (windlass effect). This stable position converts the foot into a rigid lever, ready to propel the body forward as the ankle plantarflexes from the pull of the gastrocnemius-soleus muscle group.

### Muscle Control of the Ankle and Foot During Gait

Muscles of the ankle and foot function in the following manner during the gait cycle.<sup>211,254,267</sup>

**Ankle dorsiflexors.** The ankle dorsiflexors function during the initial foot contact and loading response (heel strike to foot flat) to counter the plantarflexion torque and to control the lowering of the foot to the ground. They also function during the swing phase to keep the foot from plantarflexing and dragging on the ground. With loss of the dorsiflexors, foot slap occurs at initial foot contact, and the hip and knee flex excessively during swing to prevent the toes from catching on the ground.

**Ankle plantarflexors.** Early in stance, the ankle plantarflexors function eccentrically to control the rate of forward

movement of the tibia. Then, at around 40% of the cycle (midstance), there is a burst of concentric activity to initiate plantarflexion of the ankle for push off. Loss of function results in a slight lag of the lower extremity during terminal stance with no push-off.

**Ankle evertors.** Contraction of the peroneus longus muscle late in the stance phase facilitates transfer of weight from the lateral to the medial side of the foot. It also stabilizes the first ray and facilitates the pronation twist of the tarsometatarsal joints, as increased supination occurs in the hindfoot.

**Ankle inverters.** The tibialis anterior helps control the pronation force on the hindfoot, and the tibialis posterior helps control the pronation force on the medial longitudinal arch during the loading response of gait.

**Intrinsic muscles.** The intrinsic muscles support the transverse and longitudinal arches during gait.

## Referred Pain and Nerve Injury

Several major nerves terminate in the foot. Injury or entrapment of the nerves may occur anywhere along their course—from the lumbosacral spine to near the nerves' termination. For treatment to be effective, it must be directed at the source of the problem. Therefore, a thorough history is obtained, and an examination is performed when the patient reports referred pain patterns, sensory changes, or muscle weakness. For a detailed description and illustrations of referred pain patterns and peripheral nerve innervations in the foot and ankle region, see Chapter 13 and related figures.

### Major Nerves Subject to Pressure and Trauma

**Common fibular nerve.** Pressure on the common fibular (formerly common peroneal) nerve may occur as it courses laterally around the fibular neck and passes through an opening in the fibularis longus muscle.

**Posterior tibial nerve.** Entrapment in the tarsal tunnel, causing tarsal tunnel syndrome, may occur from a space-occupying lesion posterior to the medial malleolus.

**Plantar and calcaneal nerves.** These branches of the posterior tibial nerve may become entrapped as they turn under the medial aspect of the foot and pass through openings in the abductor hallucis muscle. Overpronation presses the nerves against these openings. Irritation of the nerves may elicit symptoms similar to those of acute foot strain (tenderness at the posteromedial plantar aspect of the foot), painful heel (inflamed calcaneal nerve), and pain in a pes cavus foot.

## Common Sources of Segmental Sensory Reference in the Foot

The foot is the terminal point for the L4, L5, and S1 nerve roots coursing through the terminal branches of the fibular and tibial nerves. Referred pain may occur with irritation to tissues derived from the same spinal segments, or sensory changes from irritation or damage to these nerve roots (see Fig. 13.2).

## Management of Foot and Ankle Disorders and Surgeries

To make sound clinical decisions when managing patients with foot and ankle disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions, and to correctly identify impairments, activity limitations, and participation restrictions. In this section, common pathologies and surgeries are presented and the conservative and postoperative management of these conditions are described using principles of tissue healing and exercise intervention.

## Joint Hypomobility: Nonoperative Management

### Common Joint Pathologies and Etiology of Symptoms

Pathologies such as rheumatoid arthritis (RA), juvenile rheumatoid arthritis (JRA), and degenerative joint disease (DJD) will affect the foot and ankle complex, as will acute joint reactions after trauma, dislocation, or fracture. Postimmobilization contractures and adhesions can develop in the joint capsules and surrounding tissues when a joint is immobilized in a cast or orthosis for a period of time. The reader is referred to Chapter 11 for background information on arthritis, postimmobilization stiffness, and etiology of symptoms. The following section is specific to joint conditions of the ankle and foot.

**RA.** Pathology of the foot and ankle as the result of RA commonly affects the forefoot early in the disease process; the hindfoot later; and, least frequently, the ankle.<sup>146,214</sup> RA in the MTP, subtalar, and talocrural joints of the foot can lead to progressive instabilities and painful deformities such as hallux valgus and subluxation of the metatarsal heads. Tendon rupture within the foot and ankle may also result from chronic inflammation and can contribute to deformity.<sup>146</sup>

**DJD and joint trauma.** Degenerative symptoms occur in joints that are repetitively traumatized, and acute joint symptoms are often seen in conjunction with ankle sprains,

chronic instability, or fracture. Posttraumatic arthritis leading to DJD is by far the most common type of arthritis affecting the ankle, accounting for approximately 70% to 80% of all ankle arthritis. In contrast, primary osteoarthritis, common in the hip and knee, is rare in the ankle, even in the older adult population.<sup>214,346</sup>

**Postimmobilization stiffness.** Contractures and adhesions in the capsule and surrounding periarticular soft tissues may occur any time the joint is immobilized after a fracture or surgery.

**Gout.** Symptoms commonly affect the MTP joint of the great toe, causing pain during terminal stance, resulting in decreased stance time and lack of smooth push-off.

### Common Impairments of Structure and Function, Activity Limitations, and Participation Restrictions

In RA, many of the impairments and deformities listed here occur with progression of the disease.<sup>146,308</sup> With DJD and postimmobilization stiffness, only the affected joint(s) is limited.<sup>44</sup> Activity limitations and participation restrictions occur primarily as a result of loss of weight-bearing abilities.

- **Restricted motion.** When symptoms are acute, the patient experiences swelling and restricted, painful motion, particularly during weight-bearing activities. When symptoms are chronic, there is restricted motion, decreased joint play, and a firm capsular end-feel in the affected joint.
- **Proximal and distal tibiofibular joints.** Restricted accessory motion in these joints can occur with periods of immobilization and limit ankle and subtalar joint motion.
- **Talocrural joint.** Passive plantarflexion is more limited than dorsiflexion (unless the gastrocnemius-soleus muscle group also is shortened, in which case dorsiflexion is limited accordingly).<sup>57</sup>
- **Subtalar, transverse tarsal, and tarsometatarsal joints.** Progressive limitation of supination develops until eventually the joint fixes in pronation with flattening of the medial longitudinal arch.<sup>57</sup> The close-packed position of the tarsals (supination) becomes more and more difficult to assume during the terminal stance (push-off) phase of gait. Moderate to severe foot pain is experienced with midfoot arthritis, especially during weight bearing.<sup>277</sup>
- **MTP joint of the large toe.** Gross limitation of extension and some limitation of flexion develop; the rest of the MTP joints are variable. Lack of extension restricts the terminal stance phase of gait with an inability to rock up onto the metatarsal heads. This exacerbates the pronation posture and inability to supinate the foot during push-off in gait.
- **Alignment deformities.** Deformities occur due to a variety of factors including but not limited to muscle imbalances,

tendon rupture, faulty footwear, trauma, and heredity. Common deformities of the forefoot are described in Box 22.1.<sup>205,308</sup>

- **Muscle weakness and decreased muscular endurance.** Inhibition resulting from pain and relatively limited use of the extremities leads to impaired muscle function.
- **Impaired balance and postural control.** The sensory receptors in the ankle joints and ligaments, as well as in the muscle spindles, provide important information for using the *ankle strategy* for maintaining balance. The ankle strategy is used in balance control during perturbations (See Chapter 8). Faulty feedback and balance deficits occur when there is instability, muscle impairments, or arthritis.
- **Increased frequency of falling.** Impaired balance or a sense of instability (giving way) of the ankle may lead to frequent falling or fear of falling, thus restricting community outings.<sup>214</sup>
- **Painful weight bearing.** When symptoms are acute, weight-bearing activities are painful, preventing independent ambulation and causing difficulty in rising from a chair and ascending and descending stairs.
- **Gait deviations.** With pain during weight bearing, there is a short stance phase, reduced single limb support, and decreased stride length on the side of involvement.

### BOX 22.1 Common Arthritis-Related Forefoot Deformities

- **Hallux valgus.** This deformity in the great (large) toe develops as the proximal phalanx shifts laterally toward the second toe. Eventually the flexor and extensor muscles of the great toe shift laterally and further accentuate the deformity. The bursa over the medial aspect of the metatarsal head may become inflamed and the bone may hypertrophy, causing a painful bunion.
- **Hallux limitus/hallux rigidus.** Narrowing and eventual obliteration of the first MTP joint space occur with progressive loss of extension. This affects terminal stance by not allowing the foot to roll over the metatarsal heads and great toe for normal push-off. Instead, the individual turns the foot outward and rolls over the medial aspect of the large toe. This faulty pattern accentuates hallux valgus and foot pronation, and usually the MTP joint is quite painful.
- **Dorsal subluxation/dislocation of the proximal phalanges on the metatarsal heads.** If this occurs, the fat pad, which normally is under the metatarsal heads, migrates dorsally with the phalanges, and the protective cushion during weight bearing is lost, leading to pain, callus formation, and potential ulceration.
- **Claw toe (MTP hyperextension and IP flexion) and hammer toe (MTP hyperextension, PIP flexion, and DIP hyperextension).** These deformities result from muscle imbalances between the intrinsic and extrinsic muscles of the toes. Friction from shoes may cause calluses to form where the toes rub.

Because of the restricting motion and loss of effective plantarflexion and supination in the arthritic foot as well as pain in the forefoot area under the metatarsal heads, push-off is ineffective during terminal stance. Little or no heel rise occurs; instead, the person lifts up the involved foot to initiate the swing phase.

- **Decreased ambulation.** Because of decreased ankle and foot mobility and resulting decreased length of stride, distance and speed of ambulation are decreased; assistive devices may be necessary for ambulation. If pain, balance, or restricted motion is severe, a wheelchair may be required for mobility.

## Joint Hypomobility: Management—Protection Phase

The interventions selected for management depend on the signs and symptoms present. For acute problems, follow the general outline presented in Chapter 10 and summarized in Box 10.1. Suggested interventions for the various goals are described in this section.<sup>158,214,308</sup> Box 22.2 lists the general non-operative intervention options for individuals with arthritis.

### Educate the Patient and Provide Joint Protection

- Teach a home exercise program at the level of the patient's abilities.
- Teach the patient signs of systemic fatigue (especially in RA), local muscle fatigue, and joint stress and ways to modify exercises and activities to remain active within safe levels.
- Emphasize the importance of daily ROM and endurance activities.
- Educate on joint protection, specifically the need to avoid faulty foot and ankle postures and to protect the feet from the deforming, weight-bearing forces and trauma imposed by improperly fitting footwear.
- If necessary, instruct the patient in safe use of assistive devices to decrease the effects of weight bearing and pain.

### Decrease Pain

In addition to physician-prescribed medication, intra-articular injections of corticosteroids or nonsteroidal anti-inflammatory

### BOX 22.2 Nonoperative Interventions for Ankle Arthritis<sup>108,242</sup>

- Nonsteroidal anti-inflammatory agents
- Corticosteroid injections
- Viscosupplementation
- Physical therapy
- Activity modification
- Orthotics

medications and therapeutic use of modalities, the following are used to manage painful symptoms:

- **Manual therapy techniques.** Gentle grade I or II distraction and oscillation techniques may inhibit pain and move synovial fluid for nutrition within the involved joints.
- **Orthotic devices.** Orthotic shoe inserts and well-constructed shoes help protect the joints by providing support and realigning forces.<sup>158,277</sup> Such support has been shown to decrease pain and improve functional mobility. An orthosis or bracing may also be used to stabilize an arthritic joint.

### FOCUS ON EVIDENCE

Kavlak and colleagues<sup>158</sup> reported the effects of prescribed orthotic devices in 18 patients with RA (no control group) and a variety of bilateral foot deformities, including pes planus, hallux valgus, hammer toe, subluxation of the metatarsal heads, and others. All patients in the study were community walkers with no history of foot or ankle surgery. All patients were prescribed custom-made orthotic inserts and shoe modifications, such as a medial longitudinal arch support, metatarsal pad, or heel and forefoot wedge, to meet their individual needs. Pain, temporal-distance characteristics of gait, and energy expenditure during walking were measured before and after the patients had been wearing the custom orthoses for 3 months. There was a significant reduction in pain and energy cost during ambulation and increases in step and stride length after use of the orthotic devices for 3 months. There were no significant changes in foot angle or the width of the base of support. The authors concluded that appropriately prescribed orthoses and shoe modifications were important elements of nonoperative treatment of foot pain and impaired gait in patients with RA.

### Maintain Joint and Soft Tissue Mobility and Muscle Integrity

- **Passive, active-assistive, or active ROM.** It is important to move the joints as tolerated. If active exercises are tolerated, the benefits of the muscle action make them preferable to passive motion.
- **Aquatic therapy.** Aquatic therapy is an effective method of combining therapeutic heat with low-impact buoyancy-assisted exercises.
- **Muscle setting.** Apply resistance to generate gentle, multi-angle, muscle-setting exercises in pain-free positions at intensities that do not exacerbate symptoms.

## Joint Hypomobility: Management—Controlled Motion and Return to Function Phases

Examine the patient for signs of decreased muscle flexibility, joint restrictions, muscle weakness, and balance impairments. Initiate exercises and mobilization procedures at a level appropriate for the condition of the patient.

**PRECAUTIONS WITH RA:** Because the disease process and use of steroid therapy weaken the tensile quality of the connective tissue, modify the intensity of joint mobilization and stretching techniques used to manage motion restrictions. It may be necessary to continue joint protection with orthotics, proper fitting shoes, and assistive devices for ambulation.<sup>308</sup> Encourage the patient to be active, but to also be aware of pain and fatigue.

### Increase Joint Play and Accessory Motions

**Joint mobilization techniques.** Determine which articulations are restricted owing to decreased joint play and apply grade III sustained or grade III and IV oscillation techniques to stretch the limitations. (See Figures 5.55 through 5.64 and their descriptions in Chapter 5 for techniques to mobilize the leg, ankle, and foot articulations.) Mobilizing the toes is the same as the fingers (see Figs. 5.42 through 5.43).

Because weight-bearing forces and arthritic joint changes accentuate pronation, mobilizing to increase pronation should be undertaken cautiously in an arthritic foot. Perform these techniques only in the stiff foot after immobilization when the foot does not pronate sufficiently during the loading response in gait.

### CLINICAL TIP

Extension of the toes at the MTP joints is important during terminal stance for normal push-off and development of the windlass effect in gait. The great toe requires from 40° to 50° extension to function effectively during this phase of gait.<sup>254,267</sup>

### Improve Joint Tracking of the Talocrural Joint

Apply mobilization with movement (MWM) techniques to increase ROM and/or decrease pain associated with movement.<sup>241</sup> The principles of MWM are described in Chapter 5.

#### MWM: Plantarflexion

**Patient position and procedure:** Supine with hip and knee flexed and heel on the table (Fig. 22.3). Stand at the foot of the table facing the patient and contact the patient's anterior tibia with the palm of your hand (for the right foot use the left hand). Produce a pain-free graded posterior glide of the tibia on the talus. The patient should now be unable to plantarflex. While maintaining the posterior tibial glide grip the talus with your other hand (for the right foot, use the right hand) and create a passive end-range plantarflexion movement, causing the talus to roll anteriorly.

The sustained plantarflexion must be painless. Repeat 6 to 10 repetitions for 3 to 4 sets and reassess range.

#### MWM: Dorsiflexion

**Patient position and procedure:** Standing with the affected foot placed on a chair or stool (Fig. 22.4). Kneel on the floor facing the patient with a mobilization belt around your

**FIGURE 22.3** Mobilization with movement to increase ankle plantarflexion. Maintain a posterior glide of the tibia while moving the talus into plantarflexion. This should not cause pain.

**FIGURE 22.4** MWM to increase ankle dorsiflexion. Maintain an anterior glide of the tibia with the mobilization belt while the patient lunges forward into ankle dorsiflexion. This should not cause pain.

buttocks and the patient's Achilles tendon (padded with a towel). Place the web space of both hands around the neck of the talus with the palms on the dorsum of the foot. Hold the foot down and back and the subtalar joint in neutral pronation/supination. Use the belt to produce a pain-free graded anterior gliding force to the ankle joint. While maintaining this mobilization, have the patient lunge forward, bringing the affected ankle into dorsiflexion and causing painless end-range loading. Repeat 6 to 10 repetitions for 3 to 4 sets and reassess.

### Increase Mobility of Soft Tissues and Muscles

Perform stretching techniques as described in Chapter 4. Self-stretching techniques are described later in this chapter.

### Regain Balance in Muscle Strength and Prepare for Functional Activities

Initiate resistive exercises at a level appropriate for the weakened muscles. Begin with isometric resistance in pain-free positions and progress to dynamic resistance exercises through pain-free ranges using open- and closed-chain exercises. Resistive exercises are described later in this chapter.

#### CLINICAL TIP

Use a pool or tank to reduce stress on the foot and ankle joints for low-load, weight-bearing exercises; ambulatory activities; and for low-impact aerobic exercises.

### Improve Balance and Proprioception

Initiate protected balance exercises, and progress the intensity as tolerated. Determine the level of stability and safety during ambulation and continue use of assistive devices if necessary to help prevent falls.

### Develop Cardiopulmonary Fitness

Low-impact aerobic exercises should be initiated early in the treatment program and progressed as the patient is able. Water aerobics, swimming, treadmill walking, and bicycling may be within the patient's tolerance. A person with OA or RA should not perform high-impact (jumping, hopping, and jogging) aerobic exercises.

## Joint Surgery and Postoperative Management

Advanced arthritis of the ankle or the joints of the foot can cause severe pain, motion limitations, gross instability or deformity, and significant loss of function during weight-bearing activities (Fig. 22.5). Unlike the hip and knee joints, the ankle is rarely affected by primary idiopathic arthritis, even in the elderly.<sup>108,242,346</sup> Instead, trauma is the most common cause of ankle and foot arthritis. When nonoperative management fails to alleviate symptoms, surgical options for early and advanced disease may be necessary.<sup>20,78,108,113,167,214,242,273,291,346,349,364</sup> Selecting a specific surgical procedure depends upon the joint(s) involved, the extent of articular damage, the severity of instability or deformity, bone quality, and the postoperative functional goals of the patient.

The goals of surgery for arthritis are pain relief with maximum function. Arthroscopic repair of small osteochondral lesions, debridement of a symptomatic joint, and distraction arthroplasty are used for management of early joint changes, particularly in an individual younger than 50 years old whose symptoms are unsuccessfully managed conservatively and who is unwilling to consider arthrodesis or arthroplasty.<sup>108,214,243</sup> These procedures, however, offer little symptomatic relief or functional improvement when there is

**FIGURE 22.5** Late-stage arthritis of the ankle. **(A)** Mortise view of the ankle shows severe loss of the normal joint space and partial erosion of the lateral tibia. **(B)** Lateral view shows tibial erosion with mild joint space loss in the subtalar region and significant osteophyte formation in the anterior ankle. (From Hasselman, CT, Wong, YS, and Conti, SF: *Total ankle replacement*. In Kitaoka, HB (ed): *Master Techniques in Orthopedic Surgery: The Foot and Ankle*, ed. 2. Philadelphia: Lippincott Williams & Wilkins, 2002, Fig. 39.1, p 583, with permission.)

significant destruction of articular cartilage.<sup>78,108,214,243,346,364</sup> For symptomatic stage 3 ankle arthritis, ankle arthrodesis and ankle arthroplasty become the most viable surgical options.<sup>103,108,113,242</sup> Arthrodesis is typically performed in younger patients with high functional demands<sup>45,108,130,214,242,346</sup> and has the advantage of pain relief during weight bearing but the disadvantage of limited motion with functional activities. Following ankle arthrodesis, pain-free compensatory motion must be available in adjacent joints to absorb weight-bearing forces during ambulation. Although ankle arthrodesis is performed 6 times more frequently than total ankle arthroplasty,<sup>276</sup> replacement arthroplasty is becoming a more common procedure in the United States.<sup>20,108,273</sup> Replacement arthroplasty of the ankle<sup>108,113,130,167,170,172,243,283,291</sup> or toes<sup>349</sup> has the advantage of motion preservation and predictable pain relief, with the disadvantage of more frequent complications.

Following joint surgery and postoperative rehabilitation for the ankle and foot, anticipated benefits include:<sup>108,214,242,243,346,349</sup>

- Pain relief with weight bearing and joint motion
- Deformity correction
- Restored stability or mobility to affected joints
- Improved muscle strength and endurance
- Improved ambulation and lower extremity function

Rehabilitation includes postoperative exercise; gait training with assistive devices; fabrication of foot orthoses; joint and soft tissue mobilization; neuromuscular reeducation; and patient education including information about activity modification (activities of daily living [ADLs] and recreational activities) and shoe fit and selection.

### Total Ankle Arthroplasty

Individuals with pain and disability from advanced, symptomatic ankle arthritis have two potential surgical procedures, total ankle arthroplasty (TAA) and ankle arthrodesis. TAA is an option for carefully selected patients who have pain and impaired functional mobility from advanced, symptomatic arthritis of the talocrural joint. TAA provides pain relief while preserving functional ankle joint motion, reducing stress on adjacent joints more effectively than arthrodesis.<sup>108,243,318</sup> Until recently, the ideal candidate for TAA was the thinner individual older than age 50 with low physical demands, minimal joint deformity, and near full ROM.<sup>113</sup> Recent reports indicate that although obesity remains a risk factor for postoperative complications, improvement in pain and function is similarly beneficial for active individuals younger than 50 years old.<sup>167,283,371</sup> Therefore, TAA is becoming a management option for younger, more active individuals (typically

those with either posttraumatic arthritis or RA) who wish to continue to participate in moderately demanding activities. Improvements in implant design, instrumentation for implant alignment, and the use of bio-ingrowth fixation have broadened the selection criteria for TAA,<sup>66,108,113,130,131,243,283,291</sup> resulting in an increased number of TAA procedures.<sup>273,276</sup>

### Indications for Surgery

Although end-stage ankle arthritis is the primary indication for TAA, there is little clinical guidance on which to base more specific indications for this surgery.<sup>66,108,113,130,243,283,291</sup> Commonly cited indications describe the adult patient with end-stage ankle arthritis who has failed conservative management and has persistent pain that compromises functional mobility. Conditions include advanced degenerative or inflammatory joint disease, including posttraumatic arthritis; primary OA, RA, or JRA; or avascular necrosis of the dome of the talus. This patient should have:<sup>108,243</sup>

- Low to moderate physical demands
- Sufficient integrity of ligaments for ankle stability
- A flexible deformity that can be passively corrected to neutral or less than 5° of hindfoot valgus
- Adequate vascular flow and soft tissue envelope to allow for wound healing.

TAA can also be performed following ankle arthrodesis as a salvage procedure for an individual with persistent pain during weight bearing and long-term, unsatisfactory functional results.

### Contraindications

There are a number of absolute and relative contraindications to current-day TAA.<sup>108,113,243</sup> Absolute contraindications include active or chronic ankle infection; severe osteoporosis or poor bone stock; avascular necrosis of a significant portion of the body of the talus; peripheral neuropathy leading to decreased sensation or paralysis; impaired lower extremity vascular supply; and long-term corticosteroid use. As with replacement of other joints, TAA is contraindicated for the skeletally immature individual.

Relative contraindications include a remote history of infection; severe malalignment (hindfoot varus or valgus deformity > 20°); presence of marked instability; restricted total arc of sagittal plane motion (combined dorsiflexion and plantarflexion) less than 20°; positive tobacco use; obesity; and the need to return to high demand, high-impact physical activity.

### Procedure

#### Implant Design, Materials, and Fixation

Current total ankle systems consist of three components: a metallic baseplate that is fixed to the tibia, a domed or condylar-shaped metal component that resurfaces the talus, and a polyethylene bearing surface interposed between the tibial and talar components.<sup>108,113,243</sup> Because contemporary prosthetic designs more closely mimic the characteristics of a normal ankle joint, ROM available in several of these

systems is nearly equivalent to that of a normal ankle.<sup>353</sup> Contemporary TAA also requires far less bony resection and typically utilizes cementless (bio-ingrowth) fixation with hydroxyapatite coated metal implants.<sup>243</sup>

Contemporary implants are divided into two basic categories: fixed-bearing and mobile-bearing. A system is considered fixed-bearing if the polyethylene bearing surface is fixed to the tibial baseplate and mobile-bearing if the polyethylene component is not fixed. The mobile-bearing design allows for joint surface sliding (anterior-posterior and medial-lateral directions) and rotation of the free polyethylene component.<sup>243,383</sup> Polyethylene component movement in a mobile-bearing design should, in theory, maintain a congruent articulation between the talar and polyethylene components, decreasing mechanical wear.<sup>243,292</sup> Valderrabano et al,<sup>355</sup> however, found very little anterior-posterior movement of the talar polyethylene component, noting that the mobile-bearing design functioned largely like a fixed-bearing design. Aside from the mobile-bearing Scandinavian Total Ankle Replacement (STAR) system, the implants approved for use in the United States are fixed-bearing designs (Fig. 22.6).<sup>243</sup>

#### Operative Overview

**General TAA procedure.** Although there are numerous variations of TAA operative techniques, the following steps represent the key components.<sup>17,34,108,130,167,209,243,307</sup> Any significant deformity above or below the ankle joint is corrected before placement of the system implants.<sup>243</sup> An

**FIGURE 22.6** Total ankle arthroplasty. Lateral view of a total ankle replacement in a 78-year-old woman 1 year after surgery for posttraumatic arthritis. (From Kitaoka, HB, and Claridge, RJ: *Ankle replacement arthroplasty*. In Morrey, BF (ed): *Joint Replacement Arthroplasty*, ed. 3, 2003, p 1148, with permission from The Mayo Clinic Foundation.)

anterior longitudinal incision between the tibialis anterior and extensor hallucis tendon is the most widely used approach. The extensor retinaculum and capsule are incised to expose the dorsal ankle and talonavicular joints. The joint is debrided and osteophytes are removed from the dorsal talonavicular joint. An external distraction device is used to separate the joint surfaces and facilitate bone resection. Small portions of the distal tibia and talar dome are excised, followed by preparation of the joint surfaces. In some cases, the medial and lateral malleolar recesses are also resurfaced. Trial implants are inserted to evaluate their alignment and the range of dorsiflexion available. Permanent implants are selected and inserted. Any necessary soft tissue balancing or repair is performed. After the wound is closed, a bulky compression dressing and well-padded, posterior orthosis or short-leg cast is applied to control swelling and limit ROM.

**Adjunctive procedures.** If there is less than 5° of dorsiflexion because of a gastrocnemius-soleus contracture, a percutaneous lengthening of the Achilles tendon is performed. When a larger surface for fixation of the tibial prosthesis is needed, fusion of the tibiofibular syndesmosis with screw fixation is performed through a lateral incision.<sup>113,170,243</sup> In the case of a significant varus or valgus hindfoot deformity, a subtalar arthrodesis is performed.<sup>130,243,307</sup> Ligamentous stability is imperative for optimal outcome, so if instability persists intraoperatively after placement of the permanent implants, a lateral ligament reconstruction is performed.<sup>243</sup>

## Complications

The current rate of complications after contemporary TAA appears to have decreased compared to rates with early implant designs and surgical techniques.<sup>114,123,167,243,371</sup> However, insufficient evidence is available to draw a firm conclusion regarding true complication rates, with reports varying widely.<sup>176,180,182,360</sup> Krause et al<sup>176</sup> pooled data from 20 studies published between 1999 and 2009 and reported an average 5-year complication rate of 29.5% (range 4.4% to 98.1%). Despite improvements in implant design, surgical technique, and patient selection, complication rates of >50% have been reported at intermediate and long-term follow-up evaluations.<sup>176,180,182,302,321</sup> Complication rates are higher in obese individuals, individuals with diabetes, and individuals who use tobacco.<sup>250,299,300,371</sup>

Complications can occur intraoperatively, in the early postoperative period, and in the long term. Fracture of the medial or lateral malleolus is the most frequent intraoperative complication, reported to occur in approximately 10% of procedures, with one report citing a 38% incidence rate.<sup>11,108,176,243,290,302</sup> Other intraoperative complications include implant malpositioning, tendon laceration, and nerve injury. As with all types of joint arthroplasty, postoperative infection is a potential complication. Deep infection rates range from 1% to 5%.<sup>176,263</sup> Postoperative edema in the ankle and foot also increases the risk of delayed wound healing by prolonging the immobilization period, delaying early ankle motion, and potentially leading to poor ROM

outcomes.<sup>108,167,209,243,245</sup> Tarsal tunnel syndrome, soft tissue impingement, or complex regional pain syndrome occasionally develop, causing foot and ankle pain. (Complex regional pain syndromes and interventions are described in Chapter 13.) Box 22.3 summarizes common early postoperative and long-term complications associated with TAA.<sup>17,108,113,130,176,180,182,243,263,291,302</sup> Any of these complications can adversely affect the progression of rehabilitation and the short-term and long-term outcomes of TAA. Persistent or severe complications may necessitate revision arthroplasty or ankle arthrodesis.

## Postoperative Management

There are few published guidelines in the literature for postoperative management of patients who have undergone TAA. Those that are available vary considerably regarding the duration of immobilization, weight-bearing restrictions, and the initiation and progression of exercise. There is a lack of evidence to support whether ROM exercises should be initiated a few days postoperatively or delayed several weeks until there is evidence of bone ingrowth into the implants. It is also unclear whether protected motion has a positive impact on ROM outcomes or if it is detrimental to implant fixation or wound healing.<sup>243,292</sup> Due to the higher rate of complications, postoperative management typically is less aggressive (longer periods of restricted weight bearing and longer periods of immobilization) for TAA when compared to total hip and knee arthroplasty.

The guidelines and precautions in the following sections for postoperative management summarize the recommendations of several authors based on their experience and training.<sup>6,17,34,130,150,209,214,291</sup>

### BOX 22.3 Potential Postoperative Complications of Total Ankle Arthroplasty

#### Early Postoperative Complications → Potential Consequence(s)

- Delayed wound healing → an extended period of restricted ankle motion
- Delayed union or nonunion of a tibiofibular syndesmosis fusion → an extended immobilization and restricted weight-bearing period
- Tarsal tunnel syndrome or complex regional pain syndrome

#### Late Postoperative Complications → Potential Consequence(s)

- Component migration or impaction → malalignment and premature component wear
- Mechanical (aseptic) loosening (most often the talar component) → pain and impaired functional mobility
- Hindfoot arthritis (most often the subtalar joint) → pain and impaired weight-bearing abilities
- Heterotopic bone formation → restricted motion

### Immobilization and Weight-Bearing Considerations

**Immobilization.** After the wound is closed following surgery, the ankle is placed in a compression dressing and immobilized in a neutral position in a well-padded short leg cast or posterior orthosis. This is left in place for 10 to 21 days, after which time it is replaced with a short-leg walking cast, controlled ankle motion (CAM) walker boot, or ankle foot orthosis. The duration of continuous immobilization and initiation of ROM exercises varies depending on the type of implant fixation used, the types of concomitant surgical procedures performed during the arthroplasty, and the surgeon's recommendations. Length of immobilization depends on the most restrictive tissue healing consideration. For example, if a tibiofibular syndesmosis or subtalar fusion was performed, no motion is allowed for 6 weeks or until there is evidence of bony union.<sup>170,150</sup> If a soft tissue procedure is required (e.g., ligamentous reconstruction), the period of immobilization may be extended. Without adjunctive procedures, immobilization following cementless fixation ranges from 2 to 6 weeks.<sup>17,150,214,291</sup>

**Weight bearing.** Recommendations for the initiation and extent of weight bearing after TAA vary significantly and can be affected by many factors including the causative pathology, the type of fixation, adjunctive procedures, patient characteristics, and physician preference. Guidelines range from non-weight bearing for 3 to 6 weeks<sup>6,150,214,291</sup> to minimal immediate postoperative weight bearing that progresses to weight bearing as tolerated within the first 2 weeks.<sup>6,17,34,130,150,176</sup> Adjunctive procedures can delay weight bearing. If a tibiofibular syndesmosis or hindfoot fusion is performed, or if an intraoperative malleolar fracture requires fixation, weight bearing is delayed for at least 6 weeks.<sup>167,170,176</sup>

In most cases, full weight bearing is generally achieved by 6 weeks following surgery.<sup>6,130,150,214</sup> Weight bearing is initiated with the leg in an ankle immobilizer.<sup>6,150,176</sup> After the initial period of restricted weight bearing, a patient gradually progresses to full weight bearing over several weeks while remaining in the immobilizer. This gradual progression to full weight bearing in the immobilizer is followed by a gradual return to full weight bearing without the immobilizer after 6 weeks.<sup>150</sup>

#### Exercise: Maximum Protection Phase

The first phase of postoperative rehabilitation, which extends for about 6 weeks, focuses on the patient becoming functionally mobile while protecting the operative ankle. Postoperative edema management and deep vein thrombosis prevention are critical in this period of restricted mobility and weight-bearing.<sup>18</sup> During this phase, ankle ROM exercises are usually initiated.<sup>6,150,214</sup>

**Goals and interventions.** In addition to elevation and compression for edema management, maintenance of mobility to joints distal and proximal to the ankle, and strength and endurance training of the upper extremities and

contralateral lower extremity, goals and interventions include the following:<sup>17,150,214,290</sup>

- **Prevent postoperative complications**
  - Patient education related to signs/symptoms associated with deep vein thrombosis and infection.
- **Re-establish independent ambulation and functional mobility**
  - Gait training with assistive devices
  - Transfers and mobility
  - Patient education regarding weight-bearing restrictions
- **Minimize atrophy of the ankle and foot muscles of the operative limb**
  - Low-intensity, isometric (muscle-setting) exercises of the ankle musculature within the immobilizer.
- **Prevent stiffness of the operated ankle and foot and loss of tissue extensibility of surrounding soft tissues.**
  - Active ROM of the toes
  - Gentle ankle active ROM exercises if removal of the immobilizer is permitted and the wound demonstrates sufficient healing. Initially include active ROM dorsiflexion/plantarflexion. Inversion, eversion and circumduction may be postponed until after 6 weeks after surgery.<sup>6,150</sup>

**NOTE:** ROM of the operative ankle may be permitted as early as 2 weeks after surgery or delayed as long as postoperative week 6.<sup>150</sup>

#### Exercise: Moderate and Minimum Protection Phases

Except in cases of poor soft tissue healing or delayed bony ingrowth, use of the immobilizer is generally discontinued and weight bearing restrictions are removed about 6 weeks after surgery. During the moderate and minimum protection phases of postoperative rehabilitation after TAA, emphasis is placed on increasing the range of functional ankle dorsiflexion and plantarflexion and increasing the strength of the plantarflexors.<sup>6,150,214</sup> Improving standing balance and ankle proprioception are also important for a gradual return to functional activities. Formal rehabilitation is generally completed 3 to 6 months after surgery.<sup>150</sup>

#### CLINICAL TIP

The level of physical activity possible after TAA depends on many factors, including patient characteristics (obesity, general health), the underlying pathology (DJD, OA, or RA), other joint involvement, prior level of activity, and the patient's goals for recovery. These factors should be considered and discussed when setting patient-centered goals.

**Goals and interventions.** During the moderate and minimum protection phases, the goals and interventions include:<sup>6,150,292</sup>

- **Achieve 100% of the ROM obtained intraoperatively.**
  - Active, pain-free ROM exercises in nonweight-bearing positions, followed by active pain-free ROM in weight

positions. Include dorsiflexion, plantarflexion, inversion, eversion, and circumduction.

- Stretching of the gastrocnemius-soleus muscle group is indicated if dorsiflexion is limited. Begin with a towel stretch in a long-sitting position; progress to standing on a wedge for an extended period of time.

**CLINICAL TIP**

An arc of motion that ranges from 20° plantarflexion to 10° of dorsiflexion is necessary for normal gait over level surfaces.<sup>267</sup> Achievement of 20° of dorsiflexion is needed for descending stairs.<sup>205</sup> The amount of ankle dorsiflexion achieved while pedaling a bicycle can be adjusted by raising or lowering the seat height. A lower seat height requires greater dorsiflexion.

- **Restore strength, muscular endurance, and balance in the lower extremities for functional activities.**
  - Low-intensity, high-repetition, open-chain, resisted exercise using elastic resistance initially, progressing to closed-chain exercises including squats, lunges, heel raises, and arch raises.
  - A progression of bilateral and unilateral balance activities beginning on stable surface and introducing progressive surface instability (refer to Chapters 8 and 23 for examples).
- **Improve aerobic capacity and cardiopulmonary endurance.**
  - Swimming, stationary cycling, and treadmill walking.
- **Resume a safe level of work-related and recreational activities.**
  - Integration of strength and balance training into simulated functional activities.

- Activity modification for joint protection.
- Patient education to help the patient return to safe and appropriate activities.

**PRECAUTION:** No clinical studies have demonstrated that participation in high-level athletic activities are associated with increased TAA failure.<sup>133</sup> However, plyometric training and other activities that involve high-impact and quick stop-and-go motions are generally considered inappropriate following TAA.<sup>197,354</sup>

**Return to fitness and sports activities.** With advances in TAA design and surgical techniques, plus expanding knowledge of long-term outcomes, it is now possible for selected patients to participate in low to moderately demanding fitness and sport activities.<sup>133,197,354</sup> These patients typically are younger (<60 years of age), were physically active prior to surgery, and underwent TAA for posttraumatic arthritis. A consensus of recommendations has recently been published, indicating activities that surgeons routinely recommend or prohibit following TAA (Table 22.1 summarizes these activity recommendations). Low-impact activities that do not require quick stop-and-go motions are routinely recommended; moderate-impact activities and activities performed in a motion limiting boot are allowed in patients with previous experience. High-impact activities, activities with risk of contact or collision, or activities that require cutting or jumping are not recommended.<sup>133,354</sup> Participation in fitness and sport activities is recommended only after completion of an individualized rehabilitation program in patients who are free from complications.<sup>197,250,354</sup>

**Outcomes**

Although early TAA afforded pain relief for a period of time,<sup>113</sup> unacceptable complication rates led to poor functional outcomes and patient dissatisfaction.<sup>113,291,292</sup> Modern

surgical techniques and more judicious patient selection have resulted in more encouraging outcomes, although long-term success rates remain unknown.<sup>17,113,122,291,292</sup> It is important to note that although prospective and retrospective studies have compared implant designs, no studies to date have compared rehabilitation factors, such as early vs. delayed weight bearing or ROM exercises following TAA.

Pain, ROM, general level of function, patient satisfaction, and postoperative complications are the outcomes most often reported in follow-up studies. A variety of quantitative assessment instruments are used to measure pain relief, postoperative function, and patient satisfaction. Two examples of validated assessment instruments are the Ankle Osteoarthritis Scale (AOS) and the American Orthopedic Foot and Ankle Society Questionnaire (AOFAS). Survival rates, the percentage of prostheses not requiring removal at given time points after surgery, are also frequently reported.

**Prosthesis survival rates.** Arthroplasty survival rates reported in the literature vary, but they appear to be trending upward.<sup>113,182,251,318</sup> Labek et al<sup>182</sup> reported 5-year survival rates just below 90% in most data sets, and limited data sets demonstrate 10-year survival rates of approximately 75%. Evidence from prospective studies suggest similar TAA survival rates for patients with OA (primary or posttraumatic arthritis) and RA at mid-term (5 years)<sup>265</sup> and long-term (14 years)<sup>173</sup> follow-up. Relative to patient age, prospective studies indicate no difference in implant survival rates for patients older or younger than 50 years of age at short-term (3 years)<sup>66</sup> or mid-term (median follow up of 6 years)<sup>170</sup> follow-up. Retrospective studies indicate that obesity negatively impacts long-term survival rates and results in increased postoperative complications.<sup>30,250,299,371</sup>

When considering reports of TAA outcomes, note that many of the published reports represent studies conducted by implant developers.<sup>165</sup> Labek et al<sup>180,181</sup> noted a significant difference in the revision rates in published sample series compared with those taken from national joint registries. Revision rates collected in national joint registries are approximately twice as high as those reported in published sample series studies. Labek et al<sup>180,182</sup> suggest that because implant developers represent 50% of the published sample series content, their data may be proportionately overrepresented and thus influence outcomes reported in systematic reviews.

**Pain relief, functional improvement, and patient satisfaction in different populations.** Bai et al<sup>17</sup> prospectively compared outcomes following mobile-bearing TAA in patients with posttraumatic arthritis versus primary OA. At a mean follow-up of 38 months, no significant between-group differences were found in ankle ROM, radiographic findings, and an ankle-hindfoot assessment scale. Survival rates of the implants were comparable between the posttraumatic and primary OA groups (97% and 100%, respectively) at the conclusion of the study. However, complication rates were

significantly higher (38% vs. 27%) in the posttraumatic arthritis group than in the primary OA group.

Gaudot et al<sup>101</sup> retrospectively compared outcomes of statistically paired individuals with mobile-bearing versus fixed-bearing TAA implants. The authors found no statistical difference for postoperative complications between the two groups at a mean follow-up of 24 months. While postoperative AOFAS scores were significantly higher than preoperative scores for both groups, the fixed-bearing group postoperative scores were significantly higher than those in the mobile-bearing group. No between-group postoperative differences were reported for ankle ROM or radiographic imaging. The authors concluded that fixed-bearing TAA had results equivalent to, if not better than, mobile-bearing.

In a multicenter study, Daniels et al<sup>58</sup> prospectively followed 281 individuals who underwent TAA for an average of 5.5 years. Seventeen percent of the patients required a subsequent revision surgery, and the major complication rate was 19%. Final AOS total, pain, disability scores, and SF-36 physical component summary score all significantly improved when compared to baseline measures. When compared to 107 individuals who underwent ankle arthrodesis, no significant postoperative group differences were found for any outcome variables.

Although several studies report no difference in pre- and postoperative ROM, Ajis et al<sup>6</sup> reported significant improvement in dorsiflexion at 6 weeks and 6 months following TAA. Dorsiflexion increased from a preoperative mean of 6.6° to a 12-month postoperative mean of 12.0°, while total arc of sagittal plane motion (terminal plantarflexion to terminal dorsiflexion) increased from 22.7° preoperatively to 24.3° postoperatively, a change that was not statistically significant.

Outcomes for a frequently used second generation, two-component system and more recently developed third generation, three-component (mobile-bearing) designs have been reported but not directly compared. Knecht<sup>170</sup> reported positive outcomes (reduced pain and increased function) in 66 patients who had undergone a two-component ankle replacement a mean of 9 years earlier. The mean total arc of dorsi- and plantarflexion measured in 33 patients was 18°.

Buechel and colleagues<sup>34</sup> followed 50 patients (mean age 49 years), who had received a mobile-bearing replacement with cementless fixation. They reported 48% excellent and 40% good results at a mean follow-up of 5 years (range 2 to 10 years). Of the 50 patients who participated in the study, 26% reported no pain after TAA, 60% reported slight or mild pain, and 14% reported moderate or severe pain that interfered with functional activities. The mean total arc of dorsi- and plantarflexion was 28°. In a short-term follow-up study of 116 patients who had a different mobile-bearing prosthesis implanted in 122 ankles, 84% of patients were satisfied, with 82% reporting good or excellent results at an average of 19.9 months.<sup>131</sup> The mean total arc of ankle dorsi- and plantarflexion was 39°. Although postoperative gains in ROM

reported in these studies were small (often as little as 5° to 10°), gains of even a few degrees have been reported to improve functional mobility.<sup>292</sup>

**Participation in physical activities.** Although most TAA outcome studies evaluate prosthetic survival rates or clinical variables, the ability to return to a physically active lifestyle is also of interest. Naal et al<sup>246</sup> compared the preoperative and postoperative activity levels of 101 patients who had undergone TAA secondary to posttraumatic arthritis (46.5%), primary OA (34.7%), or RA (18.8%). One year prior to surgery, 62.4% were active in sport and fitness activities, while 66.3% were active at an average of 3.7 years after surgery. The types of activities and the frequency of participation before and after surgery were essentially unchanged; however, 65% of those surveyed indicated that performance during their preferred activities had improved following TAA. Swimming, cycling, and weight training for fitness were the most frequently reported activities before and after surgery. Although some patients participated in high-impact sports (i.e., jogging, soccer, and tennis) before surgery, few or none participated in these activities at follow-up, perhaps because of postoperative patient education. Of the three diagnostic groups, the individuals in the posttraumatic arthritis group reported decreased sport and fitness participation and were the least satisfied with their ability to participate in sport.

Schuh et al<sup>303</sup> prospectively collected sport and recreational activity participation rates in 21 patients scheduled for TAA. Following TAA, participation rates declined from 86% to 76%, but this change was not statistically significant. The most common activities reported post-TAA were cycling (45%), swimming (45%), hiking (25%), Nordic walking (20%), and skiing (15%). A recent systematic review of post-TAA activity indicated that sport and recreation participation remains relatively unchanged following TAA, and there is no evidence identifying sport activity as a risk factor for TAA failure.<sup>133</sup> In general, surgeons are comfortable recommending low-impact sports and aerobic activities to most TAA recipients.<sup>197</sup>

Valderrabano and coinvestigators<sup>354</sup> studied 147 patients (mean age 59.6 years, range 28 to 86 years) who participated in sports and recreational activities before and after TAA. Of these patients, 89% had a preoperative diagnosis of posttraumatic arthritis or primary OA, and only 11% had a diagnosis of RA. A combined total of 83% of all patients in the study reported excellent or good results and 69% were pain-free postoperatively. Just prior to surgery, 36% of patients were active in sports/recreational activities, and 56% were active at a mean of 2.8 years after surgery. This change reflected an increase in the activity level of the patients with posttraumatic arthritis and primary OA, not of the patients with RA. The most frequently reported preoperative activities (in descending order) were cycling, swimming, hiking, and low-impact aerobics. After surgery, hiking was most frequently reported followed by cycling, swimming, and aerobics. The only

significant change in activity before and after surgery was an increase in hiking (participation spiked from 25.5% to 52.8%). The authors recommended that before initiating any sport activity after ankle replacement, a patient should complete postoperative rehabilitation and be free of complications.

## Arthrodesis of the Ankle and Foot

Ankle arthrodesis (fusion) is the most frequently used surgery for late-stage arthritis of the ankle or foot and toe joints.<sup>20,273,276</sup> Although the rate of TAA has been increasing, ankle arthrodesis is still performed over six times more frequently than replacement.<sup>276</sup> Ankle fusion (AF) is the procedure of choice for relatively young, active patients with posttraumatic arthritis and gross instability of the ankle and hindfoot.<sup>315,346</sup> Arthrodesis also is an option for patients with hindfoot or forefoot involvement as the result of RA or JRA.<sup>84,242,244</sup> Deformities of the forefoot such as hallux valgus or hallux rigidus and severe deterioration of the MTP joint of the first toe are also managed with arthrodesis.<sup>7,108,242,244</sup>

### Indications for Surgery

The following are frequently cited indications for surgical fusion of selected joints of the ankle and foot:<sup>2,7,84,113,242,244,294,346</sup>

- Debilitating pain, particularly during weight bearing, and severe articular degeneration secondary to posttraumatic or postinfectious arthritis, OA, RA, or other inflammatory arthropathies
- Marked instability or stiffness of one or more joints that is unresponsive to conservative management
- Deformity of the ankle, foot, or toes associated with chronic joint malalignment as the result of congenital anomalies, neuromuscular disorders, or arthritis
- Osteonecrosis of the talus
- A salvage procedure after failed total ankle arthroplasty

Generally, indications for arthrodesis and arthroplasty are very similar. Arthrodesis has been the “gold standard” option for younger patients with high functional demands and pain-free compensatory movements.<sup>214,242,346</sup> However, as ankle arthroplasty implants and techniques have improved, patients under the age of 50 with the above conditions can determine the most appropriate procedure based on the risks and benefits of the respective procedures.<sup>243,283</sup>

### Contraindications to Surgery

Absolute contraindications include vascular impairment or infection of the limb. Relative contraindications include uncontrolled diabetes, active tobacco use, and severe ipsilateral subtalar arthrosis or contralateral ankle arthrosis.<sup>242</sup>

**NOTE:** For patients with RA or primary RA of both ankles, bilateral arthrodesis is rarely performed because loss of dorsiflexion bilaterally limits an individual's ability to rise from a chair or ascend and descend stairs.

## Procedures

There are many types of arthrodesis; however, all involve the use of bone grafts coupled with internal fixation devices (see Fig. 12.2) or occasionally external skeletal fixation for bony ankylosis.<sup>84,242</sup> Common to all techniques is appropriate positioning of the ankle to maximize function: neutral dorsiflexion/plantarflexion, approximately 5° of external rotation, 5° of valgus, and slight posterior translation of the talus under the tibia.<sup>108,242</sup> Internal fixation is considered the best fusion technique and can be achieved via multiple compression screws, pins, an intramedullary nail, or a plate. The type of fixation selected depends on the joints involved and extent of deformity. For correction of severe deformity or tendon rupture, concomitant soft tissue procedures are required.<sup>108,145,242</sup>

Arthrodesis at the ankle or foot has traditionally been performed through an open approach. Over the past decade, however, mini-open, arthroscopically-assisted and fully arthroscopic arthrodesis of the ankle have become viable surgical options.<sup>84,102,108,145,242,260,305,341</sup> Although previously reserved for ankles with minimal deformity, arthroscopic fixation has recently been shown to be a viable option for ankles with deformity greater than 15°.<sup>59,104,289</sup> The benefit of an arthroscopic approach is the reduced rate of wound healing complications secondary to less soft tissue disruption during surgery.<sup>145,242,328,346</sup> There have also been reports of shorter hospital stays, decreased blood loss, lower morbidity, and reduced time to union with an arthroscopic approach. However, these potential benefits are based largely on data from nonrandomized, retrospective studies rather than controlled comparisons to an open approach.<sup>59,84,104,248,348,379</sup>

### Common Types of Arthrodesis

**Arthrodesis of the ankle.** This procedure fuses the talus to the tibia in a position that maximizes function: 0° dorsiflexion and 5° to 10° external rotation of the foot to match the contralateral Fick angle.<sup>108,242,294,346</sup> Slight plantarflexion may be tolerated, but a talocrural joint fixed in dorsiflexion may result in intractable heel pain.<sup>242</sup> Once osteophytes are removed and the tibial and talar articular surfaces are prepared, internal fixation is achieved with two or three screws connecting the tibia and talus. Fixation of the fibula to the talus and tibia with a plate and transmalleolar screws can provide an added measure of stability. Bone graft is often used to augment bone healing.<sup>242</sup> Although ankle arthrodesis provides pain relief and ankle stability, dorsiflexion and plantarflexion are lost, thus altering the biomechanics and speed of gait and increasing energy expenditure during ambulation.<sup>346</sup> The hindfoot and forefoot compensate to a great extent for the loss of motion at the ankle. Despite this, an asymmetrical gait pattern is detectable in most patients after ankle arthrodesis.<sup>45</sup>

### FOCUS ON EVIDENCE

Thomas et al<sup>347</sup> reported significant between-group differences in gait between 27 patients who had undergone tibio-talar arthrodesis and 27 age-matched control subjects.

Cadence and stride length were significantly decreased in the arthrodesis group as were motions of the hindfoot and midfoot during the swing and stance phases of gait. In addition, radiographic evaluation demonstrated evidence of severe hindfoot arthritis in 15% of the arthrodesis group. The arthrodesis group was analyzed at a mean duration of 44 months' postsurgery.<sup>347</sup>

**Arthrodesis of the hindfoot.** Hindfoot arthrodesis is indicated when conservative management (including arch supports, appropriate footwear, ankle and hindfoot bracing, and oral or injected anti-inflammatory medication) has failed. Severe pain, instability, or chronic hindfoot deformity (pes valgus or pes planus) as the result of advanced hindfoot arthritis may require a triple arthrodesis or a single-joint fusion.<sup>232,280,325</sup> Procedures include talonavicular, talocalcaneal (subtalar), or triple arthrodesis. A triple arthrodesis—often indicated for a rigid hindfoot deformity—involves fusion of the talocalcaneal, talonavicular, and calcaneocuboid joints.<sup>5,231,280,325</sup> A talocalcaneal arthrodesis is indicated to correct heel valgus if the midtarsal joint has been spared. A single-joint fusion, such as a talonavicular arthrodesis, may be sufficient to correct a chronic but flexible hindfoot deformity.<sup>280</sup> In most instances, the hindfoot is positioned in 5° of valgus in each of these fusions.

Talonavicular, subtalar, or triple arthrodesis provides permanent medial-lateral stability and pain relief in the hindfoot, but pronation and supination of the ankle are eliminated or substantially diminished.<sup>343</sup> It is interesting to note that fusion of the talonavicular joint alone indirectly reduces motion at the subtalar and calcaneocuboid joints, providing frontal plane stability without fusing additional joints.<sup>331,343</sup>

**Arthrodesis of the first toe.** Arthrodesis of the first MTP joint for hallux rigidus and hallux valgus provides pain relief at rest and with ambulation in 80% to 90% of patients.<sup>7,60,86,97,280</sup> The position of fusion is neutral rotation, 10° to 20° of valgus and 15° to 30° of dorsiflexion. Although the toe may not contact the ground during quiet stance, this position allows adequate push-off during ambulation and does not necessarily require customized footwear.<sup>60,97,280</sup> If the lateral MTP joints are involved, fusion of the great toe is performed after excision arthroplasty of the lateral joints.<sup>97,280,349</sup>

Comparisons of first MTP arthrodesis to arthroplasty have generally favored arthrodesis for pain relief, balance, ambulation, and cosmesis.<sup>280</sup> Recent studies report mixed results, noting higher patient satisfaction with arthroplasty but better functional results with arthrodesis.<sup>86,286</sup> Long-term outcomes of the newer generation first MTP prostheses have not yet been determined.<sup>280</sup>

**Arthrodesis of the IP joints of the toes.** Fusion of the IP joints of the toes in a neutral position for hammer toes (typically toes 2 to 3) provides relief of pain with ambulation and improved shoe fit.<sup>146,280,334</sup>

### Complications

The overall complication rate associated with arthrodesis is relatively low but can vary by patient population, the joint involved, and the surgical technique.<sup>242,346,379</sup> The most common complication is nonunion, occurring in up to 10% of arthrodesis procedures.<sup>114,242,248,280,379</sup> The smaller the area of the bony surfaces and the poorer their vascular supply, the higher the rate of nonunion. Factors that contribute to nonunion include postoperative infection, malalignment of the fused joint, and a patient’s use of tobacco before and after surgery.<sup>168,231</sup> Table 22.2 summarizes risk factors for nonunion in foot and ankle arthrodesis.<sup>242,344</sup> Arthrodesis nonunion typically requires revision arthrodesis.<sup>242,379</sup>

In addition to pain and decreased function associated with nonunion, nerve damage can occur due to the surgical procedure; and neuromas can develop postoperatively.<sup>242</sup> These conditions can lead to postoperative pain and limited function. Occasionally postoperative stress fracture of a fused bone or an adjacent bone occurs. Subsequent arthritis in adjacent joints requires arthrodesis in up to 5% of individuals.<sup>379</sup> Delayed wound healing is a particular problem in patients with poor vascularity of the foot and ankle.

### Postoperative Management

**Immobilization.** The method and duration of immobilization of the fused joint(s) are determined by the surgeon and are based on the fusion site, the type of fixation used, the quality of fixation achieved, the patient’s bone quality, and the presence of factors that affect bone healing.

After surgical fixation and wound closure, a compression dressing and orthosis are applied and worn for 48 to 72 hours for edema control.<sup>84,242,280</sup> For ankle or hindfoot arthrodesis, a short-leg, nonweight-bearing cast is applied following removal of the postoperative dressing. This is typically worn for 4 to 8 weeks and is changed as needed to accommodate limb-swelling changes. A short-leg walking cast or rigid boot is applied at 4 to 8 weeks, and immobilization continues for an additional 6 to 8 weeks.<sup>84,168,231,242,280,290,294</sup> After arthrodesis of the first MTP joint, a short-leg cast or

surgical shoe with a flat, rigid sole is worn to protect the joint as it heals.<sup>86,97,280,286</sup>

When radiographs show evidence of fusion, the patient is weaned from the immobilizer over several weeks.<sup>84,242,280</sup> After orthosis use is discontinued, the patient should be advised of proper shoe selection, modification, and fit. The use of a custom-made foot orthosis may be necessary for support, relief of pressure or shock absorption.<sup>285,314</sup> Rocker bottom shoes have been recommended following ankle arthrodesis, but a recent biomechanical study determined that running shoes provided similar—or better—beneficial effects in gait parameters including speed and forefoot maximal force.<sup>14</sup>

**Weight-bearing considerations.** As with postoperative immobilization, the timing and extent of weight bearing impermissible following arthrodesis varies widely in published guidelines.<sup>36,84,112,183,242</sup> The same considerations that influence decisions about immobilization also influence the progression of postoperative weight bearing on the operated extremity. The most prevalent practice is to substantially restrict weight bearing for a minimum of 6 weeks after ankle and hindfoot arthrodesis. Mobility is accomplished with a wheelchair, a standard walker, crutches, or rolling knee walker. When radiographs show evidence of bony union, partial weight bearing is initiated in a rigid short-leg boot or shoe. Most individuals progress to full weight bearing in typical footwear by 12 to 16 weeks postoperatively. With midfoot and forefoot arthrodesis, partial to full weight bearing is initiated earlier, either immediately or within the first 4 weeks.<sup>28,112,183</sup>

### FOCUS ON EVIDENCE

In an effort to reduce recovery time and improve quality of life following arthrodesis, early weight bearing has been explored. Cannon et al<sup>36</sup> conducted a nonrandomized, retrospective study of two groups of patients following arthroscopic ankle arthrodesis. One group (n = 15) was immobilized and instructed in either non-weight bearing or touch weight bearing for 8 weeks. A second group (n = 21) was immobilized in a removable orthosis and encouraged to begin weight bearing as tolerated immediately following surgery. No difference in time to union was found when comparing the two groups. Additional trials using randomization and controls are still needed to fully assess the effects of early weight bearing.

**Postoperative exercises.** Prior to bony fusion, care is needed to avoid stressing the fixation. Initially, postoperative exercises focus on active ROM of the nonoperated joints proximal or distal to the joints that are immobilized. If the patient is wearing a removable orthosis, active ROM exercises of the nonoperated joints confined by the immobilizer may be permissible early in the rehabilitation program as well.<sup>36,385</sup> For example, after ankle or hindfoot arthrodesis, exercises to maintain toe mobility are indicated in addition to knee

**TABLE 22.2** Risk Factors Associated With Arthrodesis Nonunion<sup>344</sup>

Patient Factors		Surgical Factors
Systemic	Local	
Diabetes	Infection	Open/ Arthroscopic
Tobacco/ Alcohol Use	Vascularity	Construct stability
Osteoporosis	Avascular necrosis	Surgeon experience
NSAID/ Corticosteroid use	Soft tissue injury	Revision arthrodesis
Weight bearing compliance		

ROM.<sup>385</sup> For a patient with RA, active ROM is essential in all involved joints not restricted by the immobilization device.

When bony fusion has occurred and use of the immobilizer has been discontinued, postimmobilization muscle weakness, balance deficiencies, and adjacent joint hypomobilities should be addressed. The type of fixation should be considered in exercise prescription. For example, a subtalar fusion will limit inversion and eversion of the foot, reducing the capacity for isotonic posterior tibialis strengthening.

**Return to physical activities.** Studies with relatively small samples have investigated the ability of individuals to return to physical activities following arthrodesis. Romeo et al<sup>285</sup> compared the rate and type of recreational sport activities in 33 patients (22 males, 11 females) after calcaneal fractures treated with subtalar joint arthrodesis. The percentage of individuals reporting sports participation did not change following arthrodesis. The authors noted a shift from high- to low-impact activities and from longer to shorter duration exercise sessions. Shuh et al<sup>303</sup> reported that 18 out of 20 patients (90%) reported sport activity prior to ankle arthrodesis and 15 out of 20 reported similar activity after arthrodesis. Although specific activity rates varied in these studies, the most common post-operative activities included cycling, swimming, hiking, skiing, and exercise walking.<sup>285,303</sup> A survey of surgeons and athletic trainers concluded that participation in low-impact sports is recommended and participation in high-impact sports is discouraged.<sup>365</sup> Low-impact sport participation that requires dorsiflexion beyond neutral, such as cycling, can be difficult following ankle arthrodesis because of the restricted dorsiflexion inherent in the procedure.

### Outcomes

**Short- and intermediate-term outcomes.** Following arthrodesis, fusion rates of greater than 90% should be expected in uncomplicated cases.<sup>84,114,176,242,348</sup> Factors contributing to nonunion include multiple fusion sites, open technique, greater preoperative deformity, and underlying inflammatory arthropathy. When healing is complete after arthrodesis, pain relief and joint stability are predictable outcomes, generally resulting in improved functional mobility. Following ankle arthrodesis, postoperative walking speed is significantly improved when compared to baseline measures; however, speed remains significantly reduced when compared to controls.<sup>19,313,340</sup> Because dorsiflexion and plantarflexion are lost, the speed and biomechanics of gait are altered, resulting in an asymmetrical gait pattern in most individuals. These alterations result in increased energy expenditure and compensation from the hindfoot and midfoot.<sup>32,96,288,313,340</sup> After ankle arthrodesis, patients face functional challenges such as difficulty walking on uneven surfaces or inclines and ascending and descending stairs.

**Long-term outcomes.** Although arthrodesis provides pain relief in the fused joint(s), biomechanical studies show that the procedure increases stress on neighboring joints.<sup>142,368</sup>

Several clinical studies demonstrate accelerated degenerative changes in the subtalar and tarsometatarsal joints following ankle arthrodesis.<sup>19,77,79,96,313</sup> Given that traditional arthrodesis indications include age < 50 years, long-term adverse functional outcomes are a concern. Coester et al<sup>45</sup> carried out a long-term follow-up study of 23 patients who had undergone isolated talocrural arthrodesis for posttraumatic arthritis a mean duration of 22 years earlier and found a significantly higher rate of arthritis in the ipsilateral hindfoot and midfoot joints compared to the same joints in the contralateral limb. In addition, based on information from standardized, self-report functional assessment instruments, ipsilateral foot pain interfered with the functional mobility of almost all patients. For this reason, the long-term cost-effectiveness of arthrodesis compared to arthroplasty has been questioned. Two recent studies concluded that although direct costs associated with arthrodesis are significantly lower than with ankle arthroplasty, arthroplasty results in approximately 2 additional quality-adjusted life years.<sup>54,179</sup>

## Leg, Heel, and Foot Pain: Nonoperative Management

The cause of pain in the leg, heel, or foot is often multifactorial, but it most commonly occurs from biomechanical stress or overload. Pain is typically described as an overuse syndrome from repetitive microtrauma, but is also described as non-inflammatory degeneration.<sup>345</sup> The increased biomechanical stress may be from obesity, work habits, faulty alignment of the lower extremity, muscle imbalances or fatigue, changes in exercise or functional routines, training errors, improper footwear for the ground, functional demands placed on the feet, or a combination of several of these factors<sup>226,345</sup> (see Table 22.3).<sup>213,226,345</sup> Symptoms persist because continued overload is placed on the tissue before it is adequately healed. A common cause predisposing this region to painful syndromes is excessive pronation of the subtalar joint during weight-bearing activities. Increased pronation could be related to a variety of causes including excessive joint mobility, inadequate neuromuscular control,

**TABLE 22.3** Intrinsic and Extrinsic Factors Associated With Heel Pain

Intrinsic Factors	Extrinsic Factors
Pes cavus foot type	Running
High BMI	Increase in exercise routine
Decreased ankle dorsiflexion	Work demands
Weak foot intrinsic musculature	Assembly line work
Faulty lower extremity alignment	Work requiring in/out of vehicles
Female gender	Improper footwear

leg length discrepancy, femoral anteversion, external tibial torsion, genu valgum, or muscle flexibility and strength imbalances in the lower extremity. Often there is a hypomobile gastrocnemius-soleus complex related to the abnormal foot pronation.

## Related Pathologies and Etiology of Symptoms

The extrinsic foot musculature symptoms can develop at or near proximal attachments in the leg (shin splints); at the ankle where the tendons course around bony prominences; or at distal attachments in the foot (tendinopathy). Symptoms may also develop in the intrinsic foot muscles as well as in the plantar fascia (plantar fasciitis). Several common syndromes are described in this section.

### Heel Pain

Heel pain is most often experienced on either the plantar surface of the heel or near the postero-superior calcaneus. Plantar surface pain at the insertion of the plantar fascia is common and may be related to overstretch of this tissue. Plantar pain may also result from calcaneal heel spurs or tissue bruising after high-impact forces related to jumping or falling. Posterior pain is most often located near the insertion of the Achilles tendon due to insertional tendinopathy or inflammation of one of the Achilles bursa.<sup>345</sup>

### FOCUS ON EVIDENCE

The Heel Pain Committee of the American College of Foot and Ankle Surgeons (ACFAS) published a revised *Clinical Practice Guideline (CPG)*<sup>345</sup> that categorizes mechanical heel pain as plantar heel pain (including plantar fasciitis, plantar fasciosis, and heel spurs) and posterior heel pain (including insertional Achilles tendinopathy and bursitis). The Orthopaedic Section of the American Physical Therapy Association has published two separate *CPGs*, one for Achilles pain, stiffness, and muscle power deficits (Achilles tendinitis), and one for heel pain (plantar fasciitis).<sup>39,213,226</sup> Recommendations from these *CPGs* are included in the following sections.

**Plantar fasciitis.** Pain is usually experienced along the plantar aspect of the heel, where the plantar fascia inserts on the medial tubercle of the calcaneus. The site is typically very tender to palpation. Pain occurs on initial weight bearing after periods of rest (start-up pain), then decreases, but returns as weight-bearing activity increases.<sup>213,226,345</sup> Associated impairments include hypomobile gastrocnemius-soleus muscles and plantar fascia pain or restriction when extending the toes (windlass effect).<sup>98,213</sup> Martin et al<sup>213</sup> suggest research to explore the role of decreased intrinsic muscle strength as a causative factor in plantar fascia pain. A high body mass

index, inappropriate footwear, and either a flexible flat foot (pes planus) or a high arch foot (pes cavus) may be predisposing factors. Pressure transmitted to the irritated site with weight bearing or stretch forces to the fascia, as when extending the toes during push-off, causes pain. Gait mechanics may be impaired, with avoidance of heel strike during loading response and decreased push-off during terminal stance. Although an infracalcaneal spur (heel spur) is frequently found in individuals with plantar fasciitis, its presence or absence does not necessarily correlate with symptoms.<sup>345</sup>

**Insertional Achilles tendinopathy and bursitis.** Pain is experienced at the calcaneal insertion of the Achilles tendon.<sup>39,345</sup> Associated impairments include decreased ankle dorsiflexion<sup>206,317,373</sup> abnormal subtalar ROM, decreased ankle plantarflexion strength,<sup>206,310,311</sup> and increased foot pronation with walking or running.<sup>376</sup> Reported risk factors include obesity, hypertension, diabetes, and use of certain medications including fluoroquinolone (antibiotic) and statin medications.<sup>39,40,210</sup> Ultrasound imaging may be able to identify tendinopathy prior to onset of pain and dysfunction.<sup>93,94</sup> Once symptomatic, pain and stiffness follow a typical tendinopathy pattern: symptoms in the tendon begin following a period of inactivity, decrease with a return to activity, but eventually increase as activity continues. Changes in shoe heel height can provoke symptoms, particularly for individuals walking long distances in a low-heeled shoe when they are accustomed to high heels.

### Tendinosis, Tendonitis, and Tenosynovitis

Tendinopathy is an umbrella term that indicates a disorder of the tendon. Tendinosis describes a long-standing, chronic, degenerative tendon that is absent of inflammatory mediators or cells. Tendinitis indicates an acute inflammatory process in the tendon. Differentiation between tendinitis and tendinosis is critical to successful physical therapy intervention. Tenosynovitis is inflammation of the tendon synovial sheath, which may occur in the sheath of the posterior tibialis tendon as it passes posterior to the medial malleolus.

Any tendon of the extrinsic foot muscles may become irritated as it approaches and crosses behind or over the ankle or at the insertion on the foot. Pain occurs during or after repetitive activity. When the foot and ankle are evaluated, pain is experienced at the site of the lesion during resistance to the muscle action and when the involved tendon is placed on stretch or palpated.<sup>39,345</sup>

A common site for Achilles tendinopathy symptoms is 2 to 6 cm proximal to the calcaneal insertion in the midsubstance of the tendon.<sup>39</sup> With Achilles tendinopathy, the affected leg will demonstrate decreased plantar flexor strength and endurance, as demonstrated by a limited ability to perform repetitive unilateral heel raises when compared to the unaffected side.<sup>310</sup> Tendon degeneration in the posterior tibialis tendon is also a common source of pain that can lead to impaired walking or acquired pes planus.<sup>178</sup> Symptoms in the anterior or posterior tibialis tendons or fibularis tendons are

often associated with athletic activities such as running and court sports.

### FOCUS ON EVIDENCE

Volume 45, No. 11 of the *Journal of Orthopaedic & Sports Physical Therapy* (November 2015) is a special journal issue encompassing current basic and applied science as it relates to the pathophysiology, examination, evaluation, and treatment of tendinopathy. Relative to the foot and ankle, Michener and Kulig<sup>233</sup> compare and contrast the pathophysiologic changes and treatment strategies for management of supraspinatus and Achilles tendinopathy. Coupe et al<sup>53</sup> review literature related to eccentric Achilles tendon loading as a treatment for tendinosis, concluding that tendon loading is generally beneficial but that current literature does not support one optimal loading strategy. Silbernagel and Crossley<sup>309</sup> describe an evidence-based decision-making process used to return an athlete with midportion Achilles tendinopathy back to full sport participation while minimizing the chance of recurrence.

### Shin Splints

This term is used to describe activity-induced leg pain along the posterior medial or anterior lateral aspects of the proximal two-thirds of the tibia. It may include different pathological conditions such as musculotendinopathy, stress fractures of the tibia, periosteitis, compartment syndrome, or irritation of the interosseous membrane. Muscle fatigue with vigorous weight-bearing exercise, often associated with a significant increase in intensity or duration, may precipitate the condition.

**Anterior shin splints.** Overuse of the anterior tibialis muscle is the most common type of shin splint. Impairments associated with shin splints include hypomobile gastrocnemius-soleus complex, weak anterior tibialis muscle, and excessive pronation with walking or running<sup>306,350</sup> Pain increases with active dorsiflexion and when the muscle is stretched into plantarflexion.

**Posterior shin splints.** A tight gastrocnemius-soleus complex and a weak or inflamed posterior tibialis muscle, along with increased foot pronation, are associated with postero-medial shin splints. Pain is experienced when the foot is passively pronated to end range with overpressure and/or actively supinated against resistance.

### Common Impairments of Structure and Function, Activity Limitations, and Participation Restrictions

- Pain with repetitive activity, on palpation of the involved site, with stretch of the involved musculotendinous unit, and with resistance to the involved muscle
- Pain on initial weight bearing and with repetitive weight-bearing activities and gait

- Muscle length-strength imbalances, especially tight gastrocnemius-soleus muscle group
- Abnormal foot posture, including that created by faulty footwear
- Decreased length of time the individual can tolerate standing
- Decreased distance or speed of ambulation, which may limit associated community and work activities and recreational and sport activities

### Leg, Heel, Foot Pain: Management—Protection Phase

If signs of local inflammation are present (erythema, edema, warmth), treat as an acute condition with rest and appropriate modalities (See Chapter 10 for general principles and guidelines). Stress relief can be achieved with immobilization in a cast or orthosis with the foot slightly plantarflexed; or with a temporary heel lift, a shoe orthotic, or calcaneal taping.<sup>39,76,134,144,213</sup> Interventions in the protection phase include:

- Cross-friction massage to the site of the lesion
- Submaximal muscle-setting contractions
- Passive stretch of the plantarflexors
- Active ROM within pain-free range
- Activity modification or avoidance
- Supportive taping or orthotic prescription<sup>39,144,178,213,226,247,345</sup>

### Leg, Heel, Foot Pain: Management—Controlled Motion and Return to Function Phases

When symptoms become subacute, the entire lower extremity as well as the foot should be examined for impaired alignment or muscle flexibility and strength imbalances. Eliminating or modifying causative factors in the lower extremity kinetic chain is important to improve outcomes and to correct alignment.<sup>44,381</sup> Orthotic devices may be necessary to correct alignment.<sup>39,144,178,213,345</sup> A comprehensive movement screen such as described by Cook et al<sup>46</sup> can also be useful in determining aberrant movement patterns, asymmetries, weakness, or tightness remote to the painful area that may be contributing to the problem. Detailed descriptions of stretching and strengthening exercises for the ankle and foot are found in the last section of this chapter.

### FOCUS ON EVIDENCE

A multicenter, randomized study of 60 subjects with plantar heel pain compared two treatment groups, one receiving electrophysical agents and exercise and the other treated with manual interventions (vigorous soft tissue techniques and joint mobilization directed at the hip, knee and ankle/foot as needed) and exercise. Both groups demonstrated significant improvement in functional measures and pain, with those

receiving the specific manual interventions and exercise showing greater increases at 4-week (function and pain) and 6-week (function only) follow-ups.<sup>44</sup> Individuals with plantar heel pain symptoms less than 7 months' duration were more likely to respond positively to treatment, while age and BMI were not related to the treatment response.<sup>218</sup>

### Educate the Patient and Provide Home Exercises

- Help the patient incorporate home exercises and soft tissue and joint mobilization into his or her daily routine.
- If the patient experiences pain when first bearing weight, especially in the morning and after prolonged sitting, teach the patient to do ROM exercises with the foot for several minutes before standing. Emphasize full dorsiflexion active ROM.
- Teach prevention, including the following principles.
  - Before intense exercise, use gentle repetitive warm-up activities followed by stretching of tight muscles.
  - Use proper foot support for the ground conditions.
  - Allow time for recovery from microtrauma after high-intensity exercise bouts.

### Increase Mobility of Range-Limiting Structures

- The gastrocnemius-soleus muscle complex is frequently hypomobile in cases of foot problems and should be stretched if limiting dorsiflexion. Restricted mobility causes the foot to pronate when the ankle dorsiflexes.

#### CLINICAL TIP

Instruct patients with pes planus to wear supportive shoes with medial arch support when performing gastrocnemius-soleus stretches to protect the foot.<sup>153</sup>

- With heel pain, apply joint and soft tissue mobilization techniques.
  - Deep massage to the insertion of the plantar fascia at the medial calcaneal tubercle and the gastrocnemius-soleus tendon.
  - Joint mobilization directed to specific limitations such as lateral glide to the subtalar joint to improve rear foot inversion and posterior glide to the talus to improve ankle dorsiflexion.
  - Joint mobilization at the knee or hip as needed.<sup>44</sup>
- Stretching exercises to the plantar fascia that includes toe extension with ankle dorsiflexion and eversion.<sup>67</sup>
- Stretching exercises to any lower extremity region that may affect alignment and function of the foot and ankle.

### Improve Muscle Performance

- Begin with resistive isometric and progress to resistive dynamic exercises to the foot and ankle in open- and closed-chain activities.

- For medial and lateral support, develop a balance in strength between the muscle groups, especially the invertors and evertors.<sup>39,178</sup>
- Emphasize muscular endurance and train the muscles to respond to eccentric loading.
- With plantar fasciitis, the intrinsic muscles need to be strengthened. Include exercises that require toe control such as gathering a towel or picking up small objects.

### FOCUS ON EVIDENCE

Barefoot running is a recent trend among recreational runners. It is proposed that barefoot running facilitates mid-foot strike during the contact phase of the running cycle, reducing ground reaction force and decreasing injuries.<sup>189,194,322</sup> Limited evidence supports an association between barefoot running and reduced ground reaction force at impact.<sup>117</sup> It is also theorized that barefoot running strengthens the muscles of the foot and lower leg and improves proprioception.<sup>190</sup> A recent prospective study randomly assigned 29 experienced runners to an 8-week running program completed in either running shoes or while barefoot. Although both groups demonstrated significant improvement in some performance outcome measures, there were no between group differences noted. The authors suggest that 8 weeks may be an insufficient amount of time to observe changes related to footwear.<sup>240</sup>

## Ligamentous Injuries: Nonoperative Management

Ankle sprain is one of the most common musculoskeletal injuries with physically active individuals who are at higher risk than the general population.<sup>90,91,370</sup> First-, second-, and third-degree (grades I-III) sprains are usually managed conservatively.<sup>154,220</sup> The most common type of ankle sprain is caused by inversion stress and can result in a partial or complete tear of the anterior talofibular (ATF) ligament and often the calcaneofibular (CF) ligament (see Fig. 22.2).<sup>69,90,154,281,370</sup> The posterior talofibular (PTF) ligament, the strongest of the lateral ligaments, is rarely torn in isolation; significant inversion stress is required to tear the PTF ligament.<sup>278</sup> If the inferior tibiofibular ligaments are torn after torsional stress to the ankle, the mortise becomes unstable.<sup>21,140</sup> Rarely do the components of the deltoid ligament become strained; rather, there is greater likelihood of an avulsion from or fracture of the medial malleolus with significant eversion stress. Depending on the severity of injury, the joint capsule also may be involved, and intra-articular pathology, including cartilage lesions, may occur.<sup>327</sup>

Prospective cohort studies note that a history of a previous ankle sprain is a risk factor for future sprain,<sup>13,62,85,129,174,175,324,351</sup> as is participation in organized or recreational athletic activities.<sup>69,90,370</sup> Using an external support (lace-up ankle brace or athletic ankle taping) has been shown to decrease the incidence

of ankle sprains.<sup>68,147,188</sup> Conflicting evidence exists related to age, gender, physical characteristics, postural control, general ligamentous laxity, and foot type as risk factors for ankle sprain.<sup>212</sup> Table 22.4 details evidence-based risk factors associated with acute lateral ankle sprains.<sup>212</sup>

## Common Impairments of Structure and Function, Activity Limitations, and Participation Restrictions

- Pain when the injured tissue is stressed in mild to moderate injuries.
- Excessive motion or instability of the related joint in the case of complete tears.
- Proprioceptive deficit manifested as decreased ability to perceive passive motion and development of balance impairments.<sup>374</sup>
- Related joint symptoms and reflex muscle inhibition.<sup>259</sup>
- Possible decreased ROM of the talocrural joint in recurrent lateral ankle sprains due to anterior subluxation and impaired tracking of the talus in the mortise.<sup>366</sup>
- Postural control deficits following an acute lateral ankle sprain in both the injured and uninjured limb.<sup>192,225</sup>
- Restricted ambulation (requiring an assistive device) during the acute and subacute phases. With chronic instability, the individual may have difficulty walking or running on uneven surfaces or making quick changes in direction. He or she may be unable to land safely when jumping or hopping.

### FOCUS ON EVIDENCE

A randomized controlled trial (N = 40) incorporated a repeated measures design to demonstrate the efficacy of a balance-training program using elastic tubing as a perturbation force. Individuals with chronic ankle instability (CAI) (n = 20) were matched with healthy normal subjects (n = 20). Subjects in each group were randomly assigned to either an elastic tubing balance exercise group or to a control. Total travel distance of the center of pressure was measured at baseline, after 4 weeks of training, and at a 4-week follow-up session. The 4-week elastic resistance balance-training program caused a significant improvement in balance for the exercise group when compared to the control; and significant improvement in the CAI group compared to the healthy normal group. Improvements in balance persisted 4 weeks following

the intervention. The authors concluded that elastic resistance for balance perturbation should be considered for both home and clinic use in individuals with CAI.<sup>120</sup>

## Ankle Sprain: Management—Protection Phase

See Chapter 10 for principles of treatment during the stages of inflammation and repair.

### FOCUS ON EVIDENCE

The Orthopaedic Section of the American Physical Therapy Association published a *CPG* to guide evidence-based management of ankle ligament sprains.<sup>212</sup> The National Athletic Trainer's Association published a position statement guiding the conservative management of ankle sprains in athletes.<sup>154</sup> Recommendations from both of these papers are incorporated into the following section.

- Use compression, elevation, and repeated intermittent applications of ice to minimize swelling.<sup>25,26,105,358</sup> Randomized controlled trials have failed to demonstrate consistent support for electrical or acoustic modalities.
  - Electrotherapy: There is moderate evidence both for and against the use of electrotherapy to manage acute pain and swelling, with a trend toward no benefit.<sup>88,208,227,316</sup>
  - Ultrasound: Clinicians should not use ultrasound for the management of acute ankle sprains.<sup>363</sup>
- Provide external support (brace, semi-rigid ankle orthotic, or walking boot) in conjunction with progressive, functional weight bearing.<sup>31,47,151</sup>
- Use gentle joint mobilization techniques to maintain mobility and inhibit pain.<sup>195</sup>
- Perform gentle sagittal plane active ROM in a pain-free range.
- Educate the patient.
  - Teach the patient the importance of RICE (rest, ice, compression, and elevation), and instruct the patient to apply ice every 2 waking hours during the first 24 to 48 hours.
  - Teach partial weight bearing with crutches and instruct in progressive weight bearing.
  - Teach muscle-setting (isometric) exercises and active toe curls to help maintain muscle integrity and assist with circulation.

**TABLE 22.4** Intrinsic and Extrinsic Factors Associated With Acute Lateral Ankle Sprain

Intrinsic Risk Factors	Extrinsic Risk Factors
Previous ankle sprain <sup>13,62,85,129,174,175,324,351</sup>	Athletic participation without external support <sup>68,147,188</sup>
Decreased ankle dorsiflexion ROM <sup>62</sup>	Failure to warm-up prior to activity <sup>124</sup>
	Failure to participate in balance/proprioceptive training <sup>141,223,224,236,282,297,356,362</sup>

### FOCUS ON EVIDENCE

Bleakley et al<sup>27</sup> randomly assigned individuals (N = 101) to either accelerated rehabilitation (AR) or standard protection (SP) groups after acute grade I and II lateral ankle sprains (average 2 days' postinjury). Individuals in the AR group (n = 50) received early therapeutic exercise as well as cryotherapy and advice for early progressive weight bearing. The SP group (n = 51) initially received only cryotherapy and advice for progressive weight bearing; therapeutic exercise was initiated after 1 week. After the first week, both groups completed a progressive therapeutic exercise regime that consisted of muscle strengthening, neuromuscular training, and sport-specific functional exercise. The AR group demonstrated significant improvement in ankle function at weeks 1 and 2 and significantly greater physical activity during the first week. At 16 weeks, both groups reported good ankle function with just four re-injuries (two in each group). This finding supports early initiation of therapeutic exercise following acute ankle sprain.

### Ankle Sprain: Management—Controlled Motion Phase

- As the acute symptoms subside, continue to provide protection for the involved ligament with an orthosis during weight bearing. Commercial orthoses, such as an air splint, provide medial-lateral stability while allowing dorsiflexion and plantarflexion.<sup>22,118,159</sup>
- Provide gait training to normalize walking over level ground and on stairs.
- Apply cross-friction massage to the ligaments as tolerated.
- Use grade II joint mobilization techniques to maintain mobility of the joint, particularly posterior glide of the talus.
- Advance therapeutic exercise resistance or intensity. Avoid end-range inversion. Exercises should be completed frequently throughout the day.
  - Nonweight-bearing active ROM into dorsiflexion, plantarflexion, inversion, and eversion; toe curls; and ankle alphabet.
  - Sitting with the heel on the floor and performing foot intrinsic exercises: towel gathering or picking up objects with the toes.
- Stretch the gastrocnemius-soleus muscle group to restore full ankle dorsiflexion. Begin with towel stretch in long sitting, then progress to weight bearing stretches.
- As swelling decreases and weight bearing tolerance increases, progress to progressive resistive exercise (strength and endurance) and neuromuscular re-education (balance and proprioception).<sup>141</sup> Include isometric and isotonic exercise, bicycle ergometry, and partial to full weight-bearing balance board exercises. Initially, have the patient wear a range-limiting brace or orthosis to prevent excessive stress on the healing ligament.

### Ankle Sprain: Management—Return to Function Phase

- Progress strengthening exercises by adding elastic resistance to foot movements in long-sitting (open-chain) and sitting with the heel on the floor for partial weight bearing.
- Progress neuromuscular reeducation training to improve balance, coordination, stability, and neuromuscular response in full weight bearing. Progressively challenge dynamic lower extremity stabilizers by introducing varying degrees of surface instability and external perturbation.
- Incorporate movement patterns, such as forward/backward walking and cross-over side stepping with elastic resistance secured around the unaffected lower extremity.<sup>120</sup>
- Utilize an unstable surface, such as a BOSU®, BAPS® board, or mini-trampoline, or an ankle destabilization shoe or boot.<sup>73,74</sup>
- Depending on the final goals of rehabilitation, train the ankle with weight-bearing activities, such as walking on uneven ground, jogging, running, jumping, hopping, and sprinting. Incorporate agility activities such as controlled twisting, turning, and lateral weight shifting. Provide distracting activities such as ball toss to increase automaticity of postural control.<sup>274,287</sup>
- When the patient is involved in sports activities, the ankle should be splinted or taped and appropriate shoes should be worn to protect the ligament from re-injury.<sup>68,147,188</sup>

### CLINICAL TIP

Use of external support during neuromuscular training has been shown to decrease muscle activation in the lower extremity.<sup>88,261</sup> To maximize the neuromuscular benefit of training, select balance and proprioception exercises that can be completed safely without external support.

### FOCUS ON EVIDENCE

McKeon and Hertel<sup>224</sup> performed a systematic literature review to determine the effectiveness of balance and coordination training for individuals with lateral ankle instability. Prophylactic balance training substantially reduced the risk of sustaining ankle sprains, with a greater effect seen in those with a history of a previous sprain. There was inadequate evidence to show that training prevented sprains for those without previous injury. The review also demonstrated that balance and coordination training substantially improved treatment outcomes after acute ankle sprains. A recent randomized controlled trial (N = 522), not included in this systematic review, found a 35% reduction in ankle sprain recurrence in individuals who completed an unsupervised proprioceptive training program following usual care for lateral ankle sprain.<sup>141</sup> Neuromuscular re-education for balance and proprioceptive training should

be performed following lateral ankle sprain to reduce re-injury rates.<sup>154,212</sup>

In a prospective study, 384 individuals with subacute ankle sprain (< 2 months from injury) were randomly assigned to one of three treatment arms: training group (n = 120), brace group (n = 126), or combination group (n = 138). The training group completed an 8-week independent neuromuscular training program; the brace group received a semi-rigid brace to be worn during all sporting activities for 12 months; and the combination group received both the neuromuscular training program and a semi-rigid brace to be worn during all sporting activities for 8 weeks. Re-injury was tracked for 1 year. During the 1-year follow up, 69 participants (20%) reported a subsequent ankle sprain: 29 (27%) in the training group, 17 (15%) in the brace group, and 23 (19%) in the combination group. The brace group re-injury rate was significantly lower than the training group, but not significantly different than the combination group. There was no between-group difference in the severity of subsequent ankle sprains. An extended period of brace wear following lateral ankle sprain is indicated to reduce re-injury rates.<sup>147</sup>

## Traumatic Soft Tissue Injuries: Surgical and Postoperative Management

### Repair of Complete Lateral Ankle Ligament Tears

A third-degree (grade 3) sprain of the lateral ankle, which usually occurs as the result of a severe inversion injury, causes a complete tear of the ATF ligament, often the CF ligament, and infrequently the PTF ligament (Fig. 22.7).<sup>281</sup>

**FIGURE 22.7** A complete tear of the lateral collateral ligament complex as the result of a severe (grade 3) inversion injury of the ankle. (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging*, ed. 3. Philadelphia: F.A. Davis, 2010, p 432, with permission.)

Tearing of both the ATF and CF ligaments leads to combined instability of the tibiotalar and subtalar joints. The ATF ligament is most likely to tear when forceful inversion occurs while the ankle is plantarflexed.<sup>164,304,357,384</sup> Injuries associated with lateral ankle sprain include articular cartilage (talar dome) lesions, fibularis tendon tearing or subluxation, a transverse fracture of the lateral malleolus, syndesmosis sprain, or an avulsion fracture of the base of the fifth metatarsal.<sup>70,89,281,284,364</sup>

In addition to significant swelling, tenderness, and pain, a complete tear of one or more lateral ligaments causes marked mechanical instability and functional instability of the ankle during weight-bearing activities.<sup>125,128,132</sup> Mechanical instability is defined as ankle mobility beyond the physiologic ROM, increased talar tilt, and an anterior drawer sign indicative of joint laxity. Functional instability is characterized by the patient's sensation of the ankle "giving way."<sup>125,132,329</sup> The severity of functional ankle instability does not appear to be directly related to the magnitude of anterior joint displacement or talar tilt.<sup>56,132</sup> It has been hypothesized that functional ankle instability results from both peripheral and central sensorimotor deficits.<sup>121,126</sup> This may account for the feeling of "giving way" experienced by many patients who have no evidence of mechanical instability with physical examination after a lateral ankle sprain. Despite normal joint motion and no apparent laxity, these individuals report significant functional limitations. Hiller et al<sup>128</sup> proposed multiple subgroupings of individuals with ankle instability symptoms, positing that ankle instability results from an interaction between mechanical, functional, and perceived instability.

After an acute, grade 3 inversion injury, nonoperative treatment is successful for most individuals. However, some patients develop chronic ankle instability with continued pain, recurrent sprains, and a consistent feeling of the ankle "giving way." For patients with demonstrated instability who do not respond to conservative management and for select patients with acute lateral ankle injuries who regularly engage in high-impact activities, surgical repair or reconstruction may be required to manage the instability and return the patient to the desired level of function.<sup>3,171,281</sup> The overall goal of surgery and postoperative management is to restore joint stability while retaining pain-free, functional ROM of the ankle and subtalar joints.<sup>3,171,281,296</sup>

### Indications for Surgery

The following have been frequently cited indications for surgical reconstruction or repair of the lateral ankle soft tissue structures:<sup>3,89,109,171,281,296</sup>

- Chronic mechanical and functional instability of the ankle during activity that is not resolved with several months of conservative management.
- Acute, radiographically or arthroscopically confirmed third-degree lateral ankle sprain resulting in complete tear of the ATF and/or CF ligaments.

## Procedures

### Types of Stabilization Procedures

There are numerous surgical procedures that may be used for reconstruction or repair of the lateral ankle ligaments and soft tissue structures (Fig. 22.8).<sup>37,52,89,109,143,171,266,281,296,320,338</sup> Procedures are dichotomized into two broad categories: repair and reconstruction.<sup>215,281</sup> Surgical repair techniques involve a direct end-to-end anatomic suturing of the torn or attenuated (overstretched) ATF or CF ligaments; surgical reconstruction uses tenodesis (tendon graft) to reconstruct the lateral ankle complex. Either procedure can be performed via arthroscopy or open procedure.<sup>3,109,336</sup>

The type of procedure selected depends on the severity and chronicity of the instability, the presence of comorbidities, the patient's age and anticipated postoperative activity level, and the surgeon's preferred method. Repair is typically the preferred procedure for patients with chronic lateral ankle instability who have normal body mass and ADL requirements. Reconstruction is reserved for individuals who may stress the ankle to a greater degree than normal.<sup>109,215</sup>

**Direct repair.** The surgery most commonly performed for a primary repair is the *modified Broström procedure*, also known as the *Broström-Gould procedure*.<sup>89,109,215,281</sup> This procedure involves an anatomic repair of the ATF and/or CF ligament(s) with one or more of the following techniques:

- Direct, end-to-end repair of midsubstance tear
- Imbrication (overlap/suture with pants-and-vest technique) of stretched ligament
- Anchoring of avulsed ligament to bone

The anatomic repair is augmented by suturing the lateral portion of the extensor retinaculum to the fibula, reinforcing the repaired structures. Retinacular reinforcement is regarded as a critical element to the success of the procedure.<sup>109</sup>

**FIGURE 22.8** Lateral view of the ankle depicting reconstruction of torn ATF and CF ligaments using a tendon graft to augment stability. Proximal advancement of the extensor retinaculum (not shown) over the reconstructed ligaments and suture attachment to the distal fibula provides additional stability.

**Reconstruction with augmentation.** Reconstruction procedures, in general, are employed when direct repair is not an option because of poor ATF and/or CF ligament tissue quality or when a patient's weight (more than 200 to 250 lb) will overly stress a direct repair. Reconstruction with augmentation is also used as a revision procedure when previous direct repair has failed to prevent a recurrence of instability. Current lateral ankle reconstruction procedures utilize anatomic reconstruction of the ATF and CF ligaments with tendon autograft or allograft. These procedures route the transferred tendon graft in such a way as to replicate the anatomic positions of the ATF and CF ligament origin and insertion sites.<sup>109</sup> The transferred tendon can be secured to the bone with anchors, interference screws, or endobutton devices.<sup>109,171,281,336</sup>

The ipsilateral fibularis brevis tendon is the most commonly used autologous graft. The tendon can be completely excised with the distal muscle fixed to the fibularis longus; or the tendon can be split, sparing the stabilizing action of the muscle.<sup>281,296</sup> To preserve the integrity of the fibularis brevis tendon, reconstruction procedures using a gracilis<sup>52,336</sup> or semitendinosus<sup>137</sup> tendon autograft, or an anterior tibialis<sup>83</sup> or bone-patellar tendon<sup>332</sup> allograft, have been developed.

### Surgical Approach

Repair and reconstruction have historically been performed as open procedures. Arthroscopy, previously reserved for perioperative examination to guide open reconstruction, has recently demonstrated promising short-term clinical results.<sup>3,48,51,110,166,217,336,337,361</sup> Arthroscopic direct repair and reconstruction have been described with early promising results in nonrandomized, case series reports. Techniques vary, but both procedures follow the general tenets for repair and reconstruction described above. In a recent systematic review that included published reports of arthroscopic repair (21 studies) and arthroscopic reconstruction (6 studies), Matsui et al<sup>216</sup> concluded there is insufficient evidence to support a high grade of recommendation for minimally invasive surgery.

### Operative Overview

Prior to an open repair or reconstruction for lateral ankle instability, arthroscopy is performed to assess the extent of intra-articular pathology. A high percentage (77% to 95%) of chronically unstable ankles exhibit associated intra-articular pathology, specifically small articular cartilage lesions, which are thought to be a precursor to osteoarthritis of the ankle.<sup>89,138,333</sup> If a chondral lesion is identified, arthroscopic subchondral drilling (microfracture) is typically performed.<sup>138,339</sup>

After arthroscopy an oblique or curvilinear incision is made beginning at the anterior aspect of the distal fibula and extending distally along the lateral aspect of the ankle and foot. If a direct repair (Broström-Gould) procedure<sup>119</sup> is used, torn or avulsed structures are repaired with permanent sutures by excision and end-to-end repair, a vest-over-pants (imbrication) technique, or through drill holes in the bone.

The repair is augmented by suturing the lateral portion of the extensor retinaculum to the distal fibula.<sup>281</sup> If an autologous fibularis brevis tendon graft is to be used to provide additional reinforcement (Chrisman-Snook procedure),<sup>43</sup> the tendon is split longitudinally. One half of the tendon is transected from the musculotendinous junction, leaving the distal insertion intact. Bone tunnels are drilled in the fibula and calcaneus. The graft is passed through bone tunnels and, after appropriate tensioning, is secured either to the base of the fifth metatarsal or to the distal fibula with permanent sutures. If a semitendinosus or gracilis graft is used, a third bone tunnel is drilled in the lateral neck of the talus and the free graft is secured in the tunnel with a biotendosis screw.<sup>52,83,281,338</sup> With either a fibularis graft or a free graft, the extensor retinaculum is advanced proximally and sutured over the ligament repair to the distal fibula for additional reinforcement.

Prior to wound closure, ankle stability and ROM are checked. The foot and ankle are placed in a compression dressing in a nonwalking bivalve cast or posterior orthosis with the ankle in 0° of dorsiflexion and slight eversion. The leg is elevated for edema management.

### Postoperative Management

Postoperative care varies by procedure and surgeon. Direct repair procedures rely on biomechanically weaker suture repair when compared to the strong fixation of allograft tissue reconstruction.<sup>215,281</sup> Because of this, post-operative progression of direct repair has traditionally been more conservative than for reconstruction, despite scant evidence to support this approach.<sup>217,270</sup>

Initial management generally consists of a period (2 to 6 weeks) of nonweight-bearing immobilization followed by 2 to 4 weeks of weight bearing to tolerance in a walking boot.<sup>264,281</sup> Protected ROM exercise is initiated after the initial immobilization period; terminal inversion is avoided. The exercise progression after surgery is similar to that used for nonoperative management of lateral ankle sprains. Postoperative management attempts to restore normal ROM and neuromuscular control while preventing re-injury.<sup>264</sup>

#### Immobilization and Weight-Bearing Considerations

**Immobilization.** After some degree of swelling has subsided, usually within 3 to 5 postoperative days, the compression dressing and protective cast or orthosis is removed and a short leg cast is reapplied. Depending on the type and strength of the repair, the cast is removed at 2 to 6 weeks and replaced with an air-stirrup-type orthosis, a removable cast boot, or a CAM walking brace, which is worn for several additional weeks.<sup>52,89,264,281,372</sup> Once in a removable boot or orthosis, patients are encouraged to perform active ROM dorsiflexion/plantarflexion and restricted active ROM inversion/eversion (10°-15° arc of motion).<sup>264</sup>

By 6 to 12 weeks, the patient gradually discontinues use of the immobilizer during ambulation. However, patients returning to athletic activities that involve jumping, running, and quick changes of direction are advised to wear a

protective orthotic device or to tape the ankle for at least 3 to 6 months to prevent re-injury.

**Weight bearing.** Although recent reports indicate that immediate weight bearing to tolerance is safe and beneficial,<sup>235,270</sup> a period of nonweight bearing in the protective orthosis or cast is still frequently recommended.<sup>264,281</sup> Following removal of the compression dressing, the return to weight bearing schedule can vary. Although Pearce et al<sup>264</sup> recommend weight bearing as tolerated 10 to 14 days following surgery, other authors recommend nonweight bearing for 6 weeks.<sup>52,281,332,338</sup> Full weight bearing without the immobilizer is typically permitted 6 to 12 weeks following surgery.

### FOCUS ON EVIDENCE

Individuals who underwent reconstruction of the ATF ligament with a gracilis autograft using interference screw fixation were randomly assigned to a typical rehabilitation (TR) group (immobilization/restricted weight bearing; n = 15) or an accelerated rehabilitation (AR) group (no immobilization/weight bear to tolerance; n = 18). All patients were followed for 2 years and outcome measures included stress radiography, self-reported functional scores (Karlsson and Peterson scoring system), and time between surgery and full return to activity. Two years postoperatively, both groups (TR and AR) demonstrated significantly improved stability and functional scores when compared to preoperative measures. There were no between group differences at 2 years in either of these measures. All patients were able to return to their previous athletic activity, with the AR group returning to activity significantly faster than the IR group (13.4 ± 2.2 weeks vs. 18.5 ± 3.5 weeks, respectively). No differences in performance ability were observed between group, and no cases of re-injury were reported in either group. The authors concluded that immediate mobility and weight bearing following reconstruction with interference screw fixation is safe and preferable.<sup>235</sup>

#### Exercise: Maximum Protection Phase

The focus of the first phase of rehabilitation, which lasts from 4 to 6 weeks, is to regain independent mobility for functional activities while protecting the repaired or reconstructed lateral ankle structures. Nonweight-bearing ambulation with crutches is typical following surgery. Some individuals may elect to use a rolling knee walker, particularly for extended periods of nonweight bearing. When the individual is seated, elevation of the operated foot is essential for edema management. The ankle may be immobilized, precluding ROM exercise. If ROM is permitted during this period, active ROM dorsiflexion/plantarflexion and restricted range inversion/eversion (10°-15° arc of motion) should be initiated.<sup>264</sup> Muscle-setting exercises in a neutral ankle position can be performed in or out of the immobilizer.<sup>235,264</sup>

**Goals and interventions.** Limited evidence guides exercise prescription during the immediate postoperative phase. The

following exercise-related goals and interventions are appropriate during the first postoperative phase.<sup>215,235,264,329,372</sup>

- **Prevent reflex inhibition of immobilized muscle groups.**
  - Submaximal muscle-setting (isometric) exercises in neutral ankle position, including the fibularis muscles.
- **Prevent stiffness of the operated ankle and foot and loss of extensibility of surrounding soft tissue.**
  - Active ROM in pain-free range for ankle plantarflexion and dorsiflexion. Active ROM in pain-free, restricted arc ROM for inversion and eversion (10°-15° arc of motion).<sup>264</sup>
  - Active ROM of the toes.
- **Maximize independent mobility.**
  - Gait and transfer training with appropriate assistive device. Adherence to weight-bearing restrictions.
- **Maintain strength of nonimmobilized muscle groups.**
  - Perform active and resistive exercises of the hip and knee of the operated lower extremity and resistance exercises of the upper extremities and non-operative lower extremity.
  - Perform mini-squats in bilateral stance with appropriate weight bearing.

### Exercise: Moderate and Minimum Protection Phases

Interventions in the moderate protection phase are initiated 4 to 6 weeks after surgery. At this time, healing structures are able to sustain controlled and progressive stress. Ankle ROM typically is limited and may be painful with end-range overpressure. Lower extremity balance and strength are impaired.

This phase is characterized by a gradual weaning from the immobilizer or brace accompanied by restoration of full, pain-free ankle joint mobility. Neuromuscular control, strength, and balance deficits are addressed while minimizing risk of re-injury. Gait training restores normal walking gait.

The minimum protection phase typically begins 8 to 12 weeks following surgery. The focus of the final rehabilitation phase is to restore full muscle strength and endurance of the operated extremity equal to that of the sound side; re-establish a normal, pain-free running gait pattern; and prepare for return to desired work-, sport-, or recreation-related activities. Interventions should emphasize restoring sensorimotor acuity, reducing functional deficits, improving postural control, and preventing re-injury.<sup>264</sup>

#### CLINICAL TIP

With proper precautions, a return to functional activities, including sport, may be possible 3 to 4 months postoperatively.<sup>235,264,372</sup> Fibularis muscle strength, assessed with handheld dynamometry, should test normal compared to the contralateral ankle.<sup>264</sup> No instability should be noted with anterior drawer or medial talar tilt tests. The following

functional tests help determine readiness for return to sport progression:

- Single-leg hop tests (for horizontal distance; for vertical distance; triple hop test; figure-of-8 hop test; and 6-meter timed hop test)<sup>192,298</sup>
- Star Excursion Balance test<sup>106,126,192</sup>
- Foot and Ankle Ability Measure functional questionnaire<sup>38,81</sup>
- Finally, a patient's perceived readiness for return to sport should be considered<sup>12</sup>

**Goals and interventions.** The following exercise-related goals and interventions are appropriate during the intermediate and final phases of rehabilitation:

- **Restore pain-free ROM of the operated ankle.** If strict immobilization was performed during the maximum protection phase, dorsiflexion will likely be limited to just a few degrees beyond neutral. To increase ankle ROM:
  - Progress AROM, achieving full ankle ROM by 8 weeks.
  - Initiate active multiplanar movements, such as figure-of-eight or ankle alphabet active ROM
  - Perform grade II or III joint mobilization techniques to the tibiotalar and tibiofibular joint if joint restriction limits dorsi- or plantarflexion.
  - Add self-stretching exercises to improve muscle flexibility, particularly for the gastrocnemius-soleus complex. Begin with a towel stretch; progress to standing on a wedge for an extended duration.
- **Increase strength of ankle and foot musculature in both lower extremities.**

#### CLINICAL TIP

Functional ankle instability has been shown to be associated with decreased strength (peak torque) of the ankle evertors of the involved ankle when compared to the contralateral ankle in individuals who have not undergone a surgical stabilization procedure.<sup>295</sup> In addition, the extent of strength loss in the ankle musculature has been shown to be associated with the chronicity of the instability.<sup>1</sup> Therefore, after surgical repair or reconstruction of the lateral ligaments, improving eversion strength is particularly important for developing dynamic stability.

- Perform progressive resistance exercises of all ankle muscles. Begin in nonweight-bearing and progress to weight-bearing positions.
- Unilateral calf raises should initially be performed with upper extremity support to minimize chance of re-injury due to balance loss.
- Emphasize strengthening of the ankle evertors. For dynamic strengthening, perform eversion against elastic or manual resistance in cardinal or diagonal planes.<sup>116</sup>

- Include bilateral hip and knee strengthening in weight-bearing positions, emphasizing proximal control (see Chapters 20 and 21).
- Progress to plyometric training when weight bearing is pain free, ankle is stable with stress testing, and 25 unilateral heel raises can be performed.<sup>264,311</sup> Begin with bilateral jumping, progress to unilateral hopping forward, backward, diagonally, and side-to-side. Plyometrics initially should be performed with external ankle support (bracing or taping).<sup>147,281</sup> Refer to Chapter 23 for a full description of plyometric activities.
- **Improve muscular endurance and cardiopulmonary fitness.**
  - Begin with pool walking, swimming, stationary bicycling, treadmill walking, or using a cross-country ski machine. Progress to deep-water running and outdoor walking, jogging, or running. Land-based activities should initially be performed with external ankle support (bracing or taping).<sup>147,281</sup>
- **Improve neuromuscular control, balance reactions, dynamic stability, and agility.**
  - Initiate progression of bilateral and unilateral balance activities beginning on stable surface and introducing progressive surface instability (refer to Chapters 8 and 23 for examples).
  - Initiate unilateral balance training at about 6 weeks postoperatively or when full weight bearing on the involved extremity is tolerated.
    - Progress from firm surface to soft surface (mini-trampoline or dense foam) to unstable surface (balance board or BOSU®)
    - Ankle proprioception may also be targeted on specific destabilization tools (ankle destabilization boot, ankle destabilization sandal, air bladder) with moderate inversion ROM (10°-15°) localized only under the rearfoot.<sup>74,92</sup>
  - Progress to activities to improve agility, such as grapevine walking (carioca), lateral shuffles, use of a slide board, and pivoting and cutting activities.
  - Refer to Chapter 23 for a sequence of balance and agility activities.

### FOCUS ON EVIDENCE

For patients with a functionally unstable ankle, proprioceptive/balance training using rocker or wobble boards has been shown to be an effective method of improving joint proprioception (joint position sense) and single-leg standing ability and muscle reaction times during balance activities.<sup>73,74,82</sup> Evidence is mixed regarding effect of balance training on postural sway, although this form of neuromuscular training is thought to demonstrate short-term effectiveness.<sup>63,212,224</sup>

In a prospective study by Verhagen et al,<sup>362</sup> 1,127 male and female professional volleyball players were randomly assigned by team to a training group or a control group. Throughout the 36-week volleyball season, the training groups participated

in a proprioceptive training program consisting of a variety of balance activities, some on balance boards. The control groups were not given any training program. Injuries were tracked for both groups over the course of the season. Among players who had a history of ankle sprains prior to the beginning of the study, those who participated in the balance training program had a significantly lower incidence of acute lateral ankle sprains during the season than those in the control group. Among training and control group players who did not have a history of lateral ankle sprains, there was no significant difference in the incidence of ankle injury during the season. The authors concluded that proprioceptive training was effective in preventing recurrence of lateral ankle injury in adult volleyball players.

Although this and other studies have not involved patients undergoing rehabilitation after repair or reconstruction of the lateral ankle ligaments, proprioceptive training programs such as these may be beneficial for the postoperative patient.

### ■ **Re-establish pain-free, symmetrical weight bearing during gait and related activities.**

- Begin gait training in a pool or land-based training on level surfaces as soon as ambulation in a controlled ankle motion brace (which allows dorsi- and plantarflexion) is permitted.
- Emphasize symmetrical weight bearing during sit-to-stand movements and eventually ascending and descending stairs
- Progress to ambulation and functional activities without the brace.
- **Safely return to functional activities and prevent re-injury.** The late rehabilitation phase typically occurs between 8 to 12 weeks postoperatively. Patients should demonstrate normal gait over level and uneven ground, and with ascending/descending stairs. Ankle strength should be  $\geq 90\%$  of the contralateral side.<sup>342</sup> Functional hop test performance (figure-of-eight, side-to-side) should demonstrate appropriate weight-bearing neuromuscular control and performance  $\geq 90\%$  compared to the contralateral side.<sup>141,270</sup> Precautions to reduce the risk of re-injury when returning to sports or high-demand activities after repair or reconstruction of lateral ankle ligaments are summarized in Box 22.4.

### Outcomes

An optimal postoperative outcome after lateral ankle repair or reconstruction is an ankle that has full mobility but remains stable and pain free during functional activities. Systematic reviews demonstrate that both repair and reconstruction procedures can predictably restore stability and return individuals to sport.<sup>63,160,268</sup> Published trials can be divided into those that treated individuals with acute lateral ankle sprain, and those that treated individuals with chronic ankle instability (characterized by recurrent ankle sprains and a feeling of “giving way”).

### BOX 22.4 Activity-Related Precautions to Reduce the Risk of Re-injury After Lateral Ligament Reconstruction of the Ankle

- Modify activities, if possible, by participating in low-impact sports, such as swimming, cycling, low-impact aerobics, or cross country skiing.
- Minimize or avoid participation in activities that involve high-impact (basketball, volleyball), rapid stopping and starting and changes of direction (tennis, soccer), or traversing uneven surfaces.
- If involved in activities associated with high risk of ankle injury:
  - Participate in a preseason injury prevention program that includes progressive proprioceptive and plyometric training and continue the program throughout a sport season.<sup>82,362</sup>
  - Wear a prescribed orthotic device, such as a functional stirrup brace or orthosis, to provide medial-lateral stability of the ankle.<sup>68,147,159,221,222,326</sup> Ankle taping has been shown to have prophylactic benefit in individuals with history of ankle sprain; however, both higher cost and higher incidence of integumentary problems favors the use of brace.<sup>186,234,253</sup>

#### ***Surgical management of acute lateral ankle sprain.***

Kerkoffs et al,<sup>160</sup> in a Cochrane Review, compared surgical to conservative management of acute lateral ankle sprain. No difference in return to previous level of sport participation was found, but surgical intervention resulted in a significant decrease in the number of individuals with recurrent ankle sprains compared to the conservative treatment group. A recent review had similar findings, noting that surgical intervention results in improved objective stability and decreased recurrence rates.<sup>268</sup> It is important to note that many of the studies included in these reviews are more than 20 years old and that only one of the included studies was published in the last 10 years. A recent randomized controlled trial of male military conscripts compared long-term outcomes for individuals with acute lateral ankle sprain treated with either direct repair (n = 25) or functional treatment (n = 26).<sup>271</sup> Functional treatment included immediate weight bearing to tolerance in a semi-rigid ankle orthotic for 3 weeks and therapeutic exercise guided by a physiotherapist. Individuals in the surgical group followed a similar postoperative weight-bearing, bracing, and exercise regimen. All patients in both groups recovered their preinjury activity level and completed military service. Fifteen (60%) of the surgical group and 18 (69%) of the functional treatment group returned for long-term follow-up (mean duration 14 years). Prevalence of re-injury was 1 out of 15 in the repair group and 7 out of 18 in the functional treatment group. Stress radiographs showed no difference between groups for anterior drawer or medial

talar tilt. Evidence of osteoarthritis on MRI was observed in 4 out of 15 individuals in the repair group and 1 out of 18 in the functional treatment group. The authors concluded that both methods of management are appropriate for return to preinjury activity level and that although surgical repair decreases risk of subsequent ankle sprain, there may be an increased risk of subsequent osteoarthritis. There is insufficient evidence from high quality randomized controlled trials to strongly recommend surgical management of acute lateral ankle sprains.<sup>160,268,271</sup>

***Surgical management of chronic ankle instability.*** Relatively few studies compare surgical to conservative management for chronic ankle instability. A recent review by de Vries et al<sup>63</sup> included four studies using several different surgical procedures including direct repair and reconstruction. All studies were judged at high risk for bias, generally related to blinding and selective reporting. The authors concluded that there was insufficient evidence to support any one surgical technique over others for chronic ankle instability. Individual should fail conservative management, specifically neuromuscular training, prior to surgical stabilization. Following surgery, postoperative management should include early mobility and weight bearing vs. 6 weeks of nonweight-bearing immobilization.

***Direct repair vs. allograft reconstruction.*** Both direct repair and allograft reconstruction result in predictable stability and good to excellent patient satisfaction.<sup>89,110,187,215,216,337</sup> Although not an optimal result, a slight loss of ankle motion (5°-10° of inversion) occurs most often after surgical reconstruction procedures.<sup>135,338</sup> Krips et al<sup>177</sup> evaluated two groups of athletes (n = 77) who had undergone either direct repair (DR) or an allograft reconstruction (AR) procedure for chronic lateral ankle instability 2 to 10 years (mean 5.4 years) earlier. There were no between group differences in preoperative age, activity level, or gender. All DR and AR participants had failed 6 months of conservative management. The AR group had significantly more patients with decreased ankle dorsiflexion than DR group (15/36 vs. 3/41). Patients did not have limited plantarflexion, eversion, or inversion in either group. Individuals in the DR group reported functional abilities as “excellent” or “good” at a significantly higher rate than those in the AR group (88% DR vs. 58% AR). AR group participants reported lower activity level, lower push-off power on the operated extremity during running, and lesser perceived ankle stability than those in the DR group. The authors concluded that direct repair was a better choice than tenodesis for primary repair of chronic ankle instability in an athletic population.

This difference in outcomes is becoming less of a concern with improved anatomic reconstruction techniques.<sup>137,301,336,338</sup> Improved allograft anatomical reconstruction surgical techniques, which more closely restores ankle kinematics, do not appear to be associated with restricted postoperative ROM or increased incidence of arthritis.<sup>272</sup> A nonrandomized cohort study compared outcomes in individuals after lateral ankle

repair (n = 61) or anatomic reconstruction (n = 25). At a minimum of 2-year follow-up, there were no significant differences in satisfaction, function (Foot and Ankle Disability Index), or activity levels (Tegner Activity Scale). ROM was not assessed.<sup>215</sup>

A recent review concluded there was insufficient high quality evidence to strongly support any specific surgical procedure for treating ankle instability.<sup>63</sup> Although direct repair is currently considered the preferred procedure for primary ankle stabilization, further research comparing allograft reconstruction techniques to direct repair are needed to draw a firm conclusion.<sup>109,135,177,187,215,216</sup> Regardless of procedure, it is unlikely that rearfoot motion mechanics are completely restored by either procedure.<sup>272</sup>

**Participation in sporting activities.** Most individuals return to previous level of sport following lateral ankle stabilization surgery.<sup>109,199,215</sup> A consecutive series of 42 professional athletes with acute grade III lateral ankle ligament injury were treated with direct repair stabilization (Broström procedure). All athletes returned to training at a median of 63 days and to full sport participation at a median of 77 days. Forty patients reported being very satisfied and two partly satisfied. There were no serious complications related to the surgery.<sup>372</sup> Long-term sport participation demonstrates increased attrition. Maffulli et al<sup>198</sup> reported sport participation rates of 38 individuals 9 years (range 5 to 13 years) after Broström repair for management of chronic lateral ankle instability. Twenty-two (58%) individuals practiced sport at preinjury levels; 6 (16%) individuals were still active but in less demanding sports (cycling and tennis); and 10 (26%) were no longer active in sport. Of the 10 patients who had abandoned sport, 6 had experienced a subsequent traumatic inversion injury on the repaired ankle and did not feel sport participation was a viable option. Comparing baseline to follow-up plain film radiographs, degenerative changes were found in 15 patients (39%); degenerative changes did not correlate with return to sport activity. Overall, 76% of individuals reported good to excellent outcomes; 68% of individuals did not experience a subsequent ankle inversion injury; and 74% of individuals continued sport participation.

## Repair of a Ruptured Achilles Tendon

Acute rupture of the Achilles tendon is a common soft tissue injury, occurring in the fourth to sixth decade of life for individuals who participate in exercise or athletic activities, with males affected about three times more than females.<sup>99,163,275</sup> The rupture usually is associated with a forceful contraction of the gastrocnemius-soleus muscles (triceps surae) during sudden acceleration or abrupt deceleration, such as jumping or landing.<sup>16,35</sup> Degenerative and mechanical factors appear to increase the risk of acute rupture.<sup>35</sup> The combination of a relatively hypovascular tendon, increased stiffness with aging, and repetitive microtrauma is thought to result in an inadequate reparative response and attrition of viable tissue. A concentric or eccentric mechanical overload completes the rupture.<sup>16,41,275,352</sup> Other factors thought to contribute to

Achilles rupture include diabetes, cigarette smoking, preinjury use of quinolone antibiotics, and preinjury steroid injections in the tendon or paratendon.<sup>127,275</sup>

The tendon most frequently ruptures 3 to 4 cm proximal to the calcaneal insertion.<sup>352</sup> At the time of injury, a complete rupture leads to pain, swelling, a palpable defect, and significant weakness in plantarflexion. On clinical examination, the concordant presence of the following three findings are highly suggestive of a complete Achilles rupture:<sup>100</sup>

- Abnormal Thompson Squeeze Test (squeezing the calf muscle while the patient is prone to elicit ankle plantar flexion)
- Decreased ankle resting compared with the contralateral side (normal resting tension is approximately 20°-30° plantarflexion)
- Palpable defect in the Achilles tendon

An acute rupture of the Achilles tendon can be managed nonoperatively or surgically. Both options have advantages and disadvantages. With surgical repair followed by rehabilitation there is a lower risk of re-rupture of the tendon than with conservative management.<sup>23,148,162,163,375</sup> However, there is also a risk of postoperative wound closure problems, infection, and nerve injury (typically sural) that is not present with nonoperative management. With either management strategy, there is a relatively long recovery period and persistent weakness compared to the contralateral limb. There is general agreement that surgical intervention is preferable for younger, active individuals and athletes who desire to return to sport<sup>64,193,200,323</sup> and that conservative management is preferable for the older, relatively sedentary individual.<sup>42,87,163,378</sup> However, recent studies employing early functional mobilization rehabilitation protocols have demonstrated similar outcomes for operative and conservative management.<sup>249,258,377,382</sup> Presently, there is insufficient evidence to clearly support conservative versus surgical management. Re-rupture rates are relatively low following either strategy as long as early mobilization is utilized.<sup>377,382</sup> Both patient and surgeon must weigh the advantages and disadvantages of surgery and nonoperative treatment and arrive at an individualized treatment strategy.

### FOCUS ON EVIDENCE

In the last decade, nonoperative management has evolved from 6 to 8 weeks of immobilization and restricted weight bearing to a more accelerated and functional rehabilitation approach.<sup>80,229,249,377</sup> Controlled and progressive loading of the tendon during the proliferative inflammatory phase (days to weeks following injury) has been shown to be beneficial to recovery.<sup>95</sup> Olsson et al<sup>258</sup> randomly assigned 100 individuals with acute Achilles tendon rupture into either a surgical repair group (surgery; n = 49) or conservative management group (nonsurgical; n = 51). Both groups completed an accelerated rehabilitation protocol that included immediate weight bearing to tolerance in a walker boot with three heel wedges

holding the foot in an equinus (roughly 20° plantarflexion) position. Over the course of 8 weeks, heel wedges were sequentially removed, allowing progressively increased dorsiflexion to neutral. Both groups were weaned from the boot and into shoes with heel lifts (surgical group at 6 weeks, nonsurgical group at 8 weeks) and then weaned from heel lifts (surgical group at 10 weeks, nonsurgical group at 14 weeks). During the first 8 weeks, both groups completed exercise, but the nonsurgical group was limited to toe flexion/extension active ROM. The surgical group completed progressive, range-limited active ROM and light resistance gastrocnemius/soleus exercises. After the initial protective phase, both groups completed a standardized rehabilitation program that included therapeutic and functional exercises; the surgical group exercise progression was progressed more quickly than the nonsurgical group. There were no between-group significant differences in self-reported symptoms, physical activity level, or quality of life. Both groups returned to preinjury physical activity level at 12 months. At 12 months, the surgical group showed significantly better performance on hop tests. Although not statistically significant, five patients in the nonsurgical group sustained a re-rupture, whereas no re-ruptures occurred in the surgical group. The authors concluded that although stable surgical repair with accelerated tendon loading could be performed without major soft tissue complications, the treatment was not superior to nonsurgical management in terms of functional results, physical activity, or quality of life.

### Indications for Surgery

The following are frequently cited indications for surgical repair or reconstruction of an acute or chronic rupture of the Achilles tendon:

- Acute, complete rupture of the Achilles tendon<sup>16,42,352</sup>
- The individual wishes to return to high-demand functional activities<sup>10,16,42,258,382</sup>
- Chronic, previously undiagnosed or untreated complete rupture in which end-to-end apposition cannot be achieved by conservative means<sup>239,369</sup>

### Procedures

#### Primary Versus Delayed Repair

A considerable number of surgical procedures and techniques have been described for repair or reconstruction of a ruptured Achilles tendon.<sup>16,24,55,249,258,369,377</sup> An open, minimally invasive, or percutaneous surgical approach can be used for a primary repair.<sup>16,42,191,352</sup> Although minimally invasive techniques have been described,<sup>199,201,196</sup> an open approach typically is used for a delayed repair requiring reconstruction of the neglected Achilles tendon rupture (>1 month postrupture).<sup>4,269,369</sup>

Primary repair of an acute rupture generally is performed within the first few days after the injury. It is usually accomplished with a direct, end-to-end repair in which the ends of the torn tendon are re-opposed and sutured together.<sup>16,352</sup>

The repair can be augmented with autograft or allograft, and this is more commonly performed with delayed repair.<sup>16,199,269,352</sup> Structures that may serve as a donor graft are the flexor hallucis longus, plantaris, fibularis brevis, semitendinosus, or a flap of fascia from the gastrocnemius.<sup>199,269,352</sup>

#### Operative Overview

**Primary repair.** In an open primary repair, an approximately 10-cm posterior incision is made at the distal leg medial to the Achilles tendon. A postero-medial incision avoids damage to the sural nerve. The tendon ends are identified, debrided, and sutured in re-opposition.<sup>16,352</sup> Core tendon sutures can be supplemented with epitendinous sutures to reinforce the repair.<sup>258</sup> Augmentation for primary repair is sometimes utilized, with inconclusive evidence.<sup>42,352</sup> With a percutaneous repair, the tendon ends are located and sutured together through several small puncture wounds that are made along the medial and lateral aspects of the Achilles tendon or through several small transverse incisions made directly over the tendon.<sup>16,115,200,201,352</sup> Mini-open repair uses a less lengthy skin incision than an open approach (approximately 5 cm). The tendon end is identified, sutured, and anchored to a bony drill hole for the repair.<sup>24,228</sup> In each of these approaches, the tendon is repaired while the ankle is maintained in a slightly plantarflexed or neutral position.

**Delayed repair/reconstruction.** With a tendon autograft reconstruction, a second incision is made to harvest the graft. For example, a fibularis brevis autograft requires release through a 2-cm incision at the base of the fifth metatarsal. The autograft is passed through, tensioned, and sutured to the opposed Achilles tendon stumps.<sup>202</sup>

Before closure, the ankle is moved into passive dorsiflexion to assess the integrity of the repair or reconstruction. After closure, a compression dressing and below knee posterior orthosis are applied with the ankle positioned in approximately 20° of equinus.<sup>16</sup> If immediate or very early weight bearing is to be allowed by the surgeon, a walking boot with heel wedges (approximately 20°) is applied.<sup>258</sup>

**NOTE:** An above-knee cast is applied (and later replaced with a below-knee cast) if the quality of the repair is tenuous.<sup>16</sup>

#### Complications

Complications associated with surgical repair or reconstruction of a ruptured Achilles tendon are summarized in Box 22.5.<sup>9,16,148,163,228,238,249,258,319,378,382</sup> Reports of complications typically separate re-rupture from other complications. Postoperative re-rupture is relatively uncommon with an incidence rate of approximately 3% to 5%.<sup>16,152</sup> Infection, adhesions, and sural nerve sensory disturbance are the most commonly reported complications.<sup>152</sup> A recent meta-analysis revealed a risk ratio of 3.9 in favor of nonoperative treatment for complications other than re-rupture; this translates to one additional complication (other than re-rupture) expected for every seven patients treated surgically.<sup>319</sup> The risk of complications associated with operative management decreases with

### BOX 22.5 Complications Following Primary Repair of a Ruptured Achilles Tendon

- Tendon re-rupture or failure of the tendon to heal (palpable gap)
- Wound complications: infection, delayed healing of the incision
- Sural nerve injury leading to altered sensitivity of the lateral border of the foot
- Adherent or hypertrophic scarring
- Deep vein thrombosis or pulmonary embolism
- Restricted ankle ROM as the result of joint hypomobility or soft tissue adhesions or contractures, leading to impaired function, such as difficulty ascending or descending stairs due to limited dorsiflexion
- Strength and muscular endurance deficits, typically of the plantarflexors
- Pain at the site of a suture knot
- Complex regional pain syndrome (rare)

minimally invasive and percutaneous procedures when compared with an open approach for repair.<sup>163,228,238</sup>

### Postoperative Management

Guidelines for postoperative rehabilitation after a primary open repair of an acute Achilles tendon rupture vary considerably in the literature and clinical practice. Historically, the surgery was followed by approximately 6 weeks of immobilization and nonweight bearing to avoid stress on the repair site. However, studies have demonstrated that the tendon benefits from early loading and motion during the healing process.<sup>15,155,169</sup> Translating basic science research into clinical practice, recent research has employed early weight bearing and mobilization following Achilles tendon repair.<sup>184,203,204,249,258,377</sup> Individuals with Achilles tendon repair following early weight bearing and mobilization protocols have demonstrated improved outcomes, including earlier return to walking, work, and pre-injury activity level; higher patient satisfaction; and no increased rate of re-rupture.<sup>33,139,359</sup> This has led to an AAOS *CPG* recommendation of no more than 2 weeks of protected weight bearing (strength of recommendation: moderate) and the use of a protective device that allows mobilization by 2 to 4 weeks postoperatively (strength of recommendation: moderate).<sup>42</sup>

**NOTE:** In the context of postoperative Achilles tendon repair literature, “early mobilization” implies that the patient is becoming more mobile; mobilization or loading of the tendon is controlled with slow, progressive ankle ROM. Early end-range ankle dorsiflexion is avoided during the protected phase of rehabilitation. Box 22.6 provides guidelines for early treatment following Achilles tendon repair.

Guidelines for management after percutaneous repair vary as well and are often quite similar to postoperative guidelines

### BOX 22.6 Features of Early Weight-Bearing and Remobilization Programs After Repair of Acute Achilles Tendon Rupture\*

#### Weight-Bearing Guidelines

- Initiated as tolerated while using crutches immediately after surgery<sup>156,203</sup> or after 1 or 2 weeks<sup>229,237,279,330,377</sup> in a below-knee orthosis with the ankle immobilized most often in plantarflexion or possibly neutral
- Progress gradually to full weight-bearing status between 3 to 6 weeks postoperatively<sup>156,279,330,377</sup>
- Orthosis worn during all weight-bearing activities for 6 to 8 weeks after surgery<sup>279,330</sup>
- Full weight bearing without the functional orthosis but wearing regular shoes with bilateral heel lifts when orthosis discontinued beginning at about 6 to 8 weeks postoperatively<sup>156,326,330</sup>

#### ROM Exercises

- Immediately<sup>58,79,81,126</sup> or by 1 to 2 weeks<sup>237,279,326,330,377</sup> after surgery, active plantarflexion and dorsiflexion of the operated ankle initiated while wearing a functional brace or orthosis to prevent dorsiflexion beyond 15° to 20° of equinus or to no more than a neutral position
- During the first 4 to 6 weeks and with the orthosis removed, ankle inversion and eversion while maintaining the ankle in plantarflexion<sup>377</sup>
- By 6 to 8 weeks, dorsiflexion to 10° beyond neutral permitted in the orthosis and inversion/eversion out of the orthosis<sup>156,237</sup>

\* During the first 6 postoperative weeks, all ankle ROM exercises are performed while seated or supine. Beyond 6 to 8 weeks postoperatively, guidelines are similar for early remobilization and conventional (traditional) programs.

following open repair or reconstruction. Early weight bearing and mobilization following percutaneous repair have demonstrated positive outcomes similar to open repair.<sup>8,61</sup> Therefore, specific guidelines for percutaneous repair are not addressed in the following sections but can be found in other resources.<sup>8,55,61,115,200</sup>

### Immobilization and Weight-Bearing Considerations

#### *Immobilization with restricted weight-bearing approach.*

This approach may be utilized for a tenuous repair or repair/reconstruction of a failed primary repair.<sup>367</sup> The ankle is immobilized in approximately 20° of plantarflexion for approximately 6 weeks. The patient remains nonweight bearing during all or most of this time.<sup>16,230,367</sup> Following the period of strict immobilization, a CAM orthosis is applied, generally allowing plantarflexion, but limiting dorsiflexion to 0°. Although this approach is safe and associated with a low risk of re-rupture, it has been shown in some studies to lead to deficits in ankle strength (gastrocnemius/soleus) and ROM (dorsiflexion).<sup>33,139,230,352,359</sup>

**Early remobilization and weight-bearing approach.** After primary direct repair of the Achilles tendon, early motion and weight bearing are now recommended because of advances in surgical procedures and a better understanding of the benefits of early loading and motion during the tendon healing process.<sup>42,229,249,330,377</sup> Postoperatively, the ankle is immobilized in equinus for a short period (less than 2 weeks) to minimize wound complications. Individuals are encouraged to use crutches and bear weight to tolerance in a protective boot or walking cast that maintains the ankle in approximately 20° of plantarflexion.<sup>42,258,352,377</sup> If a boot is used, it is typically a hinged CAM orthosis that can be locked in various positions to limit end range dorsiflexion.<sup>42,279</sup>

After the initial period of immobilization (1 to 2 weeks), the CAM brace is opened to allow movement in a protected range, generally limiting dorsiflexion beyond neutral.<sup>237,249,258,377</sup> As an alternative, a rigid dorsal orthosis that allows plantarflexion but limits dorsiflexion to 0° may be used.<sup>155,203</sup> During the first 6 weeks of rehabilitation, the protective orthosis is worn during ambulation with progressive weight bearing and at all other times (including sleep) except when removed for wound care or for therapeutic exercises.

When the patient is able to ambulate on level surfaces without pain while fully weight bearing on the operated extremity, the protective boot or orthosis is gradually discontinued (usually 6 to 8 weeks postoperatively).<sup>249,258</sup> After discontinuing the functional brace or orthosis, a 1- or 1.5-cm bilateral heel lift is used initially to prevent tendon lengthening and to reduce tendon strain during functional activities.<sup>249,258</sup>

Although published guidelines for initiating and progressing weight bearing and allowing ankle mobility have differed from study to study, it has become apparent that allowing individuals to bear weight in a range-limiting orthosis during the initial protective phase leads to higher patient satisfaction, earlier return to functional activities, and no difference in re-rupture rates.<sup>33,139</sup> Common to all protocols is the use of safe levels of applied stress while protecting the healing tendon. Close communication among the surgeon, therapist, and patient is essential for success. Table 22.5 summarizes immobilization and weight-bearing guidelines associated with postoperative Achilles tendon repair management.<sup>33,42,139,258,377</sup>

Active plantarflexion and dorsiflexion of the operated lower extremity in the CAM orthosis can be initiated immediately<sup>155,203</sup> or by 1 to 2 weeks postoperatively.<sup>201,237,249,258,330,377</sup> The CAM

<b>Beyond 8 weeks</b>	<ul style="list-style-type: none"> <li>■ Wean from heel lifts by 10 weeks</li> </ul>	<ul style="list-style-type: none"> <li>■ Full weight bearing in regular shoe without lifts by 10 weeks</li> </ul>

\*All time periods are approximately 2 weeks longer after reconstruction with tendon graft.

\*\* Immobilizer may be worn during ambulation for a longer period of time if wound healing is delayed or the quality of the repair is tenuous.

orthosis initially should restrict dorsiflexion beyond 20° of equinus. Active ROM dorsiflexion is allowed to increase as the CAM orthosis allows more motion. During the first 2 to 4 weeks, and with the orthosis removed, ankle inversion and eversion are initiated with the ankle in plantarflexion.<sup>258,377</sup> Initially, all ROM is completed actively while seated or supine. After 6 weeks postoperatively, bilateral standing exercises are introduced to improve active and passive ROM.<sup>249,258,377</sup>

## FOCUS ON EVIDENCE

Until the late 1980s, 6 weeks of cast immobilization was standard postoperative management following Achilles tendon repair. As stated above, subsequent research has demonstrated the positive effects of early functional rehabilitation.<sup>155,203,229,249,258,330,377,382</sup> However, early functional rehabilitation regimens primarily involved either early weight bearing<sup>49,50,330</sup> or early ankle motion exercises,<sup>155,156</sup> but not necessarily both in combination. High quality, randomized controlled trials have combined these approaches.<sup>8,107,161,203,204</sup> Huang et al<sup>139</sup> recently completed a systematic review with meta-analysis that compared the following approaches:

- Comparison 1 (Early WBing + ROM): Early weight bearing with an ankle motion exercise regimen versus immobilization
- Comparison 2 (Early ROM only): Isolated early ankle motion exercises without early weight bearing versus immobilization

For the Early WBing + ROM vs. immobilization comparison, a total of 279 individuals were included.<sup>203,204,50,49,161</sup> The average time to weight bearing allowance was 4.1 days. Individuals who completed early weight-bearing and ROM exercises performed significantly better on 11 of 15 outcome measures when compared to individuals who received cast immobilization. Significantly better outcomes included:

- Higher satisfaction rate (93.6% vs. 77.5%)
- Time to return to sport
- Number of individuals returning to sport
- Normal ankle ROM
- Decreased tendon elongation
- Higher percentage of heel raise ability

There was no difference in the rates of re-rupture or major complications when comparing the two groups; but the rigid cast immobilization group had a higher rate of minor complications.

For the Early ROM vs. immobilization comparison, 171 individuals were included.<sup>155,156</sup> The average time to weight bearing allowance was 3.3 weeks. When compared to the immobilization group, individuals who completed early ROM had significantly superior outcomes in time to return to sport and decreased tendon elongation. No difference was observed between the 2 groups for rates of re-rupture, major, or minor complications.

Based on these results, the authors concluded that protocols employing early weight-bearing and early ROM exercise achieve superior results when compared to cast immobilization or early ankle ROM exercise with delayed weight bearing. Relatively few advantages are demonstrated when comparing early ROM exercise without weight bearing to rigid immobilization.

Two published case series have described outcomes following early weight bearing and ROM without postoperative bracing.<sup>75,380</sup> One day following endoscopic Achilles tendon repair, Doral permitted 28 males to bear weight as tolerated with axillary crutches and no brace/orthosis/cast. At an average of 28 months after surgery, individuals demonstrated no between ankle difference in plantarflexion strength, ankle ROM, or hop test performance. No re-ruptures were reported and all patients returned to same pre-injury sports and/or ADL level. Yotsumoto et al<sup>380</sup> investigated the effectiveness of a new Achilles tendon repair technique for allowing early mobilization without a postoperative immobilization orthosis in 20 patients (14 male, 6 female). Following surgery, individuals completed active and passive ankle ROM exercise. Partial weight bearing was initiated at 1 week after confirmation of 0° dorsiflexion, and full weight-bearing ambulation was allowed at 4 weeks. Heel lifts were used in individuals with strong tension of the gastrocnemius/soleus. The authors reported the following average times to achieve outcomes:

- Symmetrical ROM: 3.2 ± 0.7 weeks
- Normal walking without pain or fear: 4.5 ± 0.7 weeks
- 20 continuous single-leg heel raises of the operative foot: 9.9 ± 1.7 weeks.
- Resumption of sport activity: 15.4 weeks
- Resumption of labor: 12 weeks

No postoperative complications were found, and subjects achieved an average Achilles Tendon Rupture Score of 98.3 ± 2.4 at 24 weeks following surgery. Both studies concluded that early mobilization without immobilization is an option in select patients following Achilles tendon repair.

## Exercise Progression

Although timing and progression of exercise may differ depending on the surgery (primary direct repair or reconstruction of a neglected rupture), the types of exercise included in a postoperative rehabilitation program are similar. In the phases of rehabilitation that follow, a progression of exercises is presented that is designed to help an individual achieve treatment goals that allow return to pre-injury function. The time frame for the initiation of weight bearing on the operated extremity, initiation of ankle ROM (particularly dorsiflexion), and resumption of pre-injury work-related and sports activities should be determined through consultation with the surgeon.

### Exercise: Maximum Protection Phase

Achilles tendon repair frequently is performed on an outpatient basis. Therefore, patient education is essential before

surgery or prior to discharge. It focuses on wound care (if the immobilizer is removable), controlling peripheral edema by elevating the operated leg, gait training with appropriate assistive device, and a home exercise program.

**Goals and interventions.** The following treatment goals are appropriate during the first 2 to 6 weeks after surgery.

- **Re-establish independent ambulation and functional mobility.** Instruct in gait and transfer training in protective orthosis with assistive devices, emphasizing weight-bearing restrictions.
- **Maintain ROM of nonimmobilized joints.** In a seated, supine or prone position, perform active ROM of the hip, knee, and toes of the operated side while wearing the immobilizer.
- **Prevent reflex inhibition of immobilized muscle groups.** Begin submaximal, pain-free muscle-setting exercises of the ankle in the immobilizer within the first few days after surgery. Start with setting exercises of the dorsiflexors, invertors, and evertors. Submaximal gastrocnemius/soleus muscle setting is typically initiated after 2 weeks, although a recent study included this exercise immediately postoperatively.<sup>258</sup> With a stable repair, it is possible to initiate nonweight-bearing isotonic strengthening against low loads (light grade elastic resistance) for the dorsiflexors, invertors, evertors, and plantarflexors after 2 weeks.<sup>258</sup>
- **Prevent joint stiffness and soft tissue adhesions in the operated ankle and foot.** Initiate ROM exercises in protected ranges. Active dorsiflexion should not exceed 0° for the first 4 weeks;<sup>33</sup> active ROM dorsiflexion can be completed in the CAM orthosis to prevent overstretching the repaired tendon. Active inversion and eversion should be performed in a plantarflexed position. Active ROM plantarflexion can be completed without restriction.
- **Begin to restore balance reactions in standing.** Perform weight-shifting activities in bilateral stance while wearing the protective orthosis. Use the parallel bars or another stable surface for upper extremity support as needed.
- **Maintain cardiopulmonary fitness.** Use an upper extremity ergometer for endurance training if available. After 2 weeks, initiate exercise bike in protective orthosis with minimal resistance.

### Exercise: Moderate Protection Phase

At the end of the maximum protection phase (typically 4 to 6 weeks after surgery), the patient is advanced to full weight bearing in a CAM orthosis or walking boot that is progressed to 0° dorsiflexion. Weaning from the orthosis and into a shoe with heel lifts begins 6 to 8 weeks postoperatively.<sup>33,184,203,258,377</sup> As the patient is weaned from the orthosis, it may be necessary to resume using a cane or crutch for a period of time to normalize gait mechanics.

During the moderate protection phase of rehabilitation, which begins at 4 to 6 weeks and extends to 12 weeks postoperatively, the stress placed on the operated tendon is gradually increased. Patients continue supervised as well as independent exercise. Initially, exercise may be completed

in the protective orthosis; as the patient weans from the orthosis, exercises are completed without the device. Precautions for progressing exercises and functional activities are noted in Box 22.7.<sup>33,139,258,330,377</sup>

**Goals and interventions.** The following goals and exercises are implemented during the intermediate phase of rehabilitation:

- **Increase ROM of the operated ankle with joint mobilization and stretching techniques.**
  - Grade III joint mobilization techniques if ankle or foot joints are restricted.
  - Gentle self-stretching exercises, such as a towel stretch in a sitting position, to increase ankle dorsiflexion with the knee slightly flexed. Progress to stretch with knee fully extended.
  - Gentle manual self-stretching to regain full inversion/eversion and dorsiflexion/plantarflexion and toe extension.
  - Active ankle ROM with patient seated and foot on a wobble or rocker board.
  - Self-stretching to increase dorsiflexion by standing on a wedge in bilateral stance with knees slightly flexed. Progress to stretch with knees fully extended. Initiate unilateral standing stretches of plantarflexors at the end of this phase of rehabilitation (approximately 12 weeks after surgery).
- **Improve strength and muscular endurance of the operated lower extremity.** Initiate or progress low-load, high repetition resistance exercises at 6 to 8 weeks. Begin with open-chain exercises, and progress to seated then standing closed-chain exercises. Emphasize controlled, eccentric loading of the plantarflexors. Perform closed-chain exercises without the orthosis as its use is gradually discontinued. Examples of resistance exercises include:
  - Open-chain resistance exercises for the hip, knee, and ankle musculature against a light grade of elastic resistance.
  - Closed chain exercises such as unilateral heel raising and lowering while seated; add light resistance as tolerated, typically by 8 weeks.
  - Standing bilateral heel raising/lowering with body weight resistance. Postpone unilateral heel raising/lowering until 10 to 12 weeks after surgery.<sup>258,330</sup>
  - Partial lunges with involved leg forward, bilateral mini-squats, and toe raises.
  - As strength progresses, add external resistance (handheld weights, weight belt, or weighted backpack) to supplement body weight with standing exercises.

### CLINICAL TIP

A resistance training program should focus on improving muscular endurance as well as strength. Substantial deficits in muscular endurance of the gastrocnemius-soleus muscles of the operated leg compared with the contralateral limb (as determined by number of unilateral heel raises performed in standing) have been shown to persist for at least a year after

## BOX 22.7 Precautions and Guidelines for Exercise and Functional Activities Following Achilles Tendon Repair\*

### General Precautions

- Progress all exercises very cautiously that place resistance or a stretch on the gastrocnemius-soleus muscle group intentionally, following postoperative guidelines.
- Postpone all unilateral weight-bearing exercises on the operated side until full weight bearing without pain is possible.

### Stretching to Increase Ankle Dorsiflexion

- Initiate active ROM dorsiflexion within the protected range by week 3 following surgery.<sup>33,258,377</sup>
- Begin stretching program in nonweight-bearing exercises (such as a towel stretch with slight knee flexion).
- Limit dorsiflexion to no more than 10° beyond neutral until 8 weeks after surgery. Progress to full ankle dorsiflexion (bilateral symmetry) by 12 weeks.
- Initiate weight-bearing stretches in *sitting* with feet on the floor, a low incline wedge (<10°), or a rocker board.
- Begin standing stretches in *bilateral* stance with knees bent only if pain free. This can be accomplished with a modified runner's wall stretch or a low incline (≤ 10°) wedge.
- Postpone *unilateral* standing stretches or bilateral standing stretches with heels over the edge of a step until advanced postoperative activities are permitted (approximately 12 weeks).

### Resistance Exercises

- Begin strengthening exercises for ankle and foot musculature in nonweight-bearing positions against low loads (light-grade elastic resistance) before progressing to closed-chain exercises against body weight.
- Initiate heel raises in a seated position with gradual addition of external resistance before progressing to bilateral heel raises in standing.

- Progress heel raising/lowering exercises from bilateral to unilateral only if performed pain free (see suggested sequence in Box 22.11). Unilateral heel raising/lowering should be postponed until approximately 10 to 12 weeks postoperatively.

### Advanced Training (Plyometric, Agility, Sport-Specific Training)

- Begin plyometric training in a pool (chest-deep progressing to waist-deep immersion).
- Initiate advanced land-based training program (running, plyometrics, etc.) after 12 weeks if the individual meets the following criteria:
  - Ambulates pain free with normal gait and no assistive device
  - Normal dorsiflexion ROM (excessive dorsiflexion compared to contralateral limb indicates elongated tendon; advanced training may be delayed).
  - Completes 5 unilateral heel raises at ≥ 90% of the limb's maximum heel-rise height
- Begin with bilateral land-based plyometric activity, teaching the individual correct landing techniques. Advance to unilateral activities when proper joint alignment and controlled deceleration on the operative limb is achieved.
- Initiate return to running progression on level treadmill.
- Teach the patient correct landing technique for proper alignment during jumping and hopping exercises
- Wear a prescribed functional ankle-foot orthosis or tape the ankle during high-impact, high-velocity activities to minimize the risk of tendon re-rupture

\* Precautions are applicable to conventional and early ROM/weight-bearing approaches to rehabilitation.

surgical repair of Achilles tendon ruptures.<sup>29</sup> The gastrocnemius-soleus complex also has been shown to produce significantly less work, calculated using force times distance with the heel-rise work test, than the contralateral limb at 1 year following repair.<sup>311</sup>

- **Improve balance reactions.** While wearing the functional orthosis, initiate or progress proprioceptive/balance training in bilateral stance on a firm surface. Progress to pliant surfaces (foam, air bladder, or mini-trampoline) and narrow the base of support (tandem stance, unilateral stance).
  - While continuing to wear the orthosis, progress to balance training in unilateral stance when full weight bearing is tolerated on the operated limb.
  - Transition to a sequence of more advanced balance exercises in supportive shoes (usually with a heel lift) after use of the functional brace has been discontinued.
- **Re-establish a symmetrical gait pattern.** When full weight bearing is comfortable and as the patient is weaned from

the orthosis, progress gait training. Emphasize symmetrical alignment and weight shifting as well as equal step lengths and timing, paying particular attention to push-off on the operated side.

- **Improve cardiopulmonary endurance.** Begin or progress level-surface treadmill walking or stationary cycling (recumbent or upright) while wearing the functional brace or a regular shoe with a heel lift. If necessary, raise the seat height of the upright bicycle to accommodate for limited dorsiflexion. Progress to treadmill walking on an incline.

### Exercise: Minimum Protection/Return to Function Phase

The final phase of rehabilitation, which begins around 12 to 16 weeks postoperatively, is directed toward returning a patient to a preinjury level of function for expected work-related demands and desired recreational/athletic activities. Stretching exercises continue if full ROM has not been achieved. During this phase, interventions should emphasize transition to independent maintenance.

Strength and muscular endurance training continues, emphasizing eccentric loading of the gastrocnemius-soleus

muscle group with heel-lowering exercises in unilateral stance (see Fig. 22.17) and with resistance equipment. Descending stairs step over step also emphasizes eccentric loading. Depending on the patient's preinjury activity level, plyometric training can be initiated in a pool (see Chapter 23).

Having achieved functional criteria, individuals begin land-based plyometric training and treadmill walking on an incline at 12 to 16 weeks.<sup>229,258,377</sup> Advance to jogging, running, agility drills (cutting, pivoting), and sport-specific training. Patient education is a priority and focuses on ways to reduce the risk of re-rupture of the repaired tendon. Emphasize appropriate active warm-up and stretching prior to strenuous activity. If the strength of the operated extremity is relatively comparable to that of the contralateral extremity (dynamometry and/or heel-rise test),<sup>335</sup> the individuals progress from bilateral to unilateral plyometrics.<sup>258</sup> Individuals are permitted to gradually return to sporting activity 4 to 6 months after surgery.<sup>249,258,352,377</sup> Clinical criteria for return to sport activity include strength and ROM within normal limits. Functional criteria include pain-free walking and running and functional hop testing with limb symmetry indexes > 90% of the contralateral limb.

### Outcomes

The ideal outcome is for a patient to return to a preinjury level of physical activity without pain or re-rupture of the repaired Achilles tendon. Patients undergoing primary repair of an acute rupture have consistently better outcomes than those who undergo a delayed repair for a chronic or neglected rupture. A surgical delay of up to 30 days following rupture has no negative impact; however, longer delays result in less satisfactory outcomes.<sup>16,352</sup> Active individuals 30 years or younger are at the highest risk of re-rupture following primary repair of an acute rupture.<sup>279</sup> The overall risk of re-rupture is approximately 3%.<sup>16,184,230,319</sup>

Numerous studies have compared methods of managing acute Achilles tendon ruptures. Operative management has been compared to nonoperative management, open procedures have been compared to minimally invasive procedures, and conservative management (strict immobilization/restricted weight) has been compared to "accelerated rehabilitation" (early motion/early weight bearing) in both operative and nonoperative management. Outcomes typically reported include re-rupture rate, ROM, strength, functional or sport-related activity level, and patient satisfaction. The following sections reflect conclusions drawn from systematic reviews of the literature as well as individual studies.

**Nonoperative versus operative management.** Despite a plethora of randomized controlled trials, it is unclear whether surgical or nonsurgical management provides superior results. Early systematic reviews concluded that operative management resulted in fewer re-ruptures when compared to nonoperative management.<sup>23,163,378</sup> However, the postoperative and nonoperative management generally included restricted weight bearing and delayed ROM for 6 weeks, a management strategy that is no longer in alignment with the current *CPG*.<sup>42</sup>

A recent meta-analysis included results from 10 randomized controlled trials comparing operative and nonoperative outcomes in individuals with acute Achilles tendon rupture.<sup>319</sup> Postoperative management (conservative vs. functional rehabilitation) was determined to be a significant cause of heterogeneity among the studies. When considering only the results from five studies that employed functional rehabilitation (early weight bearing and ROM), surgical treatment and nonsurgical treatment were equivalent with regard to the re-rupture rate. Other findings included:

- Complications other than re-rupture favor nonoperative management (relative risk: 3.9)
- Time to return to work favors operative management (19 days earlier return to work)
- ROM results did not show a clinically important difference
- Strength results did not show a clinically important difference
- Functional outcomes did not show a clinically important difference

The authors concluded that nonoperative management with functional rehabilitation should be considered as a viable management option. This conclusion is echoed by the meta-analysis conducted by van der Eng et al, who found no difference in the re-rupture rates or the occurrence of major or minor complications between surgically and conservatively managed individuals.<sup>359</sup> Despite the equivocal results of these meta-analyses, surgeons generally consider surgical management the best option for high level athletes who desire a full return to sport activity.<sup>16</sup>

Regardless of operative or nonoperative management, over 30% of individuals are reported to have some degree of impairment including pain, decreased strength, and/or decreased ROM at 1 to 5 years after injury.<sup>16,255,256,311,312</sup> Studies of National Football League (NFL) and National Basketball Association (NBA) players with an Achilles tendon rupture have demonstrated that only 61% to 78% of professional athletes are able to return to previous level of play following surgical repair.<sup>10,207,219,262</sup> NBA basketball athletes who did return to previous level of play demonstrated significantly decreased playing time and player efficiency rating when compared to matched controls.<sup>10</sup> In the season following repair, NFL athletes who underwent Achilles tendon repair played in fewer games and at a lower performance level when compared to the season prior to injury.<sup>207,262</sup>

Olsson et al<sup>257</sup> investigated predictors of clinical outcome in 93 individuals following acute Achilles tendon repair. All participants completed an accelerated rehabilitation protocol consisting of early weight bearing and ROM. Independent (predictor) variables included treatment (surgical versus nonsurgical), age, sex, BMI, and patient-reported measures at time of inclusion (Physical Activity Scale and European Quality of Life Scale). Although surgical treatment resulted in lower degree of symptoms at 6 months, no difference in function was found between surgically and nonsurgically managed individuals at 6 and 12 months. Increasing age was

a strong predictor of decreased function at both 6 and 12 months. Individuals with higher BMI experienced greater symptoms, but no effect on function was found.

**Open versus minimally invasive repair.** Traditionally, open repair has been considered the “gold standard” for Achilles tendon repair due to a low rate of re-rupture.<sup>16</sup> Percutaneous or minimally invasive techniques have been associated with a lower overall complication rate but increased risk of sural nerve injury.<sup>16,162,163</sup> Recent studies have challenged these assumptions.

A study of 211 individuals treated with minimally invasive surgical repair of an Achilles tendon rupture, sural nerve injury occurred in 41 (19%) and re-ruptures in 17 (8%).<sup>228</sup> A retrospective cohort study of 270 individuals treated with open (n = 169) or percutaneous Achilles repair demonstrated no difference in the major or minor complication rates. Most patients in both groups returned to baseline activities by 5 months following surgery.<sup>136</sup> A systematic review of compared open and minimally invasive repairs found comparable outcomes in ROM and ankle function in most of the included studies.<sup>65</sup> Open repair resulted in a higher percentage of complications when compared to minimally invasive procedures (14% vs. 6%, respectively), including a higher rate of re-rupture (3.4% vs. 2.2%, respectively). Minimally invasive repair resulted in more nerve injuries than open repair (2.9% vs. 1.8%, respectively). Individuals returned to work more quickly following minimally invasive procedures. The authors concluded that minimally invasive and open surgery are grossly equivalent procedures in terms of outcomes but that the cost and risk profile favors minimally invasive procedures.

**Summary.** In summary, there continues to be controversy as to whether surgical or nonoperative treatment is the better option for management of acute Achilles tendon rupture.<sup>111,185,352</sup> It is increasingly clear that postoperative and nonoperative management strategies previously considered “accelerated” have become the standard of care. Early weight bearing and ROM are now the recommended rehabilitation approach for primary Achilles tendon repair.<sup>33,80,139,157,184,230,249,258,319,352</sup>

## Exercise Interventions for the Ankle and Foot

### Exercise Techniques to Increase Flexibility and Range of Motion

Loss of flexibility in the ankle and foot can result from a variety of causes. Restoration of motion may be necessary to correct alignment or for normal biomechanics during

walking and running. Joint mobilization techniques are used to increase accessory motion of the joint surfaces. These techniques are described in detail in Chapter 5. Manual passive stretching and PNF stretching techniques are described in Chapter 4. Self-stretching techniques to improve flexibility and ROM are the emphasis of this section.

## Flexibility Exercises for the Ankle Region

### Increase Ankle Dorsiflexion

The muscles that restrict dorsiflexion of the ankle are the one-joint soleus and the two-joint gastrocnemius. To effectively stretch the gastrocnemius, the knee must be extended while dorsiflexing the ankle. To isolate stretch to the soleus, the knee must be flexed during dorsiflexion to take tension off the gastrocnemius. Most of the following stretching exercises can be adapted with the knee in flexion or extension, so both of the plantarflexor muscles can be stretched.

**PRECAUTION:** When a patient uses weight-bearing exercises to stretch the plantarflexor muscles, shoes with arch supports should be worn or a folded washcloth placed under the medial border of the foot to minimize the stress to the arches of the foot.

### FOCUS ON EVIDENCE

In a study of 30 subjects (15 with pes planus and 15 with neutral foot alignment), the effects of weight-bearing dorsiflexion stretches on the displacement of the myotendinous junction of the medial gastrocnemius, rearfoot angle, and navicular height were measured. Results showed a significantly greater displacement (elongation) at the myotendinous junction when the arch was supported in both groups, with a greater displacement occurring in subjects with pes planus. When the subjects with pes planus stretched without arch support, there was a significant increased rearfoot angle and drop in navicular height.<sup>153</sup>

- **Patient position and procedure:** Long-sitting (knees extended) or with the knees partially flexed. Have the patient strongly dorsiflex the feet, attempting to keep the toes relaxed.
- **Patient position and procedure:** Long-sitting or with the knee partially flexed and with a towel or belt looped under the forefoot. Have the patient pull with equal force on both ends of the towel to move the foot into dorsiflexion.
- **Patient position and procedure:** Sitting with the foot flat on the floor. Have the patient slide the foot backward, keeping the heel on the floor.
- **Patient position and procedure:** Standing. Have the patient stride forward with one foot, keeping the heel of the back foot flat on the floor (the back foot is the one being stretched). If necessary, have the patient brace his or her

hands against a wall. To provide stability to the foot, the patient partially rotates the back leg inward so the foot assumes a supinated position and locks the joints of the foot. The patient then shifts body weight forward onto the front foot. To stretch the gastrocnemius muscle, the knee of the back leg is kept extended; to stretch the soleus, the knee of the back leg is partially flexed.

- **Patient position and procedure:** Standing on an inclined board with feet pointing upward and heels downward (Fig. 22.9). Greater stretch occurs if the patient leans forward. Because the body weight is on the heels, there is little stretch on the long arches of the feet. Little effort is required to maintain this position for extended periods.
- **Patient position and procedure:** Standing, with the forefoot on the edge of a step or stool and heel over the edge. Have the patient slowly lower the heel over the edge (heel drop).

**PRECAUTION:** This stretch may create muscle soreness because it requires that the patient control an eccentric contraction of the plantarflexors.

**FIGURE 22.9** Self-stretching the gastrocnemius muscle to increase ankle dorsiflexion.

### Increase Ankle Inversion

- **Patient position and procedure:** Sitting, with the foot to be stretched placed across the opposite knee. Have the patient grasp the midfoot and hindfoot with the opposite hand and lift the foot into inversion. Emphasize turning the heel inward, not just twisting the forefoot.
- **Patient position and procedure:** Long-sitting with a towel or belt looped under the foot. Have the patient pull on the medial side of the towel to cause the heel and foot to turn inward (Fig. 22.10). This technique also can be used to turn

**FIGURE 22.10** Self-stretching the ankle and foot into inversion by pulling with the medial side of the towel.

the foot outward by pulling on the lateral side of the towel. It is important that the motion includes the heel, not just the forefoot.

- **Patient position and procedure:** Sitting or standing, with feet pointing forward. Have the patient roll to the lateral border of each foot so the soles are turned inward.
- **Patient position and procedure:** Standing or walking, with the involved foot on a slanted board, placing the lateral aspect of the foot to be stretched on the lower side of the board. Bilateral stretching can be accomplished if hinged planks are placed in an inverted-V position and the patient stands or walks on them.

### Increase Ankle Plantarflexion and Eversion

It is uncommon for plantarflexion and eversion to be restricted because gravity plantarflexes the foot in the supine position and the body's weight everts the foot in the standing position. Eversion, which is a component of pronation, is the loose-packed position of the foot and is perpetuated with weight bearing. The exception for restricted talocrural plantarflexion is when there is a capsular pattern at the joint as a result of arthritis. If the restriction is from joint hypomobility, it is treated with joint mobilization techniques.

### Increase Ankle Dorsiflexion and Eversion

**Patient position and procedure:** Long-sitting with a towel or belt looped under the foot. Have the patient pull on the lateral side of the towel to cause the heel and foot to turn outward.

## Flexibility Exercises for Limited Mobility of the Toes

Tight extrinsic muscles of the toes occur with claw toes and hammer toes, causing the MTP joints to extend and the IP joints to flex. There is often weakness of the intrinsic muscles. To stretch the intrinsic muscles, emphasize *MTP flexion* and *IP extension*.

### Passive MTP Flexion

**Patient position and procedure:** Sitting with the foot crossed onto the opposite knee. Show the patient how to stabilize the foot under the metatarsal heads (MTP joints) with the thumbs and passively flex the MTP joints by applying pressure against the proximal phalanges. Or, have the patient attempt active flexion of the MTP joints, assisting the motion if necessary.

### Passive IP Extension

**Patient position and procedure:** Sitting with the foot crossed onto the opposite knee. Teach the patient to stabilize the proximal phalanx of the involved toe and passively stretch the long flexors across each joint by moving the middle and/or distal phalanx into extension.

### Active MTP Flexion

**Patient position and procedure:** Standing with the toes over the edge of a stool or book and the MTP joints at the edge. Have the patient attempt to flex the MTP joints over the edge of the stool. Ideally, the patient should try to keep the IP joints of the toes extended, but many individuals cannot do this.

### Great Toe Extension

Extension of the great toe at the MTP joint is critical during the push-off phase of gait. In addition to joint mobilization techniques, passive stretching and self-stretching techniques should be used.

- **Patient position and procedure:** Sitting with the foot resting on the opposite knee. Show the patient how to stabilize the foot around the head of the first metatarsal with one hand and passively *extend* the MTP joint by applying pressure against the proximal phalanx.
- **Patient position and procedure:** Sitting with the feet placed on the floor. Have the patient slide the foot to be stretched backward by flexing the knee while keeping the toes on the floor and raising the heel off the floor.
- **Patient position and procedure:** Standing with the involved foot in a backward stride position. The patient may lean his or her hands against a wall for support. Have the patient keep the toes on the floor and rock forward lifting the heel until a stretch is felt under the first toe. A sustained stretch or a gentle rocking stretch can be used.

## Stretching the Plantar Fascia of the Foot

- **Patient position and procedure:** Sitting with the foot placed across the opposite knee. Teach the patient to use his or her thumbs to apply deep massage horizontally and longitudinally across the plantar surface of the foot.
- **Patient position and procedure:** Sitting with a ball, small roller, or plastic bottle under the foot. Have the patient roll the foot forward and backward across the curved surface,

using as much pressure as is comfortable. Pressing down on the knee with one or both hands can exert additional force.

## Exercises to Develop and Improve Muscle Performance and Functional Control

Causes of strength and flexibility imbalances of the ankle and foot include disuse, immobilization, nerve injury, and progressive joint degeneration. In addition, imbalances occur from the weight-bearing stresses that are imposed on the feet. Imbalances can be the cause or the effect of faulty lower extremity mechanics. Because the lower extremities bear weight, realignment by strengthening exercises alone is of limited value. Strengthening exercises undertaken in conjunction with conscious correction, appropriate stretching, balance training, and other necessary measures (such as using orthotic inserts or adaptations for shoes, bracing, orthoses, or surgery) improve alignment, so structurally safe weight bearing is possible. In addition, knowledge of the types of shoes used or surfaces encountered during walking or sports activities may be a lead to the source of faulty mechanics, which then can be adjusted. (Techniques of orthopaedic adaptations for shoes, bracing, and orthoses are beyond the scope of this text.)

Most functional demands on the ankle and foot occur during weight-bearing activities. Kinesthetic input from skin, joint, and muscle receptors and the resulting joint and muscle responses are different in open- and closed-chain activities.<sup>261</sup> Therefore, whenever possible, use of progressive weight-bearing exercises is important to simulate functional activities. In addition to the exercises described in this section, refer to Chapter 23 for total lower extremity functional exercises performed in the standing position that influence muscle control at the hip, knee, and ankle.

## Exercises to Develop Dynamic Neuromuscular Control

- **Patient position and procedure:** Long-sitting or with the knees partially flexed. Have the patient practice contracting each of the major muscles while concentrating on his or her actions—for example, dorsiflexion with inversion (anterior tibialis), plantarflexion with inversion (posterior tibialis), and eversion (fibularis muscles).
- **Patient position and procedure:** Long-sitting or with the knee partially flexed. Instruct the patient to “draw” the alphabet in space, leading with the toes but moving at the ankle. For variety, have the patient “print” using capital letters, then with lower case letters, or “write” words such as his or her name or address.

- **Patient position and procedure:** Sitting on a chair or low mat table with feet on the floor. Place a number of small objects, such as marbles or dice, to one side of the involved foot. Have the patient pick up one object at a time by curling the toes around it and then place the object in a container on the other side of the foot. This exercise emphasizes the plantar muscles as well as inversion and eversion.
- **Patient position and procedure:** Sitting with feet on the floor or standing. Have the patient curl the toes against the resistance of the floor. Place a towel or tissue paper under the feet, and have the patient attempt to wrinkle it up by keeping the heel on the floor and flexing the toes.
- **Patient position and procedure:** Sitting, with the feet on the floor. Have the patient attempt to raise the medial longitudinal arch while keeping the forefoot and hindfoot on the floor. External rotation of the tibia—but not abduction of the hips—should occur. The activity is repeated until the patient has consistent control; then it is performed while standing as a progression.
- **Patient position and procedure:** Sitting with a tennis ball placed between the soles of the feet. Instruct the patient to roll the tennis ball back and forth from heel to forefoot.
- **Patient position and procedure:** Sitting, with both feet or the involved foot only on a rocker or balance board. Have patient perform controlled ankle and foot motions (with or without the assistance of the normal foot) into dorsiflexion and plantarflexion and inversion and eversion (Fig. 22.11). If the equipment permits, the patient also can perform circumduction in each direction. Progress this activity to the standing position to further develop control and balance.

**FIGURE 22.11** Using a rocker board to develop control of ankle motions with the patient sitting. The normal foot can assist the involved side in the early phases of rehabilitation. This activity can be progressed by using only the involved foot and then performing the motions in standing.

- **Patient position and procedure:** Standing. Have the patient practice walking while concentrating on placement of the feet and shifting body weight with each step. The patient begins by accepting body weight on the heel, then shifting the weight along the lateral border of the foot to the fifth metatarsal head and across to the first metatarsal head and great toe for push-off.

## Open-Chain (Nonweight-Bearing) Exercises

### Plantarflexion

**Patient position and procedure:** Long-sitting with the leg resting on a rolled towel to slightly elevate the heel off the treatment table. Have the patient hold both ends of an elastic band that is looped under the forefoot, then plantarflex the foot against the resistance (Fig. 22.12).

**FIGURE 22.12** Resisting the ankle plantarflexor muscles with an elasticized material.

### Isometric Eversion and Inversion

**Patient position and procedure:** Long-sitting or sitting in a chair with knees flexed.

- To resist *eversion*, the ankles are crossed; instruct the patient to press the lateral borders of both feet together against each other.
- To resist *inversion*, the medial borders of the feet are placed beside each other; instruct the patient to press the medial borders of the feet against each other.

### Eversion and Inversion With Elastic Resistance

**Patient position and procedure:** Long-sitting, supine, or sitting with the feet resting on the floor.

- To strengthen *evertors*, place a loop of elastic tubing around both feet and have the patient evert one or both feet against the resistance (Fig. 22.13). Instruct the patient to keep the knees still and turn the foot outward, not allowing the thigh and leg to abduct or externally rotate.
- To strengthen *invertors*, tie the elastic band or tubing to a structure on the lateral side of the foot. Again, have the

**FIGURE 22.13** Resisting the ankle evertor muscles with an elasticized material.

patient keep the legs stationary and only turn the foot inward without allowing the hip to adduct and internally rotate.

### Adduction With Inversion and Abduction With Eversion Using Weights

**Patient position and procedure:** Sitting with the foot on the floor. Place a towel under the forefoot and a weight on the end of the towel (Fig. 22.14). Have the patient pull the weighted towel along the floor with the forefoot by keeping the heel fixed on the floor and swinging the foot either inward or outward.

**FIGURE 22.14** Resisting ankle adduction and inversion with a weight on the end of the towel. The heel is kept stationary while a windshield wiper motion of the foot is used to pull the towel along the floor. Abduction with eversion can be resisted by placing the weight on the towel on the medial side of the foot.

### Dorsiflexion

**Patient position and procedure:** Long-sitting or supine with a rolled towel under the distal leg to elevate the heel slightly. Tie both ends of an elastic band or tubing to the foot board of a bed (or other object), and loop the elastic over the dorsum of the foot. Have the patient dorsiflex the ankle against the resistance (Fig. 22.15).

**FIGURE 22.15** Resisting the ankle dorsiflexor muscles with an elasticized material.

### All Ankle Motions

**Patient position and procedure:** Sitting in a chair or standing with one or both feet in a box filled with sand, foam, dry peas, dry beans, or other similar type material to offer resistance to various foot motions. Have the patient plantarflex, dorsiflex, invert, and evert the foot and ankle, and curl the toes with the foot on top or with the foot dug into the medium.

### Closed-Chain (Weight-Bearing) Exercises

For these exercises, the patient position is standing. If the patient does not initially tolerate full weight bearing without reproduction of symptoms, begin with the patient standing in parallel bars using both hands for support, holding onto a stable object, harnessed into a body weight support system, or exercising in a pool to reduce weight-bearing forces. Progress from bilateral to unilateral stance. Refer to Table 6.9 for general guidelines for progression of closed-chain exercises.

### Stabilization Exercises

Begin stabilization exercises for the ankle and foot in bilateral stance, progressing to unilateral stance and by standing on a flat, stable surface and later on less stable surfaces.

- Apply resistance to the patient's pelvis in various directions while he or she attempts to maintain control. At first, use verbal cues, then resist without warning. Also, increase the speed and intensity of the perturbation forces.
- Have the patient hold onto a wooden dowel rod or cane with both hands. Apply the resistance through the rod in various directions and with varying intensities and speeds as the patient attempts to remain stable (Fig. 22.16).
- Progress to standing only on the involved foot.

**FIGURE 22.16** Stabilization exercises with the patient standing and maintaining balance against the alternating resistance forces from the therapist. The therapist applies force through the rod in backward/forward, side-to-side, and rotational directions. This can be progressed by standing on only the involved foot and by removing visual input.

- Have the patient stand on the involved leg and maintain a stable position of the ankle and foot while moving the opposite leg forward, backward, and to the side against the resistance of an elastic band or tubing secured around the ankle of the moving limb and a table leg (similar to Fig. 20.22).

### Dynamic Strength Training

- Have the patient perform bilateral toe and heel raises and rock outward to the lateral borders of the feet. Progress to performing these exercises unilaterally. When tolerated, add resistance with a weighted backpack, weight belt, or hand-held weights. Progress to jumping, then hopping on level surfaces and then on and off a platform for explosive concentric and eccentric loading.
- For *eccentric loading* of the gastrocnemius-soleus muscle group without concentric loading of the affected ankle, have the patient perform the following sequence.<sup>149</sup> While positioned next to a stable surface (wall, countertop) using one hand for balance, have the patient stand on a low platform on the *sound* lower extremity and the *affected* foot in maximum plantarflexion with the ball of the foot on the floor. Transfer body weight onto the ball of the foot of the *affected* side while lifting the sound lower extremity off the step; and then slowly lower the heel to the floor (Fig. 22.17) using a lengthening contraction of the gastrocnemius-soleus muscle group. Repeat the sequence by stepping back onto the platform with the sound limb.

#### CLINICAL TIP

Resistance training that emphasizes eccentric contractions of the ankle plantarflexors has been shown to decrease pain and

**FIGURE 22.17** Eccentric loading of the gastrocnemius-soleus muscle group is accomplished by shifting weight from the foot on the step to the ball of the plantar flexed foot then lowering the heel of the involved ankle.

increase physical functioning in patients with midposition Achilles tendinopathy.<sup>38</sup> Eccentric loading, emphasizing heel-lowering exercises, has also been investigated for management of insertional Achilles tendinopathy with promising results.<sup>149</sup>

### Resisted Walking

- Have the patient walk on heels and on toes against resistance. Apply manual resistance against the patient's pelvis, or have the patient walk against a weight-pulley system or elastic resistance secured around the pelvis.
- Apply an elastic band around the ankle of the sound lower extremity and secure the band to a stable object.<sup>120</sup> While bearing weight on the involved lower extremity:
  - Bring the sound leg one step forward against the resistance of the elastic band to strengthen the ankle dorsiflexors of the weight-bearing limb (Fig. 22.18 A and B).
  - Move the sound leg one step backward against the resistance of the elastic band to strengthen the ankle plantarflexors of the weight-bearing limb (Fig. 22.19 A and B).

### Functional Progression for the Ankle and Foot

As with functional training for the hip and knee, implement a progression of exercises that prepares a patient recovering from structural or functional impairments of the ankle to return safely to their desired occupational and recreational activities. To meet these challenges, a patient must develop

**FIGURE 22.18** (A) Starting position for activation of the ankle dorsiflexors of the *weight-bearing limb* by advancing the opposite limb forward against resistance of an elastic band; (B) ending position.

**FIGURE 22.19** (A) Starting position for activation of the ankle plantarflexors of the *weight-bearing limb* by advancing the opposite limb backward against resistance of an elastic band; (B) ending position.

sufficient strength, endurance, and flexibility, as well as power, balance, coordination, agility, aerobic fitness, and task-specific skills. (Refer to Chapters 7 and 8 respectively for principles of aerobic conditioning and balance training.)

A functional progression of exercises for the ankle and foot must involve the entire body—lower extremities, trunk, and upper extremities. A variety of advanced stability, balance, strengthening, plyometric, and agility exercises that could be used for the patient with dysfunction of the ankle and/or foot are described and illustrated in Chapter 23. Some of the closed-chain strengthening exercises and functional

progressions described in Chapters 20 and 21 are applicable as well (see Box 20.11).

Selected equipment also is valuable for improving function of the ankle and foot. Training on a stationary bicycle, treadmill, cross-country ski machine, or mini-trampoline is useful for developing endurance of ankle musculature. A slide board can be used to develop coordination, control, and dynamic ankle stability. Use of balance equipment, such as a rocker or wobble board or BOSU®, imposes a significant challenge on dynamic stabilizers of the ankle as does walking or running on uneven surfaces.

## Independent Learning Activities

### Critical Thinking and Discussion

- Observe how the foot and ankle function as a unit in several activities, such as walking up steps, walking on uneven surfaces, and walking in high-heeled shoes versus low-heeled shoes.
  - What motions do you observe in the talocrural, subtalar, transverse tarsal, and MTP joints? Describe how the mechanics change across activities.
  - What muscles are functioning to move or control each joint? Describe how muscle function and demand changes across activities.
- Describe the role of the ankle and foot during the gait cycle.
  - How much ROM is needed at the ankle, and which muscles are acting to cause or control the motion? What other forces are causing or controlling motion at the ankle?
  - What gait deviations occur if there is muscle shortening or weakness at the ankle? Describe potential deviations with involvement of the plantarflexors, invertors, evertors, and dorsiflexors.
  - After a unilateral arthrodesis of the talocrural joint (ankle fused in neutral), what deviations will occur in

the gait cycle? How will such a procedure affect the proximal joints of the lower extremity and/or the pelvis and trunk?

- Describe the mechanics and function of pronation and supination in the foot during the gait cycle. Explain how the gait cycle would be affected if a patient had flexible flat feet versus rigid supinated feet.
3. Compare and contrast an exercise program for a patient who has had a repair or reconstruction of torn lateral ligaments of the ankle versus a patient who has had a repair of a ruptured Achilles tendon. How will precautions and selection of exercises differ after these two types of surgical repairs?
  4. Discuss the benefits and limitations of total ankle arthroplasty versus arthrodesis of the ankle.

### Laboratory Practice

1. Review all the joint mobilization techniques for the leg, ankle, and foot; include basic glides, accessory motions, and mobilization with movement techniques.
  - Identify and practice techniques that you could use to increase ankle plantarflexion; begin with the ankle at zero, and progress at 15° increments until full plantarflexion is reached.
  - Do the same for ankle dorsiflexion, subtalar inversion and subtalar eversion, and MTP extension.
2. Set up a circuit-training course for the foot and ankle musculature to increase strength, muscular endurance, stability, balance, and neuromuscular reactions. Sequence the activities from basic to advanced, and observe accuracy and safety with each exercise. Identify other muscles in the lower extremity, trunk, or arms that are also being affected by the exercises.

### Case Studies

1. Carl has a 10-year history of RA. His acute symptoms are managed with medication, so he is able to walk with a cane. He complains of increased pain after walking 15 minutes, considerable stiffness, and generalized weakness. He walks with short step lengths and has minimal push-off. Ankle ROM: dorsiflexion 10°, plantarflexion 15°, inversion 0°, eversion 8°. He stands with pronated feet and has dorsal migration of the first phalanges and moderate hammer toes. He tolerates moderate resistance in his lower leg/ankle musculature, but he is unable to demonstrate toe walking or do bilateral toe raises even one time.
  - List his impairments and activity limitations.
  - Develop a list of short- and long-term goals
  - Develop a program of intervention to meet the goals. How will you initiate the intervention? How will you sequence the interventions? What techniques will you use and how will you progress them?
  - Describe your rationale for the manual techniques and exercises you select, for those deemed not appropriate,
2. Sandy sustained a boot-top fracture of the tibia and fibula as the result of a fall while downhill skiing. She was immobilized in a long-leg cast for 6 weeks, followed by a short-leg cast for 4 weeks. She was allowed partial weight bearing while wearing the short-leg cast. The cast was removed this morning. She now reports significant stiffness and discomfort when attempting to move her ankle and foot. Observation reveals lower leg atrophy, but no edema or joint swelling. ROM in the ankle and foot is minimal, and there is no accessory gliding of the fibula at the proximal or distal tibiofibular joints. Strength was not tested, although the patient can activate all muscles.
  - Answer the same questions posed in Case 1.
  - What are the key differences between Sandy and Carl regarding the intervention strategies and precautions?
  - How will you determine the progression of weight-bearing activities?
3. Ron is a 35-year-old computer programmer who plays recreational basketball. He sustained a severe inversion strain of his right ankle when landing on the foot of an opponent during a recent game. He wrapped the ankle with a compression wrap and applied ice to it for 2 days. On the third day, a radiograph determined that there was no fracture but he was diagnosed with a grade II instability of the ATF ligament. Observation reveals significant swelling and discoloration of the anterior and lateral ankle region. He experiences a marked increase in pain with inversion and plantarflexion motions, anterior gliding of the talus, and palpation over the ATF ligament. Because of muscle guarding, strength was not tested.
  - Identify structural and functional impairments, activity limitations, and participation restrictions.
  - Determine goals and an intervention strategy for this patient.
  - Describe how the intervention will be progressed.
  - Ron wants to know how soon he can return to playing basketball. What criteria will you use to make this judgment, and how will you protect his ankle when he does return?
4. Jamaal is an active 43-year-old dentist who ruptured his (L) Achilles tendon during a weekend tennis match. At the time of the injury, he experienced acute pain above his heel that persisted for a brief period of time. He was able to return home, where he rested for the remainder of the day while applying ice to the posterior aspect of the lower leg. Jamaal went to an urgent care facility the next day because he was having some difficulty walking and ascending and descending stairs. Physical examination suggested a ruptured Achilles tendon, which was confirmed by an MRI. An open primary repair of the tendon was performed two days later on an outpatient basis. Following surgery, the
  - Identify any precautions that are present for your interventions, as well as those that you must teach the patient.

involved ankle was immobilized in a short-leg cast with the ankle positioned in plantarflexion for 2 weeks. He has been ambulating nonweight bearing with crutches since surgery. At the 2-week postoperative visit to the surgeon, the cast was removed and replaced with an ankle-foot orthosis, which was set in slight plantarflexion. He is now permitted to bear partial weight on the involved foot within pain tolerance while wearing the orthosis. Jamaal has been referred to physical therapy to begin rehabilitation, using an early remobilization and weight-bearing

approach. He is allowed to remove the orthosis for ankle ROM exercises.

- Describe a sequence of exercises and criteria for progression that you would teach Jamaal that is consistent with this accelerated functional approach to Achilles repair management.
- What precautions are included in your treatment plan?
- Describe the additional intervention strategies that will be used to prepare Jamaal to return to playing tennis.

# Advanced Functional Training

■ LYNN COLBY, PT, MS ■ CAROLYN KISNER, PT, MS  
 ■ JOHN BORSTAD, PT, PHD

**Exercises for Stability and Balance 906**  
**Guidelines Revisited 906**  
**Advanced Stabilization**  
**and Balance Exercises 907**

**Exercises for Strength and Power 912**  
**Advanced Strengthening**  
**Exercises 913**

**Plyometric Training: Stretch-Shortening Drills 921**  
**Independent Learning Activities 936**

Functional training involves developing and progressing exercise programs that enable patients to regain their pre-injury level of function. For individuals wishing to return to high-level work, leisure, recreational, or athletic activities, rehabilitation must progress sufficiently to meet the anticipated demands of those activities. For the therapist, it requires a continuous process of decision-making that involves:

- A thorough knowledge of human anatomy, physiology, biomechanics, and function.
- An understanding of tissue healing, especially the effect of time on healing and the response of tissues to imposed stresses.
- An understanding of neuromuscular responses to various forms of exercise.
- The ability to examine and evaluate the structural and functional impairments that restrict activity and full functional participation within the context of personal and societal expectations.
- Knowledge of diagnoses, surgical and therapeutic exercise interventions, special precautions, and each patient's potential for achieving the projected outcomes.

Functional training can begin in the early phases of rehabilitation with specific muscle activation and training techniques designed to develop a balance in the strength and timing of contractions among synergists and antagonists. Because proximal stability is critical for coordinated functioning of the extremities, exercises to develop stability and balance are also incorporated into the early phases of the rehabilitation.

As muscle strength, endurance, and control of the involved region(s) improve, greater emphasis is placed on strengthening muscle groups in functional patterns, using both weight-bearing

and nonweight-bearing exercises. Care is taken to ensure that the activity of stronger muscles does not dominate the weaker, impaired muscles during the execution of these functional patterns. As function improves, the exercises can become more activity specific.

Functional motor skills encompass an array of movements completed using multiple postures, at varying speeds, and over many repetitions or durations of time. The cornerstone of a functionally relevant therapeutic exercise program is the inclusion of task-specific movements that are superimposed on sufficient stability, balance, and muscle function to meet the necessary, expected, and desired functional demands in a patient's life.

The purpose of this chapter is to describe a variety of advanced functional training exercises that involve the total body and may be appropriate for the final phase of rehabilitation. The chapter is divided into two sections. The first section focuses on advanced exercises for stability and balance and the second on advanced exercises for strength and power. Exercises selected for this phase of rehabilitation are based on the patient's desired outcome and emphasize the motor skills needed to achieve that outcome.

## CLINICAL TIP

For all exercises, always stay within the healing constraints of the impaired tissues. Be aware of the likely tissue stresses imposed by the position, motion, intensity, and speed of each exercise. Initially, emphasize correct joint and body alignment with proper movement velocity during the exercise. Then, as the intensity of an exercise can be progressed, decrease the repetitions (or time) until the patient is able to perform the activity safely and effectively.

# Exercises for Stability and Balance

## Guidelines Revisited

Stability describes the ability to maintain or adequately return a body or system to a state of equilibrium when external forces impart a perturbation to that body or system. The concept that proximal stability is a requisite for controlled distal mobility and safe and effective function can be applied not only to general postural stability, but also to individual joints.

**Joint stability.** Stability of each joint in the body is necessary for effective function. Examples of joint stability include the ability to maintain scapular position and glenohumeral joint alignment so the humeral muscles can safely coordinate movement of the upper extremity<sup>4</sup> (see Chapter 17). Other

examples include coordinated segmental and global stability of the spine for postural alignment and safe body mechanics (see Chapters 14 and 16) and stability of the hips, knees, and ankles for control during functional weight-bearing activities (see Chapters 20 through 22). Because specific exercises for joint stability are described in detail in the respective chapters, the reader is referred to those chapters for study before progressing to the advanced exercises described in this chapter.

**Postural stability and balance.** For an individual to be able to execute functional activities, balance—or postural stability—is necessary to maintain the position of the body in equilibrium within the environment. These concepts are described in detail in Chapter 8. In addition, stability and balance exercises in upright postures that are appropriate early in a rehabilitation program are described in each of the lower extremity chapters. Parameters for progressing balance exercises are summarized in Table 23.1.

**TABLE 23.1** Parameters for Progressing Balance Exercises

Parameters	Progression
<b>Upright posture</b>	<ul style="list-style-type: none"> <li>■ Sitting→kneeling→standing</li> </ul>
<b>Base of support</b>	<ul style="list-style-type: none"> <li>■ Sitting: feet on floor→feet off floor</li> <li>■ Standing: wide→narrow base</li> <li>■ Standing: Double leg stance→tandem stance→single-leg stance</li> </ul>
<b>Support surface</b>	<ul style="list-style-type: none"> <li>■ Stationary, firm, or flat surface→moving, soft, uneven surface (ball, wobble board, slide board, sand, gravel, grass)</li> <li>■ Wide surface→narrow (balance beam, half foam roll)</li> </ul>
<b>Superimposed movements</b>	<ul style="list-style-type: none"> <li>■ Head, trunk, extremity movements</li> <li>■ Small→large-range extremity movements</li> <li>■ Unresisted→resisted (free weights, elastic resistance)</li> </ul>
<b>Perturbations</b>	<ul style="list-style-type: none"> <li>■ Anticipated→unanticipated</li> <li>■ Low magnitude→high magnitude</li> <li>■ Slow speed→high speed</li> </ul>
<b>Environment</b>	<ul style="list-style-type: none"> <li>■ Surroundings nonmoving (closed)→moving (open)</li> </ul>
<b>Functional tasks</b>	<ul style="list-style-type: none"> <li>■ Simple→complex tasks</li> <li>■ Single→multiple tasks</li> </ul>

### CLINICAL TIP

As patients progress through advanced rehabilitative exercises, remind them frequently to maintain the spine in a neutral position and to activate the trunk muscles in order to stabilize the spine against imposed forces. If at any time the patient shows signs of insufficient trunk stability (such as lack of control of spinal posture or increased painful symptoms), review and implement the spinal stabilization exercises as described in Chapter 16.

## Advanced Stabilization and Balance Exercises

### Sitting

When the individual is able to sit on a firm, stable surface and maintain balance while reaching in all directions under various loads, progress training by having them perform the same tasks while sitting on an unstable surface. Surface suggestions include a foam cushion, rocker board, BOSU®, or large gym ball.

### Sitting and Reaching

Have the patient balance on an unstable surface and reach in various directions, first with one extremity, then with both. Add resistance to the motions as the patient is able (Fig. 23.1).

**FIGURE 23.1** Resisted reaching movements while maintaining sitting balance on an unstable surface.

### Sitting With External Perturbations

While the patient maintains sitting balance on an unstable surface:

- Move the surface in various directions, first slowly, then more quickly.
- Pull on a length of elastic resistance held by the patient. Alter the speed and direction of pull.
- Toss a ball to the patient, requiring him or her to reach out in various directions and return the toss (Fig. 23.2).

**FIGURE 23.2** Maintaining sitting balance while catching and returning a ball.

- Increase the challenge by integrating a plyometric component into the balance activity, such as catching and tossing a weighted ball.
- Manually push on the patient's trunk while they perform reaching activities. Vary the amount, point of application, timing, and direction of manual force used.

**NOTE:** Refer to the next section of this chapter for examples of plyometric exercises that also improve a patient's balance.

### Kneeling

Kneeling activities can be performed in the *half-kneeling* (balancing on one knee with the other extremity forward and foot planted on the floor) or *high-kneeling* (tall-kneeling on both knees) positions. The level of challenge can be

adjusted or progressed by having the patient reach in various directions under loaded and unloaded conditions, kneel on stable or unstable surfaces, and respond to perturbations.

### Kneeling on a Stable Surface

- In the half-kneeling position, loop an exercise band under the forward foot and have the patient perform diagonal upper extremity patterns against the resistance (Fig. 23.3 A).
- While in a half-kneeling or high-kneeling position, have the patient reach and lift a weighted object from the floor with one or both hands, and then move the weighted object upward and outward in various patterns of motion and return (Fig. 23.3 B).
- While in a half-kneeling or high-kneeling position, toss a ball and have the patient catch and then return it.

**FIGURE 23.3** Balancing in half-kneeling position (A) while performing diagonal patterns against elastic resistance; and (B) while moving a weighted object from a chair to the floor.

Progress this activity by gradually tossing the ball away from the trunk in multiple directions and with varying velocities.

### Kneeling on an Unstable Surface

- Have the patient kneel on a foam roller, balance board, BOSU®, or partially deflated large therapy ball and perform arm motions in various directions; progress the activity by having the patient move the arms against resistance.
- While kneeling on an unstable surface, have the patient catch and return a ball. Progress by using a weighted ball (Fig. 23.4) or adjusting the location and speed of the toss.

**FIGURE 23.4** Balancing in high-kneeling position on a BOSU® while catching and tossing a ball.

### Bilateral Stance

Once the individual can stand upright and maintain balance while reaching in all directions and while managing imposed loads (free weights, pulley system, or elastic resistance), the patient is ready to progress to exercises that provide a greater challenge to stability and balance, first in bilateral stance and progressing to unilateral stance.

#### Bilateral Stance on a Stable Surface [VIDEO 23.1](#)

- Begin with the patient standing with both feet on the floor, shoulder width apart, or in a stride position.
  - Toss a ball (unweighted or weighted) that requires the patient to reach outward, upward, or downward to catch and return it. When indicated, remind the patient to maintain a neutral spine, to contract the abdominals when reaching upward to stabilize the spine, or to rotate

at the hips rather than the spine when reaching outward or downward.

- Perform various arm motions against elastic resistance, with free weights, or while shaking a BodyBlade®.
- Progress to balancing in *tandem stance*. Have the patient stand on a stable, narrow surface, such as a line on the floor or a balance beam. Apply quick alternating manual resistance against the patient's pelvis (Fig. 23.5), or apply quick pulling motions to elastic resistance held by the patient. Vary the timing, direction, amount, and point of application of the forces used to adjust or progress this activity.

**FIGURE 23.5** Balancing in tandem stance on a balance beam with quick alternating resistance applied against the pelvis.

- Progress to *tandem walking* on a narrow but stable surface. Manual perturbations to the pelvis and trunk can be added to further challenge the patient.

### Bilateral Stance on an Unstable Surface

#### VIDEO 23.2

- While on a balance board or BOSU®, have patient rock the platform forward and backward and side-to-side while attempting to control the motion and maintain balance. Instruct the patient to prevent the edges of the platform from hitting the floor.
- Have the patient stand on a foam half-roller (curved side down), a balance board, or BOSU®; add the following perturbations as the patient is able.
  - Apply quick alternating resistance against the patient's pelvis.

- Have the patient perform various arm motions against elastic resistance, with free weights (Fig. 23.6), or while shaking a BodyBlade®.
- Toss a ball (unweighted or weighted) back and forth to the patient (Fig. 23.7).
- Have the patient perform partial squats (Fig. 23.8).

**FIGURE 23.6** Balancing in bilateral stance on a balance board while performing arm movements.

**FIGURE 23.7** Balancing in bilateral stance on a BOSU® while catching and tossing a ball.

**FIGURE 23.8** Balancing on an unstable surface while performing partial squats.

### Unilateral Stance

Begin by having the patient practice standing in unilateral stance on a stable surface, progressing to an unstable surface and adding perturbations as described in the bilateral stance exercises.

### Unilateral Stance on a Stable Surface

#### VIDEO 23.3

- Have the patient perform upper extremity diagonal patterns, unilaterally or bilaterally, using free weights or elastic bands (tubing) while balancing on one lower extremity (Fig. 23.9). When using elastic resistance, change the angle of pull to vary the challenge and balance response.
- Have the patient, while balancing on one lower extremity, practice various lower extremity patterns that replicate functional activities. The following are suggestions:
  - Place a star pattern (such as four intersecting lines) on the floor. Have the patient place one foot on the center of the pattern and then touch the opposite foot on each of the lines of the pattern: directly forward, diagonally forward, sideways, diagonally backward (Fig. 23.10 A), straight backward, and crossed behind (Fig. 23.10 B). Then switch feet and repeat the pattern on the opposite side.
  - Perform an alternating PNF pattern, such as D<sub>1</sub> flexion (flexion, adduction, and external rotation)/extension (extension, abduction, internal rotation) with one leg while holding a weight and flexing/extending the opposite elbow (Fig. 23.11).
  - Have the patient walk sideways, then progress to braiding or carioca motions using forward and backward cross-over steps. This requires alternating balance reactions from one lower extremity to the other.
  - Bend or rotate to one side while performing a partial squat to lift an object from a chair or the floor (Fig. 23.12).

**FIGURE 23.9** Balancing in unilateral stance while performing upper extremity diagonal patterns against elastic resistance: (A) unilaterally, and (B) bilaterally.

**FIGURE 23.10** Maintaining balance while touching one foot on each of the lines of a star pattern on the floor and returning to the center; (A) diagonally backward and (B) crossed behind stationary leg.

**FIGURE 23.11** Balancing in unilateral stance while performing a diagonal pattern with one lower extremity. Upper extremity motions add additional challenges to balance.

- Reach outward with arms while bending forward and extending one leg as in a “skater” position (Fig. 23.13 A). Increase the challenge by picking up a weight from the floor or by alternately moving the arms in a windmill manner (without or with weights in each hand) (Fig. 23.13 B).

**FIGURE 23.12** Partial squatting in unilateral stance, leaning to one side and picking up an object.

#### Unilateral Stance on an Unstable Surface

- Have the patient stand on the round and then flat side of a BOSU® or on a balance board or disc, and apply resistance against the patient’s trunk or to upper extremity movements using elastic resistance (Fig. 23.14).
- While balancing on an unstable surface, have the patient swing one leg forward and backward, first slowly, then with increasing speeds.

**FIGURE 23.13** Maintaining balance in unilateral stance: **(A)** while bending forward at the hips and reaching out with both arms; and **(B)** while performing a windmill motion using handheld weights.

**FIGURE 23.14** Perturbations in unilateral stance using elastic resistance while on a balance disc.

### Moving and Planting Activities **VIDEO 23.4**

Movement followed by planting the foot (or feet) not only requires coordinated movements to stop the body's progression in one direction, but also a rapid balance response to keep from falling. These activities also prepare the individual for skills that involve rapid reversals of direction and agility drills.

### Jump and "Freeze"

- Have the patient jump down from a platform or low step and hold the end position (Fig. 23.15 A). Progress to jumping up onto the platform.
- When the patient has learned one-legged balance and demonstrates control in the jump-and-freeze exercise, progress to having him or her hop up onto or down from a step and holding the end position with that one leg (Fig. 23.15 B).

### Side Shuffle and "Freeze"

- Have the patient perform two to three side shuffles and hold the end position, then shuffle in the opposite direction and "freeze" (Fig. 23.16).
- Vary the pattern to include shuffling in multiple directions, such as moving diagonally forward then backward or in a curved pattern, freezing and then reversing the direction.

### Run and "Freeze"

Have the patient run forward, sideways, and backwards and "freeze" when you call out "freeze" or blow a whistle.

## Exercises for Strength and Power

Muscle strength and power are two critical elements for successful performance of many high-demand functional tasks and activities, such as moving heavy objects in the workplace and home or meeting the demands required for many sports. Muscle endurance also is necessary when functional or recreational tasks must be repeated or sustained over time. When designing functional rehabilitation programs for patients, recognize that some functional activities may involve slow, controlled, or repetitive movements, while other activities may require bursts of movement or quick changes of direction.

**FIGURE 23.15** Jump and freeze sequence and progression: (A) jumping down from a step and holding the end position and (B) hopping up onto a step and holding the end position.

In many cases, functional activities involve some combination of these movement and force requirements and the patient should be involved in defining their specific circumstances. Once these functional activities are defined, an effective exercise program can be developed that addresses the specific areas of muscle performance associated with each patient's physically demanding activities.

The remainder of this chapter focuses on exercises designed to improve muscle strength and/or power output—specifically,

**FIGURE 23.16** Side shuffle and freeze.

advanced strengthening exercises for the upper and lower extremities, and plyometric exercises, which involve high force movements performed at rapid speeds. All of the exercises described are built on the foundational constructs of dynamic stability of proximal body regions (shoulder girdle, trunk, pelvic girdle) and balance. Somewhat paradoxically, a program of advanced strengthening exercises and plyometric training also imposes significant demands on a patient's balance and dynamic stability, which improves these areas of physical function.<sup>10</sup>

#### CLINICAL TIP

When teaching a patient a program of advanced strengthening and plyometric exercises, always emphasize the patient's use of proper exercise technique before increasing the resistance imposed, the number repetitions and sets of an exercise, or the number of exercises in a treatment session.

## Advanced Strengthening Exercises

As discussed in Chapter 6, progressive resistance is a necessary element of exercises designed to develop muscle strength, while increasing the duration of exercise (repetitions or time) is necessary to develop muscle endurance. The strengthening exercises in this section use functionally based and total body movement patterns against the resistance of body weight or external loads. They are implemented during the advanced phase of rehabilitation in preparation for the patients return to high-demand tasks and activities.

Many advanced strengthening exercises are carried out using weight machines designed to target specific muscle groups or by using a variety of set-ups with weight-pulley systems and isokinetic equipment. However, the exercises in this section can be performed using simple but versatile resistance equipment, such as handheld weights or elastic bands or tubing. Other exercises suggest using equipment typically employed for cardiopulmonary training, such as a treadmill or stepping machine. Furthermore, some of the exercises described can be progressed by performing the exercises on unstable surfaces such as balance equipment to impose greater challenges.

### Advanced Strengthening: Upper Extremities

The following upper extremity exercises, performed in either weight-bearing or nonweight-bearing positions, are designed to develop strength of selected upper extremity muscle groups. However, advanced upper extremity strengthening also requires activation of the trunk and lower extremity musculature. Therefore, be sure that the patient has developed sufficient scapular, shoulder girdle, and trunk stability plus sufficient balance in upright positions before progressing to these exercises.

#### Exercises With a BodyBlade®

- *Patient position and procedure:* While sitting or standing, have the patient hold and shake the blade with one or both hands in a variety of shoulder positions with the elbow(s) extended or flexed (Fig. 23.17 A and B). Vary the speed,

direction, and size of oscillations used by the patient to alter the perturbations generated by the blade.

- *Progression:* Move the vibrating blade through a variety of anatomical and diagonal upper extremity patterns. Incorporate trunk rotation and weight shifting on the lower extremities for a total body exercise.

#### Upper Extremity Weight-Bearing Exercises Using Selected Equipment

- *Hand-walking on a treadmill:* While kneeling at the end of the treadmill, have the patient “walk” with his or her hands while bearing weight through the shoulders. The surface can be moving forward or backward.
- *“Climbing” with hands on a stepping machine:* While in a kneeling position and with each hand on a step of the unit, have the patient alternately push on each pedal to target scapular stabilizers and elbow extensors.

#### Pushing/Pulling and Lifting/Lowering Exercises

The following exercises involve various pushing and pulling or lifting and lowering motions. They are useful for developing upper extremity strength for functional tasks that require concentric and eccentric control of shoulder, elbow, and forearm musculature in combined movement patterns for moving objects of varying sizes and weights from one place to another. Depending on the size of the object to be moved, an exercise may be performed bilaterally or unilaterally. It is important to remind the patient to use proper body mechanics by maintaining a neutral spine and contracting the trunk

**FIGURE 23.17** Exercises with a BodyBlade®: (A) bilateral isometric strengthening of shoulder rotators with additional activation of trunk stabilizers; and (B) unilateral isometric strengthening of elbow flexors/extensors.

stabilizing muscles during the task and by maintaining a stable base of support during each of these exercises.

#### ■ *Pushing or pulling motions*

- Perform pushing and pulling motions against the resistance of an elastic band by moving the upper extremities in forward, backward, upward, and downward directions.
- Using an upper extremity ergometer, perform pushing or pulling motions, “pedaling” against resistance in a forward or backward direction. Adjust the direction, speed, and arc of motion to replicate various functional tasks.
- Reposition a heavy crate on a level surface by pulling (Fig. 23.18) or pushing (see Fig. 18.21) it from one place to another.

**FIGURE 23.18** Strengthening shoulder and elbow musculature by pulling (sliding) a heavy object from one position to another.

#### ■ *Lifting or lowering motions*

- Lift a weighted crate from the surface of a table, hold it close to the body, and lower it to a different position on the table.
- Lift and lower a heavy object to and/or from high and low surfaces (Fig. 23.19).

**FIGURE 23.19** Strengthening shoulder and elbow musculature by lifting or lowering a heavy object to and from a high surface.

## Seated Push-Ups on Unstable Surfaces

### VIDEO 23.5

- *Patient position and procedure:* While in a long-sitting position on the floor with heels placed on a firm foam roller or BOSU®, have the patient lift the hips from the floor by performing a seated push-up (Fig. 23.20 A).
- *Patient position and procedure:* Have the patient sit on a firm foam roller, the flat side of a BOSU®, or a balance board with legs on the floor and hands on the unstable surface at either side of the hips and lift the hips upward by performing a seated push-up (Fig. 23.20 B). Progress by increasing the time spent with the hips lifted or by raising one leg off the support surface.

**FIGURE 23.20** Seated push-ups in a long-sitting position (**A**) with lower legs on an unstable (soft) surface; and (**B**) with hands on an unstable surface.

## Prone Push-Ups in a Head-Down Position

*Patient position and procedure:* Once the patient can perform a prone push-up with hands and feet on the floor, progress to a prone push-up in a head-down position on an incline board, over a therapy ball, or on the floor with feet elevated on a platform to shift greater body weight to the upper extremities (Fig. 23.21).

**FIGURE 23.21** Prone push-ups in a head-down position.

### Upper Extremity Step-Ups Combined With Prone Push-Ups [VIDEO 23.5](#)

**Patient position and procedure:** Have the patient perform a prone push-up with both hands on the floor. While maintaining the push-up position, move one hand up onto and then off of a low platform (Fig. 23.22). Repeat the sequence, gradually increasing the number of repetitions. This exercise increases the weight-bearing force on the extremity that remains on the floor.

**FIGURE 23.22** Upper extremity step-up with the right upper extremity following a prone push-up.

### Prone Push-Ups on Unstable Surfaces

- **Patient position and procedure:** Have the patient perform a series of push-ups with hands on the floor and knees on a foam roller (Fig. 23.23 A).
- **Patient position and procedure:** Have the patient perform a series of push-ups with hands on a foam roller or small ball and knees or feet on the floor (Fig. 23.23 B).
- **Patient position and procedure:** Have the patient perform a series of push-ups with hands on a balance board, BOSU®, or small ball and knees on a foam roller (Fig. 23.23 C).

**A**

**B**

**C**

**FIGURE 23.23** Prone push-ups on unstable surfaces: **(A)** with hands on the floor and knees on a foam roller; **(B)** with hands on a small ball and feet on the floor; and **(C)** with hands on a BOSU® and knees on a foam roller.

### Ball “Walk-Out” [VIDEO 23.5](#)

- **Patient position and procedure:** In a prone position with hands on the floor and lower extremities on a large therapy ball, have the patient “walk” forward and then backward on the hands while keeping the lower extremities in contact with the ball (Fig. 23.24). To increase the challenge, perform prone push-ups between the forward and backward “walking” phases.

**FIGURE 23.24** Ball “walk-out” on hands with lower extremities rolling on a large therapy ball.

### Plantar-Grade “Walking”

Plantar-grade walking with weight on hands and feet (also referred to as “bear-walking”) places considerable weight through the upper extremities and can be used to develop strength of the musculature that stabilizes the scapulothoracic and glenohumeral joints.

- *Patient position and procedure:* Have the patient assume the plantar-grade position on hands and feet and “walk” forward bearing weight through all four limbs.
- *Progression:* Perform plantar-grade “walking” against the resistance of an elastic cord harnessed around the pelvis and fixed to the wall or to a heavy piece of equipment.

### Advanced Strengthening: Lower Extremities

#### VIDEO 23.6

The following exercises, some of which are progressions of exercises described in Chapters 20 through 22, are performed in functional movement patterns against progressive resistance and are implemented to develop increased lower extremity strength. Many of these exercises also improve dynamic stability of the trunk and balance.

#### Unilateral Supine Pelvic Bridges

**Patient position and procedure:** With one foot planted on the floor and the other extremity off the floor in either hip/knee flexion or hip flexion and knee extension, have the patient lift and lower the pelvis first against body weight and then while holding a weighted ball in both hands. Increase the challenge by planting the weight-bearing foot on an unstable surface, such as a BOSU® or small balance disk (Fig. 23.25).

#### Supine Pelvic Bridges on an Elevated Surface

- *Patient position and procedure:* While on the floor in a long-sitting position with both feet on a chair, platform, or a large therapy ball and hands on the floor, have the patient extend the hips, lifting them from the floor (Fig. 23.26).
- *Progression:* Lift the hips from the floor with just one foot placed on the chair or platform and the other leg flexed toward the chest.

**FIGURE 23.25** Unilateral supine pelvic bridge on an unstable surface while holding a weighted ball in both hands for additional resistance.

**FIGURE 23.26** Supine pelvic bridge with the lower extremities elevated on a platform or chair and hands on the floor.

#### Supine Hamstring Curls on a Ball VIDEO 23.6

- *Patient position and procedure:* While lying in the supine position on the floor, have the patient place both feet on a large therapy ball and roll it toward the hips by flexing the knees (Fig. 23.27). In addition to strengthening the hamstrings, this exercise also challenges the trunk stabilizers.
- *Progression:* Have the patient perform the exercise unilaterally by lifting one foot off the ball and rolling the ball toward the hips with just one foot on the ball.

#### Hamstrings or Quadriceps Strengthening: Kneeling

- *Patient position and procedure:* Have the patient begin in a high-kneeling position on a padded surface for comfort.
- *To strengthen the hamstrings:* While manually stabilizing the patient’s lower legs, have the patient lean forward from the vertical position as far as possible (Fig. 23.28 A), keeping the trunk erect and maintaining balance, and then return to the upright position by flexing the knees. In addition to strengthening the hamstrings eccentrically and concentrically in a closed-chain position, this exercise provides a significant challenge to the patient’s balance.

**FIGURE 23.27** Supine hamstring curls on a ball.

- *To strengthen the quadriceps:* Have the patient lean backward as far as possible from the upright position without touching the buttocks to the heels and then return to the high-kneeling position. As the patient leans backward, the quadriceps contract eccentrically to control movement at the knees and then concentrically as the patient returns to the vertical position.
- *Progression:* Add a weight held close to the chest for additional resistance (Fig. 23.28 B).

#### Unilateral Wall Slides: Standing

- *Patient position and procedure:* While in unilateral stance with the back against a wall and weight-bearing foot several feet away from the wall, have the patient slide down the wall until the knee is flexed to 90° (Fig. 23.29), making sure the knee avoids valgus and stays posterior to the toes. Hold the position, and then return to a standing position. This exercise strengthens the hip and knee extensors eccentrically and concentrically.
- *Progression:* Hold weights in both hands for additional resistance. Gradually increase the number of repetitions and/or the duration that the 90° position is held. Increase the challenge by placing a large therapy ball behind the back for these exercises.

#### Deep Squats

- *Patient position and procedure:* In bilateral stance with feet a comfortable distance apart, have the patient perform a deep squat by flexing the hips and knees (Fig. 23.30). Keep body weight distributed posteriorly through the heels, and be sure to keep the lower legs as vertical as possible to the floor so that the knees do not move anterior to the toes. Hold the deep squat position, and then return to the standing position. Have the patient hold both arms out in front of the body for balance or place one hand lightly on a countertop, if necessary.
- *Progression:* Perform repeated deep squats while holding weights or by combining squats with resisted upper extremity motions. This activity is beneficial for developing body mechanics in individuals who do heavy lifting in the work setting.

**FIGURE 23.28** (A) Strengthening the hamstrings against the resistance of body weight by leaning forward from a high-kneeling position; (B) strengthening the quadriceps by leaning backward from the high-kneeling position while holding a weighted ball for additional resistance.

**FIGURE 23.29** Unilateral wall slides in standing with a midrange hold.

**FIGURE 23.30** Deep squats with an end-range hold, while trying to keep the knees posterior to the toes.

### Variations of Lunges VIDEO 23.6

- **Deep forward lunge:** While maintaining the trunk in an erect position, have the patient place one foot forward and perform a deep lunge, flexing the forward knee to a 90° position but keeping the lower leg vertical and the knee posterior to the toes (Fig. 23.31 A); then return to the standing position. Place one hand lightly on a stable surface (wall, countertop) for balance, if necessary.
  - As balance improves, have the patient perform deep forward lunges while holding a weighted ball away from the chest and performing trunk rotation.
  - Place the forward foot on an unstable surface, such as a balance disk, while performing the forward lunge exercise.

### FOCUS ON EVIDENCE

Although the forward lunge exercise typically is performed with the trunk erect, there is evidence demonstrating that changing the position of the trunk and upper extremities alters the recruitment of muscle groups in the lead lower extremity during the lunge. Farrokhi and colleagues<sup>9</sup> conducted a motion analysis and electromyographic (EMG) study of the lead lower extremity during variations of the forward lunge exercise with ten healthy adults (five men, five women) as subjects. The investigators found that there was a small but statistically significant increase in hip extensor muscle (gluteus maximus and biceps femoris) recruitment of the lead leg when forward lunges were performed with the

**FIGURE 23.31** (A) Deep forward lunge while lightly touching a stable surface for balance; (B) multidirectional lunges on a star pattern on the floor; and (C) deep lateral lunge against elastic resistance.

trunk and upper extremities in a forward position compared with when the trunk was erect and upper extremities were positioned along the sides of the trunk. These findings confirmed a previously held clinical assumption. In contrast, despite clinical speculation that knee extensor muscle activation may increase in the lead leg if forward lunges are performed with the arms overhead and trunk in full extension, the results of this study revealed that there were no significant differences in the levels of activation of hip or knee extensor muscle groups compared with lunges performed in the erect trunk position.

- **Multidirectional lunges:** Have the patient perform lunges diagonally forward, out to the side, diagonally backward, and then directly backward. This sequence is facilitated by placing four intersecting lines on the floor (in a star pattern or like spokes of a wheel) and having the patient keep one foot planted where the lines intersect. The patient steps out onto each line (Fig. 23.31 B) and returns to the upright position. Motion in the same direction can be repeated multiple times before progressing to the next line, or the patient can step out onto each line in succession.
- **Lunges against added resistance:** Increase the difficulty of the exercise by performing lunges against elastic resistance looped around the lower legs (Fig. 23.31 C) or holding weights or a weighted ball, wearing a weight belt, or holding a barbell on the shoulders. Controlling weights while performing lunges is beneficial for developing strength for individuals returning to work settings that require heavy lifting.
- **Lunge-walking:** Perform a series of lunges in various directions to move across the floor or to pick up objects of decreasing height (e.g., 16 to 4 in.) from various places on the floor.
- **Lunge-jumps:** Refer to the description and figure (see Fig. 23.63) in the next section on plyometric training.

### Sitting Down and Standing Up From a Chair Against Elastic Resistance

- **Patient position and procedure:** Have the patient sit down against the resistance of an elastic band looped around the posterior aspect of the pelvis (Fig. 23.32 A).
- **Patient position and procedure:** Have the patient stand up against elastic resistance looped around the anterior aspect of the pelvis (Fig. 23.32 B).

### Bilateral or Unilateral Heel-Lowering Over a Step

- **Patient position and procedure:** While standing with heels over the edge of a step or low platform, have the patient perform bilateral heel lowering and raising. Place one hand *lightly* on a railing or a stable surface for balance. Heel lowering imposes eccentric loading of the gastrocnemius-soleus musculature against the resistance of body weight.
- **Progression:** Perform the same exercise while wearing a weight belt or vest or holding weights (Fig. 23.33), then progress to unilateral stance.

### Band Walking

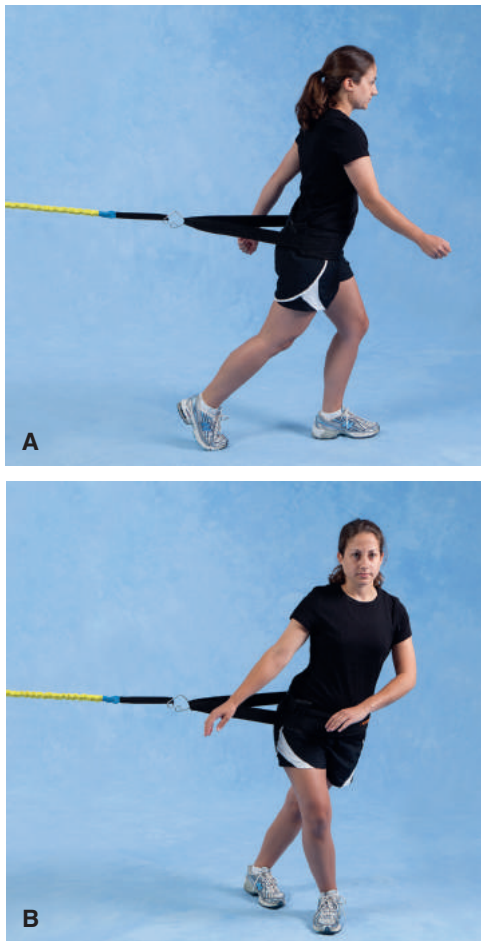

- **Patient position and procedure:** Have the patient walk forward (Fig. 23.34 A), sideward (Fig. 23.34 B), and backward against elastic resistance looped around the pelvis.

**FIGURE 23.32** (A) Sitting down; and (B) standing up against elastic resistance.

**FIGURE 23.33** Heel-lowering over a step while holding weights for additional resistance.

**FIGURE 23.34** Band walking: (A) in a forward direction; and (B) in a sideward direction against elastic resistance looped around the pelvis.

- **Patient position and procedure:** Have the patient walk forward against elastic resistance looped around the thighs for closed-chain strengthening of the external rotators (Fig. 23.35).

#### Pulling or Pushing a Heavy Object

- **Patient position and procedure:** With the arms positioned in a stable and comfortable position, have the patient use primarily lower extremity strength to pull (Fig. 23.36) or push a heavy object, such as a weighted sled or cart, across the floor. Select positions for pulling or pushing similar to the anticipated work-related tasks or sport activity. Be certain the patient uses proper body mechanics.
- **Progression:** Gradually increase the amount of weight moved from one place to another.

#### Resisted Running Start and Resisted Running

**Patient position and procedure:** While wearing a harness placed around the trunk and pelvis, have the patient move from the starting position typically assumed prior to a sprint and then run forward against the resistance of a heavy-grade elastic cord that is attached to the harness and affixed to the wall or a stationary surface (Fig. 23.37). As an alternative, the patient can perform backward running against resistance.

**FIGURE 23.35** Band walking in a forward direction against elastic resistance looped around the thighs for closed-chain strengthening of the hip external rotators.

**FIGURE 23.36** Pulling increasingly heavy objects across the floor.

### Plyometric Training: Stretch-Shortening Drills

Most pieces of equipment used for resistance training, such as free weights, weight machines, or weight-pulley systems, are designed for developing advanced levels of strength by providing resistance during slow, controlled movements. However, functional movements during high-demand occupational or sport-related activities often require reactive bursts of force or power that are not developed concurrently during most strength-building exercises. A program of high-intensity, high-velocity exercises, known as *plyometric training*, not only improves muscle strength, but also develops power output, quick

**FIGURE 23.37** Resisted running start.

neuromuscular reactions, and coordination.<sup>5,6,13</sup> This form of exercise is also recommended to improve athletic performance and reduce the risk of musculoskeletal injury.<sup>5,6,8,11,19</sup>

Plyometric training typically is integrated into the advanced phase of rehabilitation to train the neuromuscular system to react quickly in preparation for rapid starting and stopping movements or quick changes of direction. This form of training is appropriate only for carefully selected patients who wish to return to high-demand functional activities and sports.

### Definitions and Characteristics

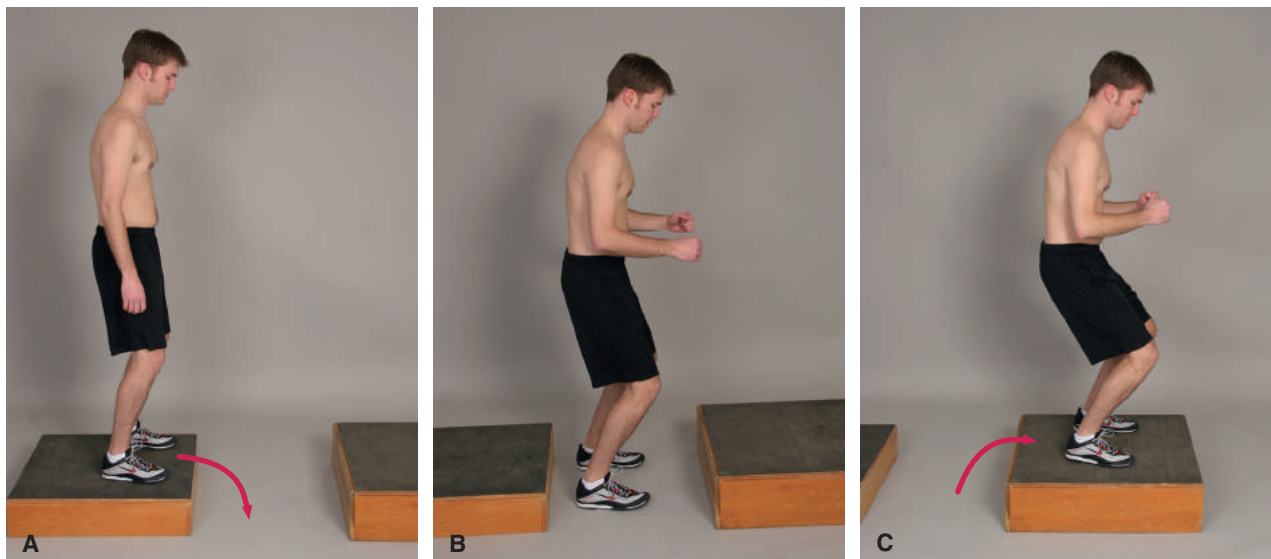

Plyometric training,<sup>5,13,16</sup> also called *stretch-shortening drills*<sup>19</sup> or stretch-strengthening drills,<sup>17</sup> employs high-velocity eccentric to concentric muscle loading, reflexive reactions, and

functional movement patterns. Plyometric training is defined as a system of high-velocity resistance training characterized by a rapid, resisted, eccentric (lengthening) muscle contraction, followed immediately by a rapid reversal of movement using a resisted concentric (shortening) contraction of the same muscle.<sup>13,18,19</sup> The rapid eccentric loading phase is the stretch cycle, and the concentric phase is the shortening cycle. The period of time between the stretch and shortening cycles is known as the amortization phase. During the amortization phase, the muscle reverses its action, switching from deceleration to acceleration of the load. It is important that the amortization phase be kept very brief by a rapid reversal of movements to capitalize on the increased tension in the muscle.<sup>6</sup>

Body weight or external forms of loading, such as elastic bands or a weighted ball, are possible sources of resistance. An example of a stretch-shortening drill for the lower extremities against the resistance of body weight is represented in Figure 23.38. Additional examples of plyometric training for the upper and lower extremities are noted in Box 23.1.

### Neurological and Biomechanical Influences

Plyometric training is thought to utilize the series-elastic properties of connective tissues and the stretch reflex of the neuromuscular unit. The spring-like properties of the series-elastic components of muscle-tendon units create elastic energy during the initial stretch phase as the muscle contracts eccentrically and lengthens under tension. This elastic energy is stored briefly and then returned to the system during the concentric contraction that follows. The storage and release of this elastic energy augments the force production of the concentric muscle contraction.<sup>1,5,13,16</sup>

**FIGURE 23.38** Plyometric lower extremity sequence against the resistance of body weight: (A) patient stands on a low platform; (B) jumps off the platform to the floor, controlling the impact with a loaded, lengthening contraction of the hip and knee extensors and plantar flexors—the stretch phase; and (C) then without delay jumps forward onto the next platform using a concentric contraction of the same muscle groups—the shortening phase.

### BOX 23.1 Plyometric Activities for the Upper and Lower Extremities

#### Upper Extremities

- Catching and throwing a weighted ball with a partner or against a wall, bilaterally then unilaterally
- Stretch-shortening drills with elastic tubing using anatomical and diagonal motions
- Swinging a weighted object (ball, golf club, bat)
- Dribbling a ball on the floor or against a wall
- Push-offs from a wall or countertop while standing
- Drop push-ups from a low platform to the floor and back onto the platform
- Clap push-ups

#### Lower Extremities

- Repetitive jumping on the floor: in place; forward/backward; side-to-side; diagonally to four corners; jump with rotation; zigzag jumping; later, jump on foam
- Vertical jumps and reaches and proper landing
- Multiple jumps across a floor (bounding)
- Box jumps: initially off and freeze, then off and back on box, increasing speed and height
- Side-to-side jumps (box to floor to box)
- Jumping over objects on the floor
- Hopping activities: in place, across a surface, and over objects on the floor
- Depth jumps (advanced): jumping from a box, squatting to absorb the shock, and then jumping and reaching as high as possible

The stretch-shortening cycle is thought to stimulate the proprioceptors of muscles, tendons, ligaments, and joints; increase the excitability of the neuromuscular receptors; and improve the reactivity of the neuromuscular system. Therefore, the term *reactive neuromuscular training* also has been used to describe this exercise approach. More specifically, the loaded, eccentric contraction is thought to prepare the contractile elements of the muscle for the concentric contraction by stimulation and activation of the monosynaptic stretch reflex.<sup>5,7,16</sup> Muscle spindles, the receptors that lie in parallel with muscle fibers, sense the length of a muscle and the velocity of stretch applied to a muscle and transmit this information to the CNS via afferent pathways. Efferent signals are returned to the muscle from the CNS, which reflexively facilitates activation of a shortening contraction.<sup>3,12</sup> Based on this mechanism, the more rapid the eccentric muscle contraction, the more likely it is that the stretch reflex will be activated and the concentric contraction enhanced.

It is suggested that the ability to capture the stored elastic energy and activate neural facilitation depends on the velocity and magnitude of the stretch and the transition time between the stretch and shortening phases (the amortization phase).<sup>4,13</sup> A decrease in the duration of the amortization phase theoretically increases the force output during the shortening cycle.<sup>1,5,16,18</sup>

### Effects of Plyometric Training

The evidence supporting the effectiveness of plyometric training for developing muscle strength and power is substantial.<sup>13</sup> There is also evidence indicating that plyometric training is associated with an increase in a muscle's ability to resist stretch, which may enhance the muscle's dynamic restraint capabilities.<sup>1</sup> In addition, there is promising evidence to suggest that plyometric training may enhance physical performance<sup>2,11</sup> and decrease the incidence of lower extremity injury.<sup>14,15</sup>

#### FOCUS ON EVIDENCE

The results of a recent systematic review and meta-analysis of the literature support the conclusions of many previous studies that plyometric training is an effective method to improve muscle strength and power. Greatest gains in strength have been shown to occur when plyometric training was combined with progressive weight training. The review also indicated that plyometric training is beneficial for individuals with moderately low as well as high fitness levels prior to the start of training.<sup>13</sup>

Studies also have investigated the impact of plyometric training on performance of selected upper and lower extremity activities. Carter and colleagues<sup>2</sup> carried out a prospective study of the effect of a plyometric program on throwing velocity in a group of intercollegiate baseball players. Following pre-testing of throwing velocity and isokinetic strength of the shoulder rotators, participants were randomly assigned to either the plyometric training group (n = 13) or the control group (n = 11). Both groups participated in an off-season strength and conditioning program that included exercises with elastic resistance for the shoulder rotators, but only the experimental group performed a program of six plyometric exercises with a weighted ball for the upper extremities twice weekly for 8 weeks. At the conclusion of the program, the throwing velocity of the plyometric group increased significantly compared with the control group, but there continued to be no significant differences in shoulder strength between groups. The investigators concluded that a combined program of strengthening exercises and plyometric training is superior for improving throwing velocity than strengthening exercises alone.

In a prospective study by Hewett,<sup>11</sup> two groups of high school-aged female athletes were monitored during a season of participation in one of three sports (soccer, volleyball, and basketball). One group (n = 366) participated in a 6-week preseason training program, whereas the other group (n = 463) did not. The preseason training focused on jumping and landing techniques. At the end of the sport season, there was a significantly higher incidence (3.6 times higher) of knee injury in the untrained group than in the trained group. The investigators concluded that preseason plyometric training may reduce the risk of knee injury in female athletes, possibly owing to increased dynamic knee stability.

## Application and Progression of Plyometric Exercises

Plyometric training is appropriate only in the advanced phases of rehabilitation for carefully selected, active individuals who must achieve a high level of physical performance during specific, high-demand activities.

**CONTRAINDICATIONS:** Plyometric activities should not be implemented in the presence of inflammation, pain, or significant joint instability.<sup>4,6</sup>

**Preparation for plyometrics.** Prior to initiating plyometric training, the patient should have an adequate base of muscle strength and endurance, as well as flexibility in the muscles to be exercised.<sup>6</sup> Criteria that should be met to begin plyometric training usually include an 80% to 85% level of strength of the involved muscle groups (compared to the contralateral extremity) and 90% to 95% *pain-free* ROM of the moving joints.<sup>5</sup> Sufficient strength and stability of proximal regions of the body (trunk and limb) for balance and postural control are also necessary. For example, scapulothoracic stability with the absence of scapular winging is necessary before engaging in a progression of advanced push-ups.

**Specificity of training.** A plyometric exercise should be designed with specific functional activities in mind and should include movement patterns that replicate the desired activity.

**Progression and parameters.** When planning and implementing a plyometric training program, exercises should be sequenced from easy to difficult and progressed gradually. Box 23.2 summarizes a sequence of sample activities for upper extremity plyometric training.<sup>2,5,16,18,19</sup> Programs should also be individually designed to meet each patient's needs and goals. Note that prior to initiating each session of plyometric activities, a series of warm-up exercises should be performed to reduce the risk of injury to the contracting muscle groups.

The following parameters should be considered when progressing a plyometric program:

- **Speed.** Exercises should be performed rapidly but safely. The rate of stretch of the contracting muscle is more important than the amount of stretch.<sup>13,16</sup> Emphasis should be placed on decreasing the amortization phase when transitioning from the eccentric to the concentric contraction. This trains the muscle to generate tension in the shortest time possible. If a jumping activity is performed, for example, progression of the plyometric activity should center on reducing the time on the ground between each jump.
- **Intensity.** Resistance should be increased gradually so as not to slow down the activity. Methods for increasing external resistance include using a weight belt or vest, heavier weighted balls, or heavier grade elastic resistance; progressing from double-leg to single-leg activities; and increasing the height of platforms for jumping and hopping activities. Intensity also may be increased by progressing from simple to complex movements.

### BOX 23.2 Sample Plyometric Sequence for the Upper Extremities

#### Warm-Up Activities

- Trunk exercises holding lightweight ball: rotation, side-bending, and chopping motions
- Upper extremity exercises in anatomical and diagonal planes of motion with light-grade elastic tubing
- Prone push-ups

For each of the following plyometric activities, perform a quick reversal between the eccentric and concentric phases.

- Bilateral throwing motions with a weighted ball to and from an exercise partner: bilateral chest press, bilateral overhead throw, and bilateral side throw
- ER/IR against elastic tubing (first with the arm positioned slightly away from the side of the trunk in some shoulder abduction and then in the 90/90 position of shoulder and elbow)
- Diagonal patterns against elastic resistance
- Unilateral catching/throwing motions with a weighted ball: side throws→overhead throws→baseball throws

#### Additional Exercises

- Trunk exercises holding weighted ball: abdominal curl-ups, back extension, sit-up and bilateral throw, and long sitting throws
- Push-offs from a wall or countertop while in a standing position
- Clap push-ups
- Drop push-ups: prone push-ups from platform to floor and back to platform

- **Repetitions, frequency, and duration.** The number of repetitions of an activity should be increased as long as proper exercise technique is maintained by the patient. The number of plyometric exercises in a single session also is increased gradually, working up to perhaps six different activities.<sup>2</sup> The optimal frequency of plyometric sessions is two sessions per week, which allows a 48- to 72-hour recovery period between sessions.<sup>5,13,16</sup> Maximum training benefits typically occur within an 8- to 10-week duration.<sup>13</sup>

**Precautions.** Because of the emphasis on eccentric loading and rapid reversal to concentric muscle contractions, the potential for tissue damage is increased with plyometric activities. As with other forms of high-intensity resistance training, special precautions must be followed to ensure patient safety.<sup>5,6,16</sup> These precautions are listed in Box 23.3.

### Plyometric Exercises: Upper Extremities

Plyometric exercises for the upper extremities can be performed in a variety of nonweight-bearing and weight-bearing positions, using motions and resistance that target a muscle group or using combined movement patterns that involve multiple muscle groups throughout the entire upper extremity.<sup>2,4,6,8,19</sup> Many combined patterns used in plyometric

**BOX 23.3 Precautions for Plyometric Training**

- If high-stress, shock-absorbing activities are not permissible, do not incorporate plyometric training into a patient's rehabilitation program.
- If a decision is made to include plyometric activities in a rehabilitation program for children or elderly patients, select only beginning-level stretch-shortening drills against light resistance. Do not include high-impact, heavy-load activities—such as drop jumps or weighted jumps—that could place excessive stress on joints.
- Be sure the patient has adequate flexibility and strength before initiating plyometric exercises.
- Wear shoes that provide support for lower extremity plyometrics.
- Always warm-up prior to plyometric training with a series of active, dynamic trunk and extremity exercises.
- During jumping activities, emphasize learning techniques for a safe landing before progressing to rebounding.
- Progress repetitions of an exercise before increasing the level of resistance used or the height or length of jumps.
- For high-level athletes who progress to high-intensity plyometric drills, increase the rest intervals between sets and decrease the frequency of drills as the intensity of the drills increases.
- Allow adequate time for recovery with 48 to 72 hours between sessions of plyometric activities.
- Stop an exercise if a patient can no longer perform the plyometric activity with good form and landing technique because of fatigue.

activities incorporate trunk stability and balance into the movement sequence and often simulate desired functional motor skills that occur during work or recreational activities.

A variety of plyometric exercises for the upper extremities that could be incorporated into the final phase of rehabilitation as a component of advanced functional training are presented in this section.

**Bilateral Diagonal Upper Extremity Movements**

**Patient position and procedure:** While standing and holding a weighted ball with both hands, have the patient perform diagonal patterns ( $D_1$  or  $D_2$ ) with a quick transition from the flexion to extension patterns. Incorporate trunk rotation into the movement patterns. These exercises also develop dynamic stability of the trunk rotators and lower extremities.

**Bilateral Chest Press and Throw: Supine**

**Patient position and procedure:** Supine with both hands reaching toward the ceiling. Have the patient catch a weighted ball dropped from above by the therapist (Fig. 23.39), control and lower it to the chest (eccentric phase), and then quickly throw it vertically back to the therapist. As the ball moves toward the chest, shoulder flexors and elbow extensors are loaded eccentrically.

**FIGURE 23.39** Bilateral chest press and throw—supine.

**Bilateral Chest Press and Throw: Standing**

**Patient position and procedure:** While standing and with feet placed in a stride position for balance, have the patient catch a weighted ball with both hands, bringing it to the chest (eccentric phase) (Fig. 23.40), and then throw it back to the therapist or onto a rebounder (concentric phase).

**Bilateral Overhead Catch and Throw**

**Patient position and procedure:** While standing and with feet placed in a stride position for balance, have the patient use both hands to catch a weighted ball thrown over the head, controlling the momentum of the ball with shoulder and

**FIGURE 23.40** Bilateral chest press and throw—standing.

elbow musculature (eccentric phase), and then throw the ball back quickly to the therapist or onto a rebounder (concentric phase) (Fig. 23.41). This exercise targets the shoulder and elbow extensors.

**FIGURE 23.41** Bilateral overhead catch and throw.

### Bilateral Horizontal Side Throw and Catch

#### VIDEO 23.7

**Patient position and procedure:** While standing with one side of the body about 10 feet away from a rebounder, have the patient hold a weighted ball in both hands with arms positioned across the chest and then throw the ball toward the rebounder by rotating the trunk and moving the arms across the chest in the transverse plane. The patient then catches the ball as it bounces back from the rebounder, controlling the momentum of the ball by allowing the arms to move back across the chest and rotating the trunk (eccentric phase). The patient then throws the ball back to the rebounder by reversing the movements of the arms and trunk (concentric phase) (Fig. 23.42). This exercise targets the horizontal abductors and adductors of the shoulder and trunk rotators. If a rebounder is not available, the exercise can be performed with a therapist or exercise partner.

### Hand-To-Hand Overhead Catch and Throw

**Patient position and procedure:** While standing or kneeling with both upper extremities elevated to about 120° (aligned just anterior to the frontal plane of the trunk), elbows

**FIGURE 23.42** Bilateral side throw and catch using horizontal abduction and adduction of the shoulders and trunk rotation.

extended, and forearms supinated (palms facing upward), have the patient throw a bean bag or weighted ball over the head with one upper extremity and catch it with the opposite hand, controlling the weight of the ball with that shoulder (eccentric phase). Then throw the ball back to the other hand by abducting the shoulder (concentric phase). Repeat the sequence as if juggling the ball overhead (Fig. 23.43). This exercise targets the shoulder abductors.

### Unilateral Plyometric Shoulder Exercises Using Elastic Resistance

Plyometric activities using elastic resistance can be set up to target individual or multiple muscle groups depending on the patient's position, the line of pull of the elastic, and which joints are moving during the exercise. (Refer to Chapter 6 to review the principles of use of elastic resistance products.) Set-ups for the shoulder rotators are described here.

- **Patient position and procedure:** To target the external rotators of the shoulder, have the patient stand facing a wall or doorframe and grasp one end of a length of elastic tubing or band attached to the wall at eye level. Begin with the shoulder and elbow in the 90/90 position (shoulder abducted 90° and in full external rotation and the elbow flexed 90°) (Fig. 23.44). Have the patient release the externally rotated position, controlling movement into internal rotation (eccentric phase), and then quickly reverse the motion by moving the shoulder into external rotation (concentric phase). The elastic should remain taut throughout the exercise.
- **Patient position and procedure:** To target the internal rotators of the shoulder, have the patient stand facing away from the doorframe or wall to which the elastic resistance is

**FIGURE 23.43** Hand-to-hand overhead catch and throw.

**FIGURE 23.44** Unilateral plyometric exercise for the shoulder external rotators using elastic resistance.

attached. Begin with tension on the elastic while the shoulder is in 90° abduction and full internal rotation, and control movement of the shoulder into external rotation (eccentric phase), then quickly return to internal rotation (concentric phase).

#### **Bounce a Weighted Ball: Prone-Lying**

**Patient position and procedure:** While lying prone on a table with the scapula retracted and the upper arm supported on the table, position the shoulder in 90° abduction and external rotation and the elbow in 90° flexion. Have the patient

bounce a weighted ball on the floor by internally rotating the shoulder; catch it, moving the shoulder back into external rotation under control (eccentric phase); and quickly bounce it again by internally rotating the shoulder (concentric phase) (Fig. 23.45). This exercise targets the shoulder internal rotators.

**FIGURE 23.45** Unilateral plyometric exercise for the shoulder internal rotators—bounce a weighted ball in the prone-lying position.

#### **Unilateral Side Catch and Throw**

These exercises target the internal rotators of shoulder.

- **Patient position and procedure:** While standing in the stride position and with the shoulder positioned in some degree of abduction (upper arm slightly away from the trunk), have the patient face the therapist, catch a weighted ball thrown to one side by the therapist, allowing the shoulder to externally rotate to control the momentum of the ball (eccentric phase) (Fig. 23.46 A), and return the ball using primarily shoulder internal rotation (concentric phase). If a rebounder is available, the patient can perform the exercise independently.
- **Patient position and procedure:** While standing in the stride position and with the shoulder abducted and externally rotated and the elbow flexed, have the patient catch and throw a weighted ball using shoulder rotation (a simulated baseball throw) (Fig. 23.46 B). Incorporate trunk rotation in the backward and forward motion of the shoulder. **VIDEO 23.7** 🌐

#### **Unilateral Reverse Catch and Throw**

This exercise primarily targets the external rotators of the shoulder in the end-range.

**Patient position and procedure:** Have the patient assume a half-kneeling position, facing away from the therapist, with the involved shoulder abducted 90° and externally rotated, the elbow flexed to 90°, and the forearm pronated (palm facing therapist). Instruct the patient to look at the hand and catch a soft, lightweight object (ball or bean bag) thrown toward the hand by the therapist; control the momentum of the object by allowing the shoulder to move into internal rotation;

**FIGURE 23.46** Unilateral plyometric exercise for the shoulder internal rotators: (A) side catch and throw; and (B) a simulated baseball throw with the shoulder abducted to 90° and elbow flexed.

and then quickly throw the object back to the therapist by externally rotating the shoulder (Fig. 23.47 A, B, and C).

#### Throw and Catch With Elbow Action

- **Patient position and procedure:** While in a standing position and with the arm positioned along the side of the trunk, have the patient throw a weighted ball into the air with one hand, using primarily elbow flexion; catch it, allowing the elbow to extend with control (eccentric phase); and then quickly throw it into the air again (concentric phase) (Fig. 23.48). This exercise targets the elbow flexors.
- **Patient position and procedure:** While standing and with one or both arms positioned overhead, have the patient catch a weighted ball and return it to the therapist or to a rebounder using primarily elbow action. This exercise targets the elbow extensors and can be done bilaterally or unilaterally.

#### Unilateral Throw and Catch With Wrist Action

**Patient position and procedure:** While seated, have the patient stabilize the elbow on the thigh in about 90° flexion, and with the forearm supinated, toss a weighted ball or bean bag into the air using primarily wrist flexion; catch it, allowing the wrist to extend under control (eccentric phases); and then quickly toss it into the air again (concentric phase) (Fig. 23.49). This exercise targets the wrist flexors.

**FIGURE 23.47** Unilateral plyometric exercise for the shoulder external rotators—reverse catch and throw: The patient (A) catches a soft, lightweight object with the shoulder abducted and externally rotated and the elbow flexed; (B) allows the shoulder to internally rotate with control; and (C) externally rotates the shoulder to throw the object back to the therapist.

#### Simulated Sport Activities

- Dribble a weighted ball or basketball against a wall (Fig. 23.50) or on the floor using either elbow or wrist actions. This activity targets either the elbow extensors or wrist flexors.
- Bounce a tennis ball or racquetball into the air or onto the floor (forearm supinated or pronated, respectively) with a short-handled racquet, progressing to a long-handled racquet. These activities emphasize the wrist flexors. In

**FIGURE 23.48** Unilateral plyometric exercise targeting the elbow flexors.

**FIGURE 23.50** Dribble a ball against the wall to target the wrist flexors.

**FIGURE 23.49** Unilateral plyometric exercise targeting the wrist flexors.

**FIGURE 23.51** Using a short-handled racquet, bounce a ball into the air with the forearm pronated to target the wrist extensors.

### Upper Extremity Weight-Bearing Movements on a Slide Board

Use of a slide board, such as a ProFitter™, provides an unstable, moving surface for performing shoulder exercises that require quick changes of direction combined with weight bearing through the upper extremities.

- contrast, bouncing a ball into the air with the forearm pronated emphasizes the wrist extensors (Fig. 23.51).
- Swing a weighted golf club (Fig. 23.52) or baseball bat. The backward motion followed by a rapid reversal forward provides the plyometric stimulus.

- *Patient position and procedure:* Have the patient place both hands on a spring-loaded slide board while kneeling along one side of the equipment. Shift the arms side-to-side from the shoulders (Fig. 23.53), gradually increasing the speed of the shoulder movements and changes of direction.

**FIGURE 23.52** Practice a golf swing using a weighted club.

**FIGURE 23.53** Bilateral plyometric exercise while bearing weight through the upper extremities—side-to-side movements with quick changes of direction on a ProFitter®.

- *Patient position and procedure:* Have the patient kneel at one end of the slide board and move the arms forward and backward from the shoulders.
- *Progression:* Perform the same movements while kneeling and bearing weight on one hand.

#### Push-Offs From a Wall

- *Patient position and procedure:* While the patient is standing several feet away from a wall (or countertop), gently push the patient directly forward toward the wall. Instruct the patient to catch himself/herself with equal weight on both

hands, allowing the elbows to flex under control (eccentric phase) as the trunk moves toward the wall (Fig. 23.54 A). Then have the patient quickly push away from the wall with both hands (concentric phase) (Fig. 23.54 B), catch the patient as he/she falls backward, and then push the patient forward again to repeat the sequence.

**FIGURE 23.54** Repeated push-offs from a wall: (A) falling directly forward toward the wall and catching self with both hands; and (B) pushing away from the wall to the upright position.

- **Alternative activity:** Have the patient perform the sequence independently by falling forward to the wall and quickly pushing away.
- **Progression:** Have the patient use one hand to catch self and push away from the wall.

### Side-to-Side Push-Offs From a Waist-Level Surface

#### VIDEO 23.8

**Patient position and procedure:** While standing and maintaining both feet approximately 3 feet away from a waist-height, stable surface (countertop, heavy table), have the patient fall forward and slightly to the right of midline and catch self with hands on the edge of the countertop or table; push off and shift arms and trunk to the left; catch self with both hands; and push off again, moving arms and trunk back to the right, past midline (Fig. 23.55). This exercise alternately places greater weight on the right and then the left upper extremity.

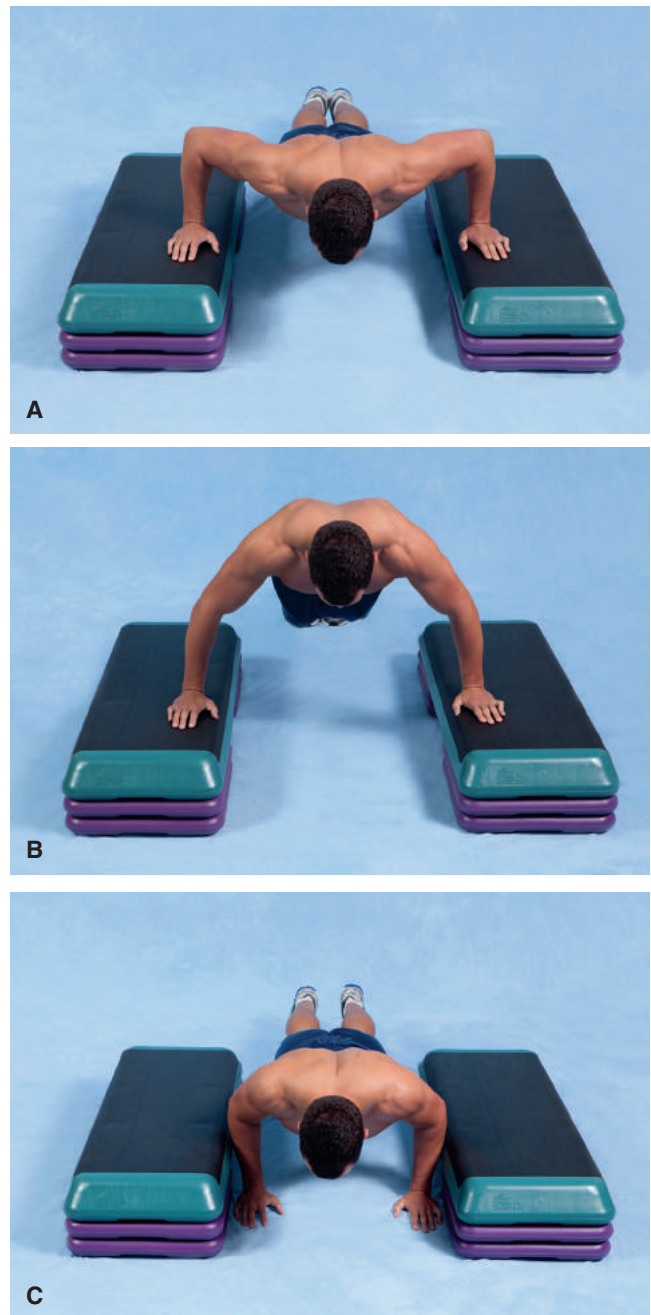

### Variations of Prone Push-Ups

#### VIDEO 23.8

- **Clap push-ups:** While on the floor, have the patient perform a forceful prone push-up from knees or feet; clap hands together; catch self with both hands, allowing elbows to flex (eccentric phase); and quickly perform another push-up (concentric phase).
- **Drop push-ups:** Have the patient perform a prone push-up from knees or feet with hands on platforms positioned shoulder width apart. Drop both hands and the chest to the floor, controlling the descent of the trunk (eccentric phase); quickly perform another push-up (concentric phase); and return both hands to the platforms (Fig. 23.56 A, B, and C).

**FIGURE 23.55** Alternating side-to-side push-offs to and from a stable, waist-high surface.

**FIGURE 23.56** Drop push-ups in the prone position: (A) Starting position; (B) prone push-up; and (C) drop hands to floor, allowing elbows to flex. Push up from the floor and quickly return hands to platforms as in (A).

### Plyometric Exercises: Lower Extremities

Most plyometric exercises for the lower extremities are performed while standing and require eccentric and concentric control of the hip and knee extensors and ankle plantarflexors against body weight.<sup>6</sup> These exercises require postural stability and balance because of the quick changes of direction involved. Plyometric activities can be progressed by adding an external load (a weighted belt, vest, or backpack) to augment body weight or by first performing the exercises

in bilateral stance (jumping) and then in unilateral stance (hopping).

The following plyometric exercises are examples of lower extremity activities that can be incorporated into the final phase of rehabilitation in preparation for functional activities ranging from community ambulation to high-intensity sports.

### CLINICAL TIP

Have the patient wear supportive footwear when performing jumping and hopping activities. When teaching these activities, reinforce proper landing techniques. Specifically, make sure the patient flexes the knee(s) for shock absorption but maintains the lower leg(s) vertically aligned in the coronal plane, thus avoiding valgus collapse at the knee(s).

### Kicking a Ball

These exercises involve rapid eccentric and concentric open-chain contractions of hip musculature. Be sure the patient is wearing shoes during kicking activities.

- *Patient position and procedure:* While standing and facing an exercise partner, have the patient swing one lower extremity backward into hip extension (eccentric phase), then quickly swing the same extremity forward into hip flexion (concentric phase) and kick a ball to the partner with the anterior aspect of the foot. This activity targets the hip flexors and knee extensors.
- *Patient position and procedure:* While standing with one shoulder positioned toward an exercise partner, have the patient stand on the leg closer to the partner, swing the opposite hip into abduction, and then quickly adduct the hip to kick the ball back to the partner using the medial aspect of the foot (as in a soccer kick). This exercise targets the hip adductors.

### Sit-to-Stand From a Ball

- *Patient position and procedure:* While sitting, have the patient bounce on a therapy ball (stabilized by the therapist), come to a partial standing position, and then sit back down on the ball and quickly come to a partial standing position again (Fig. 23.57). Progress the exercise by eventually coming to a full standing position. This activity requires contraction of the hip and knee extensors against the resistance of body weight. To be effective, rapid reversals must occur between the lowering (eccentric) and standing-up (concentric) phases.

### Bilateral Heel Raises on a Mini-Trampoline

*Patient position and procedure:* In bilateral stance, have the patient bounce on a mini-trampoline by performing repeated heel raising and lowering. This activity targets the gastrocnemius-soleus muscle groups.

FIGURE 23.57 Moving from sit-to-stand by bouncing on a ball.

### Side-to-Side Shuffle

*Patient position and procedure:* Have the patient take several quick side steps to the right and then back to the left, and repeat. This exercise requires rapid contractions of the hip abductors and adductors against body weight during each change of direction.

### Side-to-Side Movements on a Slide Board

*Patient position and procedure:* While standing on a slide board, such as a Pro-Fitter®, have the patient shift body weight side-to-side (Fig. 23.58), gradually increasing the speed of the directional changes as skill and coordination improve.

### Squat Jumps VIDEO 23.9

*Patient position and procedure:* Have the patient move quickly from a standing position into a squat position (eccentric phase) (Fig. 23.59 A), quickly transition to a vertical jump (concentric phase) (Fig. 23.59 B), return to the squat position, and then perform another vertical jump. When landing and moving into the squat position, be sure the patient keeps the lower legs aligned as close to vertical as possible to prevent valgus collapse.

### Bounding

- *Patient position and procedure:* Have the patient start with the feet positioned shoulder width apart and take multiple jumps forward in a straight line across the floor (Fig. 23.60).
- *Progressions:* Increase the speed at which the activity is performed, and then increase the distance of each jump. When able, have the patient perform single-leg forward hopping across the floor.

**Four-Quadrant Jumps or Hops** VIDEO 23.9

- *Patient position and procedure:* Using two lines on the floor intersecting at right angles as a guide, have the patient jump forward, backward, side-to-side, and diagonally from one quadrant to another, using quick directional changes (Fig. 23.61).

**FIGURE 23.58** Side-to-side movements on a Pro-Fitter®.

**FIGURE 23.59 (B)** vertical jump.

**FIGURE 23.59** Squat jumps: (A) from a squat position, perform a

**FIGURE 23.60** Bounding: a series of forward jumps across a floor.

**Tuck Jumps**

- *Patient position and procedure:* Have the patient begin in standing position, quickly lower the body into a squat position (eccentric phase), perform a tuck jump as high as possible, bringing the knees toward the chest (Fig. 23.62), and then land in proper alignment and return to the squat position to initiate the next tuck jump.
- *Progression:* Perform a series of side-to-side tuck jumps over a barrier.

**FIGURE 23.61** Four-quadrant jumping or hopping.

**FIGURE 23.62** Tuck jump.

### Lunge Jumps [VIDEO 23.9](#)

■ *Patient position and procedure:* Have the patient begin in a symmetrical standing position, jump vertically, and land in a forward lunge position (eccentric phase); then quickly jump vertically (concentric phase) and again land in a forward lunge position. Perform multiple repetitions by landing with the same foot forward each time.

- *Alternative activity—Scissor-lunge jumps:* Perform a sequence of lunge-jumps, alternately bringing the right and then left foot forward, as in a scissoring motion (Fig. 23.63 A, B, and C).
- *Progression:* Increase the challenge by performing lunge-jumps while wearing a weighted vest or holding weights in both hands.

**FIGURE 23.63** (A), (B), and (C) Lunge-jumps: alternately landing with right, then left lower extremity forward.

### Zigzag Forward Jumping or Hopping

**Patient position and procedure:** Have the patient jump or hop across the floor in a zigzag pattern marked on the floor (Fig. 23.64). Progress by increasing the speed of jumping or hopping and the distance between jumps or hops.

**FIGURE 23.64** Zigzag forward hopping.

### Hopping Over Objects VIDEO 23.9

**Patient position and procedure:** Have the patient hop over objects of various sizes placed on the floor like an obstacle course (Fig. 23.65).

**FIGURE 23.65** Lateral hopping over objects of varying sizes set up in an obstacle course on the floor.

### Single Platform Jumping or Hopping

**Patient position and procedure:** Have the patient jump and progress to hopping onto and off of a single, low platform in forward (Fig. 23.66), backward, and lateral directions, being certain to use proper landing technique. To progress, first increase the speed and repetitions of the jumping or hopping activity, then increase the height of the platform.

**FIGURE 23.66** Hopping onto and off of a single platform using proper landing technique.

### Multiple Platform Jumping or Hopping

**Patient position and procedure:** Have the patient jump (or hop) in a forward direction off of a platform to the floor and then jump forward again onto another platform (see Fig. 23.38 A, B, and C). Progress by performing the sequence more rapidly or by increasing the height of the platforms.

## Independent Learning Activities

### Critical Thinking Questions

1. Review the principles of balance training described in Chapter 8. Describe how each of the advanced balance activities presented in this chapter (Chapter 23) can be used to enhance the static, dynamic, anticipatory, or reactive aspects of balance.
2. Develop a sequence of balance activities in the standing position from least to most difficult, using progressively more challenging movements and equipment.
3. Identify the benefits, as well as the risks, of performing a program of plyometric exercises (stretch-shortening drills).
4. Analyze the plyometric training activities listed in Box 23.1, and determine in which muscle groups training-induced gains in strength and power would occur and what functional tasks each of the activities could enhance.
5. Develop a plyometric sequence for the lower extremities and trunk progressing from simple to more difficult (similar to the sequence for the upper extremities described in Box 23.3).

### Laboratory Activities

1. Practice the sequence of balance activities in the standing position that you developed to answer Critical Thinking Question #2. Take turns with a laboratory partner role-playing the therapist and the patient. If you are the therapist, use proper safety precautions, critically analyze how your patient performs each balance task, and give your patient feedback to facilitate learning correct alignment and technique.
2. Perform and analyze a variety of plyometric exercises for the upper or lower extremities, and identify which muscle groups are loaded eccentrically or concentrically during the two phases of each activity.
  - Catch and throw a weighted ball with both hands (or one hand) while in the supine, prone, and upright positions.
  - While kneeling and with hands placed on a slide board and elbows extended, move the arms forward and backward or side-to-side.
  - While standing a few feet from a wall, fall forward, catching yourself with both hands, and then push off the wall to return to a standing position.
  - In the prone position, perform bilateral drop push-ups to and from two low platforms.
  - While standing on a mini-trampoline, bounce your heels off and on the surface using only ankle motion.
  - Jump off of and back onto a low platform—forward, backward, and side-to-side.

### Case Studies

#### Case Study #1

You have been following a 21-year-old female college volleyball player who underwent an arthroscopic ACL reconstruction of the left knee 4 months ago. She now has full, pain-free range of motion of the knee and 80% to 85% strength of left knee and hip musculature compared with the sound right lower extremity. Arthrometer measurements indicate that A-P stability of the operated knee is comparable to the sound side. However, her performance on a single step-down test reveals continued evidence of abnormal alignment of the operated lower extremity (excessive hip adduction, and internal rotation, knee valgus, and foot pronation). She has been given approval by her surgeon to return to intercollegiate play by 6 months postoperatively following completion of an advanced training program individualized to her needs and goals.

- Develop an 8-week training program of advanced strengthening, balance, and plyometric drills for this patient. Identify specific exercises that would be included in each training session and how the exercises will be progressed over the 8-week period.
- In addition to exercises to enhance stability, control, and strength of the lower extremity, identify exercises that should be included to improve her upper extremity function.

#### Case Study #2

You have been working with a 35-year-old “weekend warrior” who was diagnosed with chronic tennis elbow. His symptoms are now under control, and he wants to return to competitive play at the local tennis club. Develop a training program of advanced strengthening and plyometric drills for this individual. Identify each exercise and its progression in terms of repetitions, resistance, control, and precautions. Include both upper and lower extremity drills and progressions that include total body-coordinated effort.

### Additional Case Studies

For additional study, review the following case studies from previous chapters and modify your exercise interventions to include advanced drills based on the information you studied in this chapter.

1. Case study #4 in Chapter 17
2. Case studies #2 and #3 in Chapter 20
3. Case studies #2, #3, and #4 Chapter 22

## Summary 973

## Independent Learning Activities 974

The “graying of America” and “graying of the world” are realistic descriptors of the population trend in the United States and many parts of the world. The graying of the population is a universal, developmental gift of 20th century science and technology. With the introduction of antibiotics, insulin, vaccinations, modern surgical techniques, and other medical advancements, adults are living longer.

The life expectancy in North America, most of Europe, and Australia is an average of 75 years of age.<sup>201</sup> In the US, life expectancy at birth for the total population is 78.8 years, 76.4 for men and 81.2 for women.<sup>47</sup> Thirteen percent to 14% of the 318 million citizens of the US (approximately one out of eight) are over 65 years of age.

This is in comparison to 20% of the German and Italian populations and only 3% of the population in Uganda. The age structure of the world has also changed; between 1970 and 2014, the world’s population of individuals over 65 years of age or older increased from 5% to 7%. Thus, in the profession of physical therapy, most clinicians can anticipate working with the older adult in some capacity.

“Aging leads to a decline in strength and an associated loss of independence.”<sup>65</sup> The importance of this specialty chapter is succinctly stated in the above quote! Physical therapists are

able to appropriately adapt interventions to meet the needs of the older adult and enable them to optimize their functional potential. Throughout this chapter, the value of exercise and physical activity for older adults will be addressed.

## Definitions and Descriptions Applied to Older Adults

### Definitions: Quantitative and Qualitative

Who are older adults? The answer is quite variable when considering roles that change as one ages. Historically, the standard has been 65 years of age based on Medicare eligibility. With the increase in life expectancy, coupled with a 117% increase in the percentage of adults over 65 years of age employed in the workforce,<sup>52</sup> one could question if this continues to define the “older adult.” But, 65 years of age is still being used as the “specified age” for categorizing an individual as an “older adult.”

The presentation of an older adult is quite variable.<sup>175</sup> A 75-year-old individual may be an athlete, may be working full

or part time, or may be a sedentary individual with multiple medical problems having difficulty performing basic activities of daily living (ADLs). Clinicians may document, “patient appears younger than chronological age” or “patient appears older than chronological age.” In reality, there is great variability in the older adult population which is reflected in the three case scenarios described in Box 24.1.

As illustrated in Box 24.1, the older adult population can be subdivided into young-old, mid-old, and old-old. However, these stages are overgeneralizations and may not reflect all older adults.

- The *young-old* are those 65 to 74 years of age and generally includes recently retired people who enjoy the results of their employment. The young-old may be busy caring for their parents and assisting with babysitting and transporting their grandchildren in their leisure time. Or, this individual may continue to work because of interest in their work, financial needs, social interaction, or some combination of above. Lou, in Case 1, is in the group of young-old.
- The *mid-old* are 75 to 84 years of age. Generally, the mid-old are experiencing more age-related changes and may work toward simplifying their lives; many may rest

during the day. Mary Jane, in Case 2, is an example of mid-old.

- The *old-old* are over 85 years of age and typically have significant decline in physical functioning. They may reflect on the meaning of their lives, their relationships, and contributions to society.<sup>180,243</sup> As noted in Case 3, Juan has just entered the old-old stage at age 85.

### Example of Progression of Aging

When Juan was in the young-old stage he was busy caring for his mother and mother-in-law, was actively engaged in helping to care for his grandchildren, and maintained a small business as a part-time endeavor. In the mid-old stage he began to have more complaints of hip pain due to osteoarthritis (OA). As his grandchildren aged and parents died and he no longer maintained his business, he was less engaged and subsequently, less active. During this stage he continued to do yard work and car maintenance but became very sedentary. In his current old-old stage, he is experiencing more medical problems and numerous issues related to inactivity; he spends extended periods of time isolated and reflective.

#### BOX 24.1 Three Case Scenarios of Older Adults

##### Case 1: YOUNG-OLD:

Lou is a 72-year-old male who works out regularly at the local YMCA. He is also a part-time employee in the fitness center at the same facility. His past medical history is unremarkable, and he describes himself as a long time exercise advocate. He has run two to four marathons a year for more than 10 years and also participates in sprint triathlons. Lou recently ran a marathon and reports that this marathon seemed much longer than 26 miles and that it was his worst time ever. He complains of left knee pain. On inspection, Lou is healthy appearing and looks much younger than his chronological age; he has tortuous veins in both legs below the knees.

##### Case 2: MID-OLD:

Mary Jane is an 82-year-old female who has a long-standing history of cardiac disease, multiple myocardial infarctions, coronary artery bypass grafting (20 and 35 years ago), hypertension, Raynaud’s phenomenon, and arterial insufficiency, as well as a history of uterine cancer and a radical hysterectomy 40 years ago. She has long-standing low back, cervical, hip, and shoulder pain attributed to osteoarthritis. Mary Jane reports she takes 13 medications each day. She demonstrates a pronounced kyphosis and forward head posture. She reports she is 5’2” and weighs 89 pounds, but appears to be approximately 4’9” in height. Mary Jane reports that the doctor did not say she has osteoporosis. The therapist believes it is likely due to Mary Jane’s vertical height loss of 5”. She admits to having occasional falls but no real injuries. She describes days of dizziness where she has difficulty getting out of bed. Her children report an increase in

confusion, but that it appears to be episodic. They believe their mother is having mini-strokes. The strokes have not been diagnosed. Mary Jane is independent in IADLs and manages the finances for rental properties. She enjoys cooking, working in her yard, spending time with family, and participating in church events. She denies participating in regular exercise but reports she is able to walk three to four blocks, go up and down flights of steps several times/day, and perform arm exercises with the elastic band she was given when she attended outpatient physical therapy 4 months ago.

##### Case 3: OLD-OLD:

Juan is an 86-year-old male who is a retired steel mill worker and who resides with his wife. He is being seen by a home health physical therapist following an episode of internal bleeding, a 3-day acute hospitalization, and two blood transfusions. Currently his primary complaint is shortness of breath. Prior to this illness, he was independent in ADLs, including yard work and car maintenance, driving, visiting a fraternal organization, and attending his grandchildren’s activities. His past medical history includes osteoarthritis bilaterally in hips, hands, and knees (including left total hip arthroplasty 10 years ago), as well as T2DM, asbestosis, obesity, obstructive sleep apnea (he does not use a continuous positive airway pressure [CPAP] machine), and diminished hearing. He gets up at approximately 11:00 a.m. each day and takes a nap at 2:00 p.m. Although not diagnosed, he has characteristics of sarcopenic obesity. At his peak, Juan was 5’8” and 225 pounds. His hospital record reveals he is 198 pounds, and he appears to be 5’5” in height.

## Healthy People 2020

The *Healthy People 2020* vision for an older adult is to “increase the proportion of older adults with reduced physical or cognitive function who engage in light, moderate, or vigorous leisure-time physical activities.”<sup>111</sup> It is reported that 29.3% of the older adult population experience moderate to severe functional limitations. In addition, approximately one in three “older adults with reduced physical or cognitive function engaged in light, moderate, or vigorous leisure-time physical activities in 2008.”<sup>111</sup> Males are more engaged in physical activities than females, and Caucasians are 10% more involved in physical activities than other racial groups.

## Complexity of Diagnoses in the Older Population

The medical model of a one-to-one ratio of symptoms to diagnosis is atypical in the older adult population seeking medical care or physical therapy services. More characteristic of older adults is the presence of multiple medical problems or a chronic disease, which may cause a myriad of problems. In the prior paragraph, the incidence of functional limitations was described. Those functional limitations may be due to various factors and may reflect the presence of multiple medical problems. Approximately 92% of older adults are reported to have at least one chronic condition, while 77% of older adults have a minimum of two chronic conditions.<sup>170</sup>

The case of Mary Jane (see Case 2 in Box 24.1) exemplifies this concept of multiple medical problems. Mary Jane had a radical hysterectomy at age 37 secondary to cancer and subsequently experienced early menopause. Severe coronary artery disease, myocardial infarction, and coronary artery bypass grafting were other medical problems she experienced. In the absence of hormone replacement or other preventative intervention, Mary Jane appears to have osteoporosis based on her height loss and flexed posture, although she has not had clinical testing to confirm the diagnosis. Mary Jane takes 13 medications each day. Adverse drug reactions from her cardiac medications and polypharmacy may result in orthostatic hypotension and her complaints of dizziness. The polypharmacy and cardiac medications are a risk factor for falls.

Chronic conditions, injuries, and new medical problems may each impact the quality of life in older adults. Type II diabetes mellitus (T2DM), OA, congestive heart failure, and dementia are chronic conditions that many older adults experience.<sup>170</sup> For example, Juan (see Case 3 in Box 24.1) had end-stage OA of the hip during the stage of young-old. Consequently, he restricted his walking due to pain. This restricted mobility impacted strength, functional mobility, and balance. Now his sedentary behavior further impacts his quality of life including the development of T2DM. This cascading effect is cyclical resulting in even greater problems.<sup>87,128</sup>

## Health Trends in the Aging Population

Fair or poor health is the descriptor that almost 25% (23.1%) of the older adult population in the US use to describe their health.<sup>169</sup> A snapshot view of the “older person’s health” and incidence of diagnoses can be found in ONLINE Table 24.1 available on the FA Davis web site.

The incidence of diseases varies slightly from the mortality incidence. For example, heart disease and cancer account for approximately half of all deaths in the US, while arthritis is the most common disability.<sup>44,47,115,169,186</sup> The 15 leading causes of death among individuals 65 years of age and older in the US in 2013 were heart disease, cancer, stroke, chronic lower respiratory disease (such as emphysema), accidents (such as falls), cerebrovascular accident, Alzheimer’s disease, diabetes, influenza and pneumonia, kidney disease, suicide, septicemia, chronic liver disease, hypertension, Parkinson’s disease, and pneumonitis.<sup>245</sup>

## Wellness Aging Model Related to Illness, Injury, and Immobility

As people age, loss of strength, loss of muscle mass, and senescence occur. This results in impaired function and greater dependence in the performance of functional activities.<sup>27,36,54,70,92,128,206,208,213,216</sup> These functional impairments can be quantified, with 14% of older adults requiring assistance with ADLs and 35% having difficulty with functional activities necessary for independence.<sup>65</sup> Sehl and Yates<sup>216</sup> extrapolated information from 54,274 subjects into a linear model on various systems of the body and described a loss rate of every system of the body. This loss rate is up to 3% per year beginning at age 30 and continuing up to the age of 70. When individuals are physically active, they typically function more independently than people who have disease or pathology. Illness, chronic disease, injury, and immobility each impact age-related changes. Kauffman<sup>128</sup> refers to the concept of age-related declines in function as “linear senescence,” while Brown<sup>36</sup> refers to this concept as the “compression of infirmity.” These concepts are collectively depicted in the Wellness Aging Model Related to Illness, Injury, and Immobility (WAMI-3) illustrated in Figure 24.1.

In this model, age is depicted on the X-axis while impairments of structure and function, such as muscular and bone strength, longevity, mental well-being, fall risk, and functional mobility, are depicted on the Y-axis. This right skewed curvilinear shape demonstrates the need for physical activity and exercise as one ages. Individuals who are physically active may have a rightward shift in function while disease, injury, and inactivity result in a leftward shift in function. Billek-Sawhney and Wells<sup>22</sup> applied this relationship to individuals undergoing cancer treatment. Disease specific factors such as cancer related fatigue and nausea were plotted on the Y-axis and the effect of cancer treatments over time on the X-axis. With physical activity and exercise improvement was seen in strength, energy

**FIGURE 24.1** Wellness Aging Model related to Illness, Injury, and Immobility (WAMI-3) demonstrating the effects of immobility, illness, and/or injury on wellness and aging. Age is depicted on the x-axis; impairments of structure and function, including but not limited to strength, power, bone density, fall risk, and functional mobility, are depicted on the y-axis. Wellness, physical activity, and exercise will result in a rightward shift to decrease the slope of the curve.

level, mental well-being and functional status. This model can be applied to a multitude of medical diagnoses, immobility, and physical inactivity and serves as the basis for the importance of remaining active as one ages. The WAMI-3 is a modification and compilation from numerous diagrams and exemplifies the concept that physical activity and exercise add life to years.<sup>22,36,67,128,168</sup> Wellness, physical activity, and exercise will result in a rightward shift to decrease the slope of decline.

### FOCUS ON EVIDENCE

In a study of almost 900 older adults, a slower rate of decline in mobility was reported to be associated with a greater rate of physical activity.<sup>38</sup> Each additional hour of physical activity was associated with about a 3% decrease in the rate of mobility decline when measured on an 8-foot walk and 360° turn. It was concluded that both physical activity and leg strength predict decline in mobility in older adults.

## Aging: Primary and Secondary

Primary aging is a universal, developmental process from the passage of time. This differs from secondary aging in the older adult resulting from disease, disuse, the environment, and other factors.<sup>180,233</sup> An example of secondary aging is an older adult with T2DM who develops cardiac disease and peripheral neuropathies.

## Effects of Aging or Senescence on the Body Systems

*Senescence* (*senescere* in Latin, meaning “to grow old”) occurs with a decrease in physiological effectiveness of the various systems at an average of 2% per year starting at 30 years of age.<sup>155,216</sup> Through the aging processes, there is a degradation of function of the vital organs. As we age, every cell, tissue, organ, and system of the body changes. Most visible is the graying of the hair, the flexed posture, muscle mass loss, and the wrinkles on the face. Similar aging processes are masked but still occurring beneath the skin.

Immune dysregulation, described as *immunosenescence*, is the age related deterioration of the immune system causing cancer, infection, and autoimmune disease. The changes in the immune system are evident with the increased prevalence of cancer in the older adult. The decreased effectiveness at the cellular and tissue level results in increased susceptibility to infection and impaired surveillance or monitoring of one’s condition for the presentation of an illness.<sup>101</sup> In addition, the initial presentation of illness may differ. For example, the presentation of a urinary tract infection in an older adult may be an altered mental status rather than the usual signs of fever or infection.

The impact of exercise and physical activity on aging can be illustrated by looking at results of stress testing. The maximum oxygen consumption, better known as  $VO_{2MAX}$ , is described in Chapter 7. The calculation of  $VO_{2max}$  is typically done with stress testing. Viewing the formula and seeing the components of the formula change in response to aging, immobility, and exercise/physical activity, as summarized in Table 24.1, enhances the reader’s understanding of the importance of the WAMI-3. The reader is referred to several sources for detailed information on stress testing and calculating  $VO_{2max}$  using the Fick Equation.<sup>18,161,164,249</sup>

### Cellular and Organ Changes

Cellular changes occur with aging and may include atrophy, hypertrophy, hyperplasia, dysplasia, and neoplasia. In older adults, atrophy of muscles and the brain may occur, hypertrophy can occur at the heart and kidneys, hyperplasia may occur of the prostate, dysplasia in the cervix, and neoplasia in squamous cell carcinomas. These changes are also reflected in the maximal oxygen consumption at the heart, vascular system, and muscular level.

Senescence at the cellular level results in lipofuscin, a fatty brown pigment and other fatty substances, which build up in tissue. The accumulation of lipofuscin is a hallmark of aging and is not degradable.<sup>235</sup> Connective tissue becomes stiffer. Therapists recognize these changes in the musculoskeletal system, but it also occurs in organs, blood vessels, and airways, making them more rigid. The changes occurring in the membranes of tissues in the lungs impact the transport of oxygen and nutrients to tissues and negatively affect the removal of carbon dioxide and other wastes. These changes or losses occur gradually and are not noticeable unless coupled with

**TABLE 24.1** Maximal Oxygen Consumption and the Impact of Aging, Illness, Injury, Immobility, and Exercise on Physical Activity

	Maximal Oxygen Consumption (VO <sub>2</sub> max)	=	Cardiac Output (CO or Q)	x	SV	x	Arteriovenous Oxygen Difference (a-vO <sub>2</sub> )	Comments
	VO <sub>2</sub> max		HR				(a-vO <sub>2</sub> )	CO = HR x SV
Aging	↓		RHR- no change MHR- ↓		↓		↓	With aging declines are seen in the effectiveness of each component.
Illness	↓		RHR- ↑or↓ MHR- ↓		↓		↓	With illness various factors can be impacted; for example, heart muscle weakness from a myocardial infarction decreases SV.
Immobility	↓		RHR- ↑ MHR- ↓		↓		↓	Similar to aging, immobility impacts each component negatively.
With exercise/ physical training	↑		RHR- ↓ MHR- ↑		↑		↑	Greater capillary density. Enhanced ability to extract oxygen. Increase in number and size of mitochondria.

disease, at which time a causal chain type of effect may occur leading to a cascade of medical issues.

**Organ Reserve Changes**

Generally, there is a reserve associated with the function of organs. Cardiac reserve exemplifies this concept. At age 20, the heart “is capable of pumping about 10 times the amount of blood that is actually needed to keep the body alive. After age 30, an average of 1% of this reserve is lost each year.”<sup>156</sup> Organ reserve losses have the greatest impact on the heart, lungs, and kidneys.<sup>75</sup> The amount of loss varies among organs in the same individual and between individuals. This concept can be applied to the case of Mary Jane described in Box 24.1; Mary Jane has severe cardiac disease but does not appear to have age-related losses in her respiratory system.

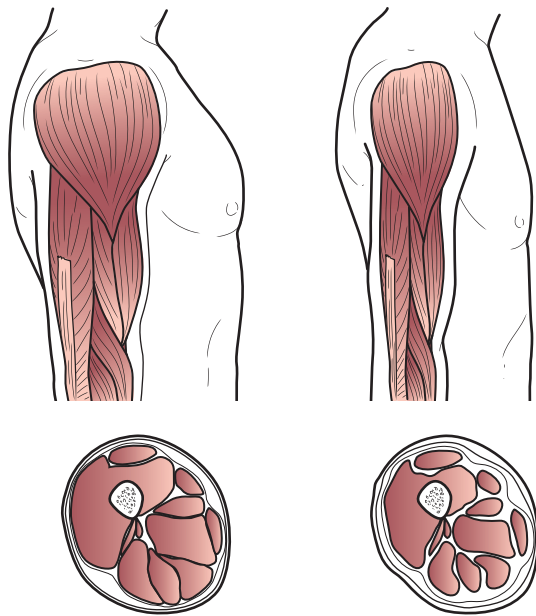

**System Changes**

The endocrine (hormone production), immune, integumentary, musculoskeletal, reproductive, urinary, cardiopulmonary, vascular, sensory, and central nervous systems are each impacted by the aging process, and their function can be viewed as the solid line in the WAMI-3 (see Fig. 24.1). Many, although not all, systems of the body demonstrate a rightward shift from exercise. For example, the musculoskeletal system demonstrates a rightward shift with exercise, but conversely, the integumentary system with the thinning, graying, and loss of hair does not appear to respond to exercise and activity.<sup>86</sup> In response to aging, changes

in the systems of the body not only impact the function of the organs, but can also impact the body’s ability to function. Age-related changes in the musculoskeletal system impact strength; posture; gait; coordination; speed of movement; and, consequentially, an individual’s ability to function. The age-related changes to the musculoskeletal system are highlighted in ONLINE Table 24.2.

**Neuromuscular and Musculoskeletal System Changes**

Normal aging results in muscle mass loss beginning in the fourth decade of life but escalates with advancing age. Over the age of 40 muscle mass loss/year is 0.5%, over the age of 50 it increases to 1% to 2%, and over the age of 60 loss/year is 3%.<sup>131,210,258,274</sup> In older adults who are sedentary, this rate of decline is increased. This is coupled by changes in the quality of the muscle tissue. The rate of decrease in strength and power are greater in sedentary individuals as compared to those who are physically active, resulting in a leftward shift in senescence (see Fig. 24.1).<sup>210</sup> Older adults 70 years of age and older, when compared to younger adults, demonstrate a 50% decrease in strength and a 75% decrease in power.<sup>31,112</sup> The loss of muscle mass and strength occurs as a result of many factors, including a reduction in both size and number of muscle fibers, a selective reduction in Type II fibers, a decrease in neural activation, and an increase in antagonistic co-activation (Fig. 24.2).<sup>110,213,229</sup> When a muscle fiber loses its innervation, motor units will

**FIGURE 24.2** Age-related changes in muscle mass in the arm showing a lateral view and the related cross-sectional area.

die and compound the loss of muscle fibers. By 60 years of age, there is approximately a 50% loss of the motor units innervating individual muscle fibers because of the death of the alpha-motorneurons at the spinal cord.<sup>213</sup> The disease of sarcopenia, which is associated with aging and the loss of muscle mass, will be discussed in the section on sarcopenia later in this chapter.

Muscle weakness affects gait and activities such as ascending and descending stairs. Gait disorders are commonly associated with aging; 35% of adults over 70 years of age have an abnormal gait. Decreases in gait speed and stride length commonly occur.<sup>39,152</sup> Walking, the most prevalent physical activity, has a greater energy cost in older adults than younger adults. Wert and colleagues<sup>261</sup> stress the need for the physical therapist to assess gait and to specifically evaluate older adult patients for the absence of hip extension, for wider step width, and for slower gait speed. These gait deviations result in a loss of efficiency. Similar losses in efficiency with greater effort required also occur with ADLs in older adults.<sup>125</sup> Thus, older adults are less energy efficient and expend more energy when walking and performing ADLs than younger individuals.

Changes in the musculoskeletal system, such as osteoporosis, osteopenia, and OA, with accompanying pain, stiffness, and deformity, affect balance and the number of falls experienced by older adults.<sup>119</sup> Neuromuscular changes result in mobility loss and impaired function. Coupled together, these changes affect the independence and quality of the older adult's life.<sup>229</sup>

### Sensory Changes

Sensory changes associated with aging profoundly impact older adult patients at a functional level resulting in quality

of life issues. For example, when considering loss of vision, the older adult may have difficulty reading his or her prescribed home exercise program or completing the necessary patient registration and/or outcomes questionnaires. With aging, the amount of peripheral vision (known as peripheral visual field) has decreased. This, combined with loss of rotation in the cervical spine, may affect driving safety. Wearing bifocals to address the presbyopia affects walking and use of stairs and curbs, thus putting the older adult at risk for falls.<sup>51</sup> In addition, use of bifocals, coupled with changes in position sense and muscular weakness, affects balance and risk of falls. (See Chapter 8 for a discussion on balance exercise programs to address fall risk in the elderly.)

## Effects of Decreased Activity

### Immobility

Historically, bed rest was prescribed for a multitude of medical problems from back pain to myocardial infarction. Immobility negatively impacts every system of the body and results in a leftward shift on the WAMI-3 (see Fig. 24.1). There are various medical complications associated with prolonged immobility, including orthostatic hypotension, increased heart rate, decreased cardiac reserve, atelectasis, pneumonia, deep venous thrombosis, pulmonary emboli, urinary retention, constipation, muscle atrophy (leading to generalized weakness), contractures, soft tissue changes, metabolic inflexibility (including insulin resistance), osteoporosis, impaired sensory perception, skin breakdown, and psychological manifestations such as depression.<sup>62,71,103,223</sup> The need for early mobilization of patients is now commonly practiced; where it is not, it should become a standard of practice.

Similar to the effects of aging, each organ system is impacted negatively by immobilization. For example, when considering cardiac function, the stroke volume decreases approximately 12% following the first 30 days of inactivity, and the maximal heart rate is also decreased. Subsequently, maximal oxygen uptake is decreased, and total blood volume and hemoglobin concentration are also decreased, making a less efficient cardiovascular (CV) system and less reserve.<sup>14,103,128,231,264</sup> These concepts are highlighted in the impact on maximal oxygen consumption in Table 24.1.

Muscle disuse results in atrophy and loss of muscle strength at the rate of approximately 12% a week or 1% to 1.5% per day from bed rest.<sup>124</sup> Loss of strength in the legs occurs twice as fast as in the arms, with the quadriceps and back extensors showing the greatest loss. As much as 50% strength loss can occur with 3 weeks of bed rest, while the recovery of strength is only 10% per week.<sup>23,56,138,182</sup> In muscles that are larger and better trained, there is quicker recovery of strength.<sup>124</sup> The loss of strength and muscle atrophy impacts much more than just strength and power; muscle fatigue due to reduced oxidative capacity in extracting oxygen, metabolic activity, protein breakdown and loss, increased concentrations of cortisol, and glucose metabolism and function are also affected.<sup>23,124</sup>

## Hypokinesia

Hypokinesia is defined as an “abnormally diminished muscular function or mobility.”<sup>166</sup> This sedentary behavior in older adults is manifested in minimal energy expenditure and inactivity. Juan in Case 3 (see Box 24.1) illustrates the concept of hypokinesia. Juan is recumbent or sits for extended periods of time and is inactive. At the age of 85, he sleeps in a recliner or in his bed until 11:00 a.m. each morning, and then after eating breakfast, he goes back to bed for a nap. He is upright and watching television until dinner at 5:00 p.m. The only time Juan leaves home is for medical appointments and occasionally to go to a fraternal organization. Generally, he is back to sleep before 10:00 p.m.

### FOCUS ON EVIDENCE

A systematic review by Harvey and colleagues<sup>107</sup> on the prevalence of sedentary behaviors in older adults reports that the majority of older adults are sedentary, that approximately 60% of older adults report sitting >4 hours/day, and one study described 67% of the older population as sedentary >8.5 hours/day.

### Sedentary Behavior

The lack of physical activity, or sedentary behavior, is now recognized as a modifiable risk factor for a multitude of illnesses. Sedentary behavior is described as spending a great deal of time in a recumbent or sitting position and low energy expenditure behavior (<1.5 METS during waking hours). As a reference, the performance of basic ADLs, such as grooming, eating, toileting, bathing, and dressing, has a metabolic equivalent level of 1.0 to 2.5 METS. Instrumental ADLs, including light housekeeping, doing laundry, washing dishes, setting the table, or making a bed, increase the energy required to 1.5 to 4.0 METS. The American Heart Association reports the risk of CV disease is directly related to sedentary behavior. Adults who watch >4 hours of television/day have a 46% increased risk of death from any cause and 80% increased risk of death from CV disease. In addition, those who are physically active and maintain a healthy weight live approximately 7 years longer than inactive adults who are obese.<sup>10</sup> (See Chapter 7 for additional information on energy expenditure and training for patients with chronic illness.)

### Loss Of Functional Mobility

The WAMI-3 (see Fig. 24.1) visually depicts the decreases in functional mobility, musculoskeletal strength and power, bone strength, CV and pulmonary function, but it fails to describe how these changes impact an individual’s ability to participate in daily activities in the home and community. The association between the recommended strength training guidelines of twice a week and functional limitations has been described by the National Health Interview Survey of 6,763 older adults.<sup>48</sup> Almost 51% of the older adult population reported functional limitations with stooping, bending,

or kneeling. The older adults who performed strength training twice a week reported having less difficulty with the nine functional activities investigated. The nine activities included:

1. Walking 0.25 miles, approximately 3 city blocks
2. Ascending 10 steps without resting
3. Standing for approximately 2 hours
4. Sitting for 2 hours
5. Stooping, bending, or kneeling
6. Reaching overhead
7. Grasping or handling small objects with fingers
8. Lifting and carrying 10 pounds (“like a full grocery bag”)
9. Pushing or pulling large objects (“like a living room chair”)

The report found that older adults with functional limitations were the least likely to perform strength training. Kraschnewski and colleagues<sup>135</sup> report that older adults with functional impairments believe they are too weak to perform strengthening activities. This belief impacts self-efficacy and requires a paradigm shift. As physical therapists, we can be instrumental in making this shift through education, mentoring, and guiding the older adult in strengthening interventions.

The WAMI-3 can also apply to the loss of functional activities such as ambulation. The walking ability of older adults changes with the aging process. This is exemplified in the US, where 17.3% of adults aged 55 to 64 years and 56.1% of individuals over age 85 report difficulty walking 0.25 miles (402 m).<sup>214</sup> Ambulation is directly impacted as one ages but may be improved through strength training.<sup>81,93,135,164,178,233</sup> Sayers<sup>213</sup> describes a curvilinear relationship between the strength of muscle and the ability to perform functional activities.

When individuals gain strength, there is an improvement in the performance of function to a specific point at which further strength improvements result only in minimal changes of function. When applying this concept to Cases 1 and 3 in Box 24.1, if the ages of both Lou and Juan are hypothetically reset at age 75, Lou will be stronger than Juan at baseline. Then, even if they have the same strength gains, Lou’s functional improvements will be less than Juan’s due to a higher baseline level.

## Benefits of Physical Activity and Exercise

There are a multitude of benefits to being physically active, especially in older adults. The primary benefits include (1) slowing physiological changes of aging; (2) optimizing body composition; (3) supporting psychological and cognitive health; (4) managing chronic disease; (5) decreasing the risk of developing chronic diseases; (6) minimizing risk of physical disability; and (7) increasing lifespan.<sup>195</sup> The phrase “adding life to years” is used by multiple sources<sup>272</sup> to address the need for healthy aging and is also a benefit of physical therapy

rehabilitation. This concept can be further stated that “adding life to years” requires physical activity and resistance training.

## The Choosing Wisely Initiative

It is not unusual to observe older patients performing exercise programs that do not provide enough resistance to develop strength to improve function. To merely sit and perform leg kicks or marches with a 1- or 2-lb weight for 3 sets of 10 repetitions may be underdosed and nonspecific and should lead the therapist to question the purpose of the exercises.

In 2014, the “Choosing Wisely” initiative between the American Physical Therapy Association (APTA) and the American Board of Internal Medicine Foundation addressed underdosed strength training programs in older adults. In one of its five recommendations, the APTA stresses the importance of developing an exercise program that matches frequency, intensity, and duration of exercise to the older adult’s abilities and goals. Box 24.2 cites the statement and provides an explanation. It is critical when developing a strengthening program that the patient’s needs are fully assessed and appropriate interventions are prescribed that improve function.

## Justification for Exercise and Physical Activity

With resistance training, muscular strength, power, and endurance can improve in the older adult and deter the effects of aging and improve mobility. Improving strength and mobility has been shown to improve balance and reduce the incidence of falls and resulting fractures.<sup>117,120,137,145,220,221,238</sup> Activities of daily living can be performed with less effort, and thus functional independence can be maintained for a longer period of time.<sup>195</sup> Despite this, only about 21% of all older adults and less than 10% of older adults greater than 85 years of age regularly perform physical activities.<sup>195</sup> The importance of power

is well documented as being more strongly related to performance of ADLs than strength alone.

Interestingly, there is strong evidence that physical activity reduces the risk of premature death. There is a dose response associated with this concept. Therefore, the risk of premature death declines with greater time and frequency (minutes/week) of physical activity. These benefits are described in Box 24.3.

Progressive resistance strength training can increase muscle mass, strength, power, functional mobility, and the performance of ADLs.<sup>117, 206</sup> High intensity or power training results in even greater strength adaptations compared to low and moderate intensity training. Power training enhances functional tasks like sit to stand and climbing stairs<sup>229</sup> and minimizes functional limitations and disabilities.<sup>203</sup> Functionally, the ability to perform sit-to-stand, ambulate without an assistive device, and alter the ability for an older adult to increase their self-selected gait speed have been shown to improve with high intensity progressive resistance training.<sup>206</sup> The benefits of physical activity increase as the intensity, frequency, and duration of exercising increases.<sup>21</sup>

It should be noted that skeletal muscles have secondary roles that include metabolism, glycogen storage, body temperature regulation, joint stabilization, and endocrine function. Thus, the importance of increasing muscle mass or minimizing its loss with aging must be considered as a secondary benefit to resistance training.<sup>238</sup> This is critical when considering pharmacokinetics and aging. Most simplistically, pharmacokinetics is drug absorption, distribution, metabolism, and secretion.<sup>204</sup> With aging, the sensitivity to drugs may be impacted.<sup>154</sup>

The decline in bone density that generally occurs with increased age can be lessened with exercise. There is a lower risk of hip fracture in physically active older adults, especially women. Individuals who perform 120 to 300 minutes of moderate intensity physical activity each week have a reduced risk of hip fracture. Both physical activity and exercise are beneficial and require voluntary movements resulting in calorie expenditure. Physical activities incorporate any movements like household cleaning, stair climbing, gardening, and shopping at stores. Exercise, a form of physical activity, is planned, structured, and repetitive in nature; it includes weight training, exercise classes, and aerobics.<sup>171</sup>

### BOX 24.2 APTA Choosing Wisely Statement on Strength Training Programs in Older Adults

“Don’t prescribe under-dosed strength training programs for older adults. Instead, match the frequency, intensity and duration of exercise to the individual’s abilities and goals.”<sup>8,11</sup>

“Improved strength in older adults is associated with improved health, quality of life and functional capacity, and with a reduced risk of falls. Older adults are often prescribed low dose exercise and physical activity that are physiologically inadequate to increase gains in muscle strength. Failure to establish accurate baseline levels of strength limits the adequacy of the strength training dosage and progression, and thus limits the benefits of the training. A carefully developed and individualized strength training program may have significant health benefits for older adults.”<sup>8,11</sup>

### FOCUS ON EVIDENCE

A meta-study looking at 160 trials on the benefits of exercise on the CV system found that not all people experience the same benefits from exercise. They reported that exercise has multiple beneficial effects and significantly improves CV fitness and biomarkers, such as lipid profiles, and also that in individuals less than 50 years of age; men; and individuals with T2DM, hypertension, dyslipidemia, or metabolic syndrome the benefits to exercise are greater.<sup>144</sup>

The long-term impact of a 1-year strength-training program in older adults was studied by Kennis and colleagues.<sup>131</sup> After 1-year of training, muscular performance improved for those in the exercise group. Seven years after cessation of the

### BOX 24.3 Benefits of Physical Activity and Exercise in the Older Adult (Reprinted with permission from the Office of Disease Prevention and Health Promotion<sup>185</sup>)

#### Strong Evidence

- Lower risk of early death
- Lower risk of coronary heart disease
- Lower risk of stroke
- Lower risk of high blood pressure
- Lower risk of adverse blood lipid profile
- Lower risk of type II diabetes mellitus
- Lower risk of metabolic syndrome
- Lower risk of colon cancer
- Lower risk of breast cancer
- Prevention of weight gain
- Weight loss, particularly when combined with reduced calorie intake
- Improved cardiorespiratory and muscular fitness
- Prevention of falls
- Reduced depression
- Better cognitive function (for older adults)

#### Moderate to Strong Evidence

- Better functional health (for older adults)
- Reduced abdominal obesity

#### Moderate Evidence

- Lower risk of hip fracture
- Lower risk of lung cancer

- Lower risk of endometrial cancer
- Weight maintenance after weight loss
- Increased bone density
- Improved sleep quality

#### Other Benefits

- Enhanced immune function through aerobic training. Aerobic, not resistance, training has been shown to impact chronic inflammation and thereby impact the immune system.<sup>101</sup> This strengthens the argument to employ a multidimensional program in conjunction with a resistance training program.
- Improved spatial awareness, visual, and physical reactions. Fregala et al<sup>86</sup> found that spatial awareness and visual and physical reactions are each improved with resistance training. This benefit may be related to the decreased risk of falls, accident avoidance, and improved cognitive function. The potential cognitive benefits of resistance exercise may enhance the quality of life in older adults.
- Increased joint ROM. This is believed to be due to the actual performance of movement rather than the strengthening exercises.<sup>206</sup>
- Less symptomatic intermittent claudication.<sup>190</sup>
- Decreased fall risk.<sup>17,68,137,145,187,206,226</sup>

exercise intervention, age-related declines were less for the exercise participants than for nonparticipants.

Detraining was studied by Harris et al.<sup>106</sup> Following cessation of a training program, there were significant decreases in strength at weeks 6 and 20 postexercise, but strength was significantly greater than prior to the start of the training program.

Physical therapists play a unique role in enhancing the quality of life of older adults by addressing impairments through exercise, health promotion, and disease prevention. There is a plethora of evidence supporting the positive benefits of exercise and activity in aging adults.<sup>86,91,101,104,131,149,153,190,196,197,206,226,233,238,257,259</sup> The rightward shift in Figure 24.1 provides a visible display of the benefits of exercise.

## Considerations Prior to Implementation of Exercise

Examination and evaluation of the older adult are critical prior to establishing exercise interventions and must take into consideration the normal aging of the body systems as well as the complexity of diagnoses as described in the previous section of this chapter. The reader is referred to several physical therapy texts cited in the reference list that describe examination procedures.<sup>151,60,100,209</sup> ONLINE Table 24.3 available on the

FA Davis web site summarizes inspection, interview, tests and measures, and patient management considerations for the older adult. Key items to emphasize when examining the older adult are described in this section.

## Examination of the Aging Adult: Highlights

### Medications

During the interview it is critical to not only review the medications, but also to count the number of medications that a patient is taking. Polypharmacy is defined as the use of  $\geq$  three or four medications and is a fall risk factor in older adults. In addition, when the medications include diuretics, antiarrhythmics, and psychotropics, the risk of falls is increased.<sup>105,139,140,242,276</sup> The pharmacokinetics of drugs and how the drugs are removed from the body occur at a slower rate in older adults, and lower doses may be necessary. Unfortunately, the side effects of medications may result in a multitude of secondary symptoms. The role of the physical therapist and pharmacotherapy is variable by practice setting and beyond the scope of this chapter. The patient's ability to take their medications as prescribed, follow the prescribed regimen, and continue blood testing when taking medications are each critical issues for the older adult. For example, Mary Jane (see Box 24.1) defers taking her diuretics when leaving her house to minimize her frequency of urination.

This may result in greater fatigue and uncompensated heart failure.

### The 2016 PAR-Q+

The Physical Activity Readiness Questionnaire (PAR-Q) was developed in 1978 and revised in 2002. The PAR-Q has been used worldwide as a preparticipation health screening tool to determine if an individual is healthy enough to participate in exercise and physical activity. Unfortunately, both of these self-report forms are outdated and were designed for individuals aged 15 to 69.<sup>35,195,239</sup> When used on older adults, there are numerous false-positive responses, leading to a large portion of older adults being required to have medical clearance prior to engaging in physical activity and exercise.<sup>41,42,122,212,237,254,255,256</sup> The PAR-Q+ was introduced in 2011 and is frequently revised. The 4-page 2016 PAR-Q+ is available online on the FA Davis web site and is also available at [http://eparmedx.com/?page\\_id=79](http://eparmedx.com/?page_id=79). The 2016 PAR-Q+ begins with seven screening questions. If the questions are answered negatively, the patient is cleared to participate in exercise. If any of the items are positive, there are follow-up questions. The 2016 PAR-Q+ differs from prior forms by reducing the barrier of seeing a physician for medical clearance before participating in physical activity. “The risks of being physically inactive far outweigh the small, transient risks seen after acute exercise in both asymptomatic and symptomatic populations across the lifespan.”<sup>35</sup> The 2016 PAR-Q+ is recommended for preparticipation screening for outpatient physical therapy as a component of the physical therapy examination process.

As physical therapists, use of the 2016 PAR-Q+ does not eliminate applying clinical expertise employed as exercise professionals but builds upon basic examination skills. Ongoing monitoring is a critical component of physical therapy. Obtaining vital signs at resting, immediate post activity, and recovery, plus perceived exertion (see page 968 on the Borg scale) help determine if interventions are at the appropriate level or if they need to be adjusted in intensity.

### Global Health Initiative and the Physical Activity Vital Signs

The concept of “Exercise is Medicine”<sup>67</sup> is a global health initiative developed in 2007 by the American College of Sports Medicine (ACSM) to elevate physical activity.<sup>7,108,135,146</sup> The focus of EIM is based on the premise that physical activity is integral for the prevention and treatment of disease.<sup>7</sup> This initiative is also important for older adults.

To assess the level of physical activity, the ACSM advocates employing the Physical Activity Vital Signs (PAVS). The PAVS was first introduced in 2010, demonstrated validity,<sup>58</sup> and can be quickly performed in less than a minute.<sup>7</sup> Two questions comprise the PAVS, which query the average number of days and minutes an individual performs physical activity. The questions are:

1. “How many days a week do you engage in moderate to strenuous exercise (like a brisk walk)?”
2. “On average, how many minutes per day do you exercise at this level?”

The PAVS has been found to have a positive impact on metabolic outcomes.<sup>97</sup> In addition, body mass index and obesity are related to the PAVS; the higher the activity level the lower the body mass index and obesity.<sup>98</sup>

### Fracture Risk Assessment Index and Balance

Perry and Downey<sup>193</sup> stress the need for physical therapists to incorporate routine screening of older adults using the World Health Organizations Fracture Risk Assessment Tool<sup>269</sup> (FRAX<sup>®</sup>) and screening for fall risk. The FRAX<sup>®</sup> tool is available online and is available in multiple languages. This tool looks at country, bone mineral density, age, gender, and clinical risk factors to calculate the 10-year probability of a fracture. The clinical risk factors include low body mass index, prior fragility fracture, parental history of a hip fracture, use of glucocorticoids, current smoking, alcohol intake of  $\geq$  three units/day, rheumatoid arthritis, or other secondary causes of osteoporosis.<sup>163,269</sup> Falls are the causal factor for approximately 90% of all appendicular fractures. Thus, it is critical to assess fall risk and perform appropriate interventions coupled with strengthening exercises.<sup>184</sup> Refer to Chapter 8 for an in-depth discussion of balance assessment and interventions.

### Objective Measures to Assess Strength, Power, Fall Risk, and Functional Mobility in the Older Adult

To assess strength, power, fall risk, and functional mobility in older adults, various tests and measures can be used. Some commonly performed tests for the older adult to assess strength and power are handgrip strength, five-time sit-to-stand test (FTSTS), 30-second sit-to-stand (30s-STs), and the time to ascend stairs.<sup>72,220,252</sup> When working with the older adult, the use of a standardized test with a temporal component may provide greater insight into the power, balance, endurance, reserve, morbidity, and mortality. Table 24.2 highlights several measures that may be used when examining the older adult. The temporal component to a test provides insight into the individual’s power. The specifics and written guidelines for the tests and measures described in Table 24.2 can be found at several Internet sites, including but not limited to the ones identified in Box 24.4.

**Power.** It is imperative for physical therapists to use tests and measures to assess power because power is lost quicker than strength with aging. Power is directly related to an individual’s ability to maintain independence and the risk of falls. The greater a person’s power, the more independent and lower the fall risk.<sup>220,238</sup> Because of the explosive nature and time factor in most of the tests listed in Table 24.2, they provide an objective measure of power. Of the various tests described in Table 24.2, grip strength is only slightly associated with power. This test is valuable as it is a predictor of mobility. In addition, the 6-minute walk test (6MWT) looks at the maximum distance a person can cover in 6-minutes and thus how CV pulmonary considerations and muscular endurance impact performance. The energy pathways used for each of these tests can be found in Chapter 7. For example, the 30s-STs is anaerobic and uses

**TABLE 24.2** Tests for Older Adults<sup>2,14,88,114,183,192,228,234</sup>

Test	Description	Interpretation												
Stair Climb Power Test	Test not standardized. Functionally based measure of leg strength, power, and functional performance in older adults. Patients are timed on their ascent of stairs. A handrail can be used for safety but not to assist the ascent.	This test, although sensitive, has great variability and lacks norms. Recommended to compare pre- and post-interventions, keeping all factors the same; i.e., number of steps, use of railing, up and down or ascent only, reciprocal or non-reciprocal pattern, and directions. <sup>183</sup> Stair climbing is an item of the Dynamic Gait Index, and Functional Gait Assessment scoring is not temporal but is on the impairment scale.												
Gait Speed Self-Selected AND Fast-Paced	A straight path is used of 10 m or 20 m in length, individuals are timed for the middle 5 m or 10 m to eliminate acceleration and deceleration time. Comparing the self-selected to fast-paced gait speed provides input on a person's gait reserve.	Normal walking speed is 1.2 to 1.4 m/s; speeds of $\leq 0.4$ m/s are classified as household ambulators, speeds of 0.4 to 0.8 m/s are classified as limited community ambulators, and those walking at speeds of 0.8 m/s to 1.2 m/s are classified as community ambulators.												
Timed Up and Go (TUG)	From sitting in a standard chair, individuals are timed as they rise from sitting, walk 3 m (10'), turn, walk back to chair, and sit.	Older adults who take $\geq 12$ s are at high risk for falling.												
30-Second Sit to Stand	From sitting in a standard chair, the number of repetitions an individual performs of sit to stand are counted in 30 s.	An older adult scoring $\leq 14.5$ repetitions is at increased risk of falling.												
Five Time Sit to Stand	From sitting in a standard chair, individuals are timed for the repeated performance of five repetitions from sit to stand.	A cutoff score of $< 15$ s is predictive of fallers in older adults.												
Grip strength	From sitting in a standard chair with back, pelvis, and knees close to 90°, shoulder adducted and neutrally rotated, elbow flexed at 90°, forearm neutral, wrist held between 0°-15° of ulnar deviation; forearm is not supported by examiner or armrest; dynamometer is presented vertically and in line with the forearm; the maximum grip is the mean of three trials.	In women, 20 kg was identified as a predictor for decreased mobility (sensitivity = 0.67, specificity = 0.73). In normal-weight men, it is 33 kg; in overweight men, it is 39 kg; in obese men, it is 40 kg.												
6-Minute Walk Test (6MWT) <sup>14</sup>	A submaximal walking test measuring the maximal distance an individual can walk in 6 minutes. Walkway recommended is 30 m (100 ft), instructed to walk pathway for 6 minutes continually. Permitted to rest as needed. The distance walked in 6 minutes is measured. Gathering data on the level of perceived exertion and vitals enhances interpretation.	This test was originally developed for chronic respiratory disease and has since been modified in length and applied to different populations (geriatrics, pulmonary disease, stroke, Parkinson's, osteoarthritis). <sup>114</sup> The minimal detectable age in geriatrics is 58.21 m (190.98 ft). <sup>192</sup> For the community-dwelling elderly without assistive devices, the mean distances by age and gender are as follows: <sup>228</sup> <table border="1" data-bbox="922 1696 1458 1879"> <thead> <tr> <th>Years</th> <th>Males</th> <th>Females</th> </tr> </thead> <tbody> <tr> <td>60–69</td> <td>572 m</td> <td>538 m</td> </tr> <tr> <td>70–79</td> <td>527 m</td> <td>471 m</td> </tr> <tr> <td>80–89</td> <td>417 m</td> <td>392 m</td> </tr> </tbody> </table>	Years	Males	Females	60–69	572 m	538 m	70–79	527 m	471 m	80–89	417 m	392 m
Years	Males	Females												
60–69	572 m	538 m												
70–79	527 m	471 m												
80–89	417 m	392 m

ATP-PC and lactic acid while the 6MWT is aerobic and uses oxidative phosphorylation.<sup>162</sup>

**Gait, falls, balance, endurance.** Gait or walking speed is a commonly performed test that can predict future health status, functional decline, risk of falling, and fear of falling. The progression or regression of walking speed is linked to changes in the quality of life.<sup>88</sup>

- The Timed Up and Go (TUG) can assess fall risk and shed insight into power, gait, and balance status of an individual.<sup>51,160,199,219,262</sup>
- The 30s-STS is used to assess lower body strength, power, muscular endurance, and balance.<sup>51,126,165,273</sup> Another option to assess STS is the FTSTS test, which assesses strength, power, and balance.<sup>26,37,66</sup> Assessing STS for 30 seconds allows greater insight about the patient's muscular endurance.<sup>263</sup>

**Grip Strength.** Grip strength, similar to gait speed, is reported to predict mortality, disability, and time spent in a hospital and can be considered a vital sign.<sup>24,25</sup> Negative health outcomes can be predicted from a weaker hand grip value.<sup>24,25,69,136,158,188,241</sup>

## Exercise Prescription for the Older Adult

### Multidimensional Program

A balanced exercise program of aerobic, flexibility, balance, and resistance exercises should be a part of healthy living (Fig. 24.3) and is essential for the older adult.<sup>43,129,164</sup> The

principles of developing exercises for each of these parameters are described in Part II of this textbook, with guidelines for each region of the body in Part IV. The effects of aging on the body systems and special concerns that these have in older adults are presented earlier in this chapter. Also, the importance of a detailed examination for the older

**FIGURE 24.3** A balanced exercise program includes (A) aerobic, (B) flexibility,

C

D

**FIGURE 24.3—cont'd** (C) resistance, and (D) balance exercises.

patient in order to identify the structural and functional impairments and related comorbidities is emphasized in order to develop a safe exercise program. The key point is, the exercise program should challenge the patient at his or her current level and then must be progressed so functional goals can be attained while monitoring the older adult for safety at all times.

## Aerobic Exercise for the Older Adult

Principles of aerobic exercise are described in Chapter 7, including specific guidelines for patients with coronary disease, the deconditioned individual, and patients with chronic diseases, as well as for the older adult in general.

### Guidelines Revisited

When providing instructions for aerobic exercises with the older adult, it is important to remember:

- Maximum heart rate is age related and decreases with age (220 minus age is a general guideline).
- Stroke volume decreases with age, resulting in decreased cardiac output.
- Arteriovenous oxygen difference decreases as a result of decreased lean body mass and low oxygen-carrying capacity.
- Maximum oxygen uptake decreases so that aerobic capacity decreases about 10% per decade in sedentary men.
- Blood pressure increases because of increased peripheral vascular resistance.
- Respiratory rate increases and maximum voluntary ventilation decreases with age.

### Recommendations

Recommendations for aerobic training are to participate in 150 minutes of moderate-intensity aerobic activity (brisk walking) or 75 minutes of vigorous-intensity aerobic activity (jogging or running) every week or an equivalent mix of moderate and vigorous intensity aerobic activity. Bouts of activity may be as short as 10 minutes at a time, just so the total time is obtained per week.<sup>197</sup>

**Talk test.** The talk test is a simple concept that can be employed when working with patients. The concept of being able to maintain a conversation or talk while performing an activity is thought to correlate with moderate-intensity aerobic exercise, while only being able to say a few words without taking a breath or having difficulty maintaining a conversation correlates with vigorous intensity. The talk test has been demonstrated to be a gauge of aerobic exercise intensity.<sup>50,84,194,207,268</sup>

## Flexibility Exercises for the Older Adult

Principles of stretching and flexibility exercises are presented in detail in Chapter 4.

### Guidelines Revisited

When providing instructions for mobility exercises with the older adult, it is important to remember:

- A low-intensity, long-duration stretch is the safest and most effective form of stretch.
- With age, there is a decrease in the maximum tensile strength and the rate of adaptation to tissue stress is

slower resulting in increased tendency for tears with stretching.

- With co-morbidities such as nutritional deficiencies, hormonal imbalances, and dialysis, connective tissue may become injured at lower levels of tissue stress.

### Recommendations

For long-lasting effects of flexibility and stretching, it is critical to use any newly gained range of motion (ROM). Encourage the older adult to include daily activities that require reaching overhead, out to the side, and behind the back, as well as moving their trunk, neck, and lower extremity joints through as much ROM as possible.

## Balance Training for the Older Adult

Chapter 8 provides background material and principles of exercises for impaired balance and includes an extensive section on evidence-based balance exercise programs for fall prevention in the elderly. Later in this chapter (see the section on Common Disorders in Older Adults and Exercise Recommendations), there is a discussion on the risk of falls in the older adult with a detailed discussion on the importance of balance training as well as strengthening exercises and task-specific exercises to reduce the risk.

### Guidelines Revisited

When providing instructions for balance exercises with the older adult, it is important to remember:

- Be sure the person has good sitting balance before proceeding to standing activities
- Have safety measures in place such as a secure surface where the individual can grab with one or two hands if necessary
- Challenge the person at a level where they are safe. Consider:
  - Base of support (standing double leg, tandem stance, single leg stance)
  - Support surface (stationary, flat, moving, soft, wobble board)
  - Superimposed movements (head, trunk, extremity, small to large range)
  - Perturbations (anticipated, magnitude, speed)
  - Surroundings (nonmoving, moving)
- Incorporate functional tasks when ready
  - Sit to stand using hands on arm rests, progress to no use of hands
  - Rising up on toes; progress to toe walking
  - Rocking back onto heels; progress to heel walking
  - Walk, then turn around
  - Side walking, backward walking
  - Reaching overhead, behind, to each side, toward the floor

### Recommendations

Exercise classes such as tai chi or other group balance exercise programs may provide a fun environment while teaching movement patterns that require balance. Encourage each

individual to perform balance activities independently at home at least 15 to 20 minutes per day and progress to more challenging activities as able.

## Resistance Exercise for the Older Adult

Principles of resistance exercise and general procedures for developing resistance programs are described in detail in Chapter 6. Resistance exercises are often neglected as a person ages, yet research has documented the value of strength training for maintaining functional independence as well as recovery from various pathologic conditions.<sup>101,104,117,137,185,187,190,206</sup> High intensity progressive resistance exercise has been demonstrated to be safe in older adults up to 96 years of age.<sup>206</sup> Although the principles of resistance exercise training for younger adults also apply to older adults,<sup>233</sup> the exercises may need to be modified due to medical conditions such as osteoporosis, progressions may be slower because of degenerative changes, greater attention to safety and injury prevention may be necessary due to cognitive as well as physical changes, and sessions may be delayed due to fluctuations in blood glucose (BG) levels. This fluctuation in BG is not unique to older adults; it is mentioned here due to diabetes being one of the most common causes of death in older adults and one of the most common chronic diseases in older adults (see ONLINE Table 24.1).

Although nonspecific exercise is better than no exercise, it is essential for older adults to receive an individualized examination of their specific needs and be prescribed a program to meet those needs. This must be coupled with ongoing monitoring and changes in the program.<sup>17</sup> Each exercise session should incorporate a warm-up, flexibility, functional or sport-specific exercise, and cool-down.<sup>196</sup> The “sport-specific exercise” component is interpreted as functional retraining and balance exercises for the older adult who is not involved in sports.

As with any patient, when initiating progressive resistance exercises with the older adult, the exercise must be supervised and modified so the patient performs the exercise correctly. Too often patients use compensatory strategies when exercising or may fail to do the exercise correctly. Thus, when introducing a patient to resistance exercises, initially use a lower weight to enhance learning the correct technique.<sup>206</sup> This also enables the connective tissue to adapt to the training with gradual increases in the number of repetitions and resistance to achieve overload.<sup>195,197</sup>

### Safety and Special Precautions

Although resistance training has been shown to be safe in older adults, ongoing exercise supervision is necessary to assess for overtraining weakness, exacerbation of a musculoskeletal complaint, or exercising above the patient’s level of the CV, pulmonary, or musculoskeletal capabilities. Use subthreshold intensities if symptoms increase with exercise. When performing resistance exercises, normal breathing is advocated,<sup>164,195</sup> and work only within the pain-free ranges.<sup>195</sup>

## Guidelines Revisited and Recommendations

### Exercise and Equipment Choices

Based on the results of the examination, determine what muscles and patterns of movement need to be strengthened to achieve the established goals. Determine safe positions and appropriate equipment that will match the capability of

the patient at his or her current level, provide a challenge to progress, and address the specificity of training principle in order to meet the needs of the patient. For example, a patient who is seen in a home care setting may do well with functionally based resistance exercises such as those illustrated in Figure 24.4.

**FIGURE 24.4** An example of a program that can be done in the home-care setting. (A) Ambulation and stairs, (B) mini-squats, (C) modified push-ups and/or planks, (D) lateral step-ups,

**FIGURE 24.4—cont'd** (E) hip abduction, (F) heel rises, and (G) repeated sitting push-ups/sit to stand.

A patient who has access and enjoys using a fitness facility may prefer machines that provide resistance, while another patient may prefer free weights. The use of elastic resistance bands has also been found to be effective and valuable for strength and power training in older adults and can easily be adapted for use in the clinic, gym, or home setting (Fig. 24.5).<sup>89,110,148,157,238</sup> Some forms of resistance

may meet several goals. For example, patients may wear a weighted vest for strengthening purposes and/or to increase body weight with the benefit of enhancing bone density. (The use of a weighted vest will be discussed in the osteoporosis section.) A secondary benefit to using weight training machines is improvement in balance. This is due to the need for multiple transfers and transitional movements to

get on and off of the exercise equipment. If a person does 3 sets of 10 different exercises on 8 machines, that individual will perform many transfers.

Table 24.3 provides suggestions of exercises that can be used to include 8 to 10 muscle groups in a resistance training program for the older adult. Many of the exercises are

illustrated in the spine and extremity chapters (see Chapters 16 through 23).

#### Exercise and Equipment Choices: Modifications

When working with an older adult patient, the presence of comorbidities such as shoulder OA, rotator cuff injury, osteopenia,

**FIGURE 24.5** Examples of exercises that can be done using elastic resistance bands in the home setting. (A) Mini-squats/leg press, (B) hip abduction with lateral rotation, (C) shoulder presses, (D) lat pull-downs,

**FIGURE 24.5—cont'd** (E) biceps curl, and (F) weight-bearing hip abduction with the patient walking sideways (or performing repeated hip abduction).

**TABLE 24.3** Resistance Training of Key Muscle Groups for Older Adults Using Machines, Weight Bearing, and Dynamic Constant External Resistance

Muscle Group	Machine	Weight Bearing	Dynamic Constant External Resistance (DCER) Using Free Weights, Resistance Bands, Weighted Balls, Cable System, etc.
Hip Extensors	Leg press Hip extension machine	Bridging (hamstring recruitment is greater with less knee flexion; gluteal recruitment is greater with more knee flexion)	Hip extension Knee curls Hip extension with knee flexion
Knee Extensors	Knee extension machine	Mini-squats Wall squats Steps Lunges	Knee extension with long and short arc quads Straight leg raise
Hip Abductors	Hip abduction machine	Standing hip abductions, works the limb abducting and isometrically the weight-bearing limb Elastic resistance around distal thighs or ankles and monster walk	Supine, prone, and side-lying hip abductions Clam shells Standing/cable, elastic band hip abductions

Continued

**TABLE 24.3** Resistance Training of Key Muscle Groups for Older Adults Using Machines, Weight Bearing, and Dynamic Constant External Resistance—cont'd

Muscle Group	Machine	Weight Bearing	Dynamic Constant External Resistance (DCER) Using Free Weights, Resistance Bands, Weighted Balls, Cable System, etc.
Hip External Rotators		Monster walks with elastic resistance around knees Diagonal hip abduction/external rotation with elastic resistance around ankles to emphasize gluteus medius	Sitting or side-lying clam shells with elastic resistance around knees
Ankle Plantar Flexors	Leg press	Heel rises	Heel rises holding weights; long sitting with elastic resistance under foot
Trunk Flexors	Straight and rotational abdominal machine  <b>CONTRAINDICATION:</b> Trunk flexion with potential or actual diagnosis of osteopenia/osteoporosis. Alternative is stabilization exercises.	Plank Side plank Ball roll out using a large gym ball Modify exercises if painful, shoulders may need to be in less flexion	Curl-up/crunches Stabilization exercise progression beginning supine, progressing to sitting and standing with resistance  <b>CONTRAINDICATION:</b> Trunk flexion (curl-ups and crunches) with osteopenia/osteoporosis
Trunk Extensors	Trunk extension machine  <b>CAUTION:</b> arthritis or stenosis may cause neurologic symptoms	Bridging	Stabilization exercise progression beginning in quadruped, progressing to sitting and standing with resistance
Scapular Retractors, Shoulder Extensors	Pull down machine, rowing	Corner press-out (with back to corner)	Y and T positions with weight in prone or over a large gym ball; sitting using elastic resistance/cable system
Shoulder External Rotators	Cable system		Side-lying or sitting shoulder external rotation
Shoulder Abductors	Lateral raise machine	Quadruped moving diagonally or straight plane Moving a ball on the wall	Lateral raises Shoulder flexion Shoulder extension
Elbow Flexors	Biceps curl machine	Pull-ups and assisted pull-ups; using an assist may enable successful performance of pull-ups; seated pull-ups	Curls
Elbow Extensors	Elbow extension machine	Push-ups with a plus Wall push-ups with a plus Dips	Elbow extension

or a loss in ROM, result in a need to modify exercises to the patient's ability (Fig. 24.6). The exercises should not be painful or exacerbate a potential problem. For example, rather than performing trunk curls or crunches, which cause vertebral body compression, have the patient with osteoporosis do partial range on a large gym ball or BOSU(tm) to a neutral spine position avoiding full range into trunk flexion.

Exercise modifications that challenge the individual can also be adapted for those who have the loss of independent ambulation (Fig. 24.7). The patient's constraints dictate the selection of the interventions. For example, if a patient has limited space, performing exercises at their kitchen counter may provide a stable surface for closed chain and balance exercises (see Fig. 24.4 B, C, E and F and Fig 24.9 later in the chapter).

**FIGURE 24.6** Examples of exercise modifications to meet the needs of older adults. **(A)** Abdominal strengthening without going into trunk flexion using a large gym ball through partial range, **(B)** sitting balance combined with strengthening extensor postural muscles, **(C)** posture training using a wall for tactile cues, and **(D)** weight-bearing plantar flexion with support.

**FIGURE 24.7** An example exercises that have been modified to meet the needs of an older adult in a wheelchair. (A) Scapular protraction with resisted band, (B) seated step ups (raise height as patient improves), (C) sitting push-up with feet on the floor, and (D) seated diagonal patterns with ball (can use weighted ball).

### Intensity of Exercise

Intensity is based on load, repetitions, and sets as described in Chapter 6. Avers and Brown<sup>16</sup> report that when exercise or activities are performed below the 60% 1 RM, slight improvements of 5% to 10% may occur on strength tests but that recruitment of motor units and motor learning rather than actual strength changes in the muscle may be the reason. The initial

rapid strength gains achieved following the start of resistance training is attributed to neural adaptations and motor learning. Patients are often discharged from therapy before the 12 weeks necessary to achieve actual strength gains.<sup>210</sup> Thus, it is essential for therapists and assistants to educate the patients on the need to continue exercising following discharge by participating in community based programs or by exercising independently.

**Borg scale.** The original Borg 6 to 20 scale (see Box 25.4 in Chapter 25) was designed to match the heart rate response; i.e., a score of 9 was correlated with very light effort and a heart rate of 90 beats/minute.<sup>30</sup> The 6 to 20 scale was considered difficult to understand, so the revised 0 to 10 scale was developed (see Box 6.6 in Chapter 6). Although subjective measures of exercise intensity, both Borg scales provide valuable insight into the intensity of exercise. To determine 60% of a 1-RM intensity, various strategies may be employed. Avers and Brown<sup>16</sup> report the 60% threshold is when an individual can perform 15 repetitions with a rating of perceived exertion (RPE) of 12 to 13 on the original Borg scale or a 3 to 4 on the modified Borg scale. This is described as work or effort of “fairly light” to “moderately hard.” When using either Borg scale to measure intensity, it is critical to take the time to explain the scale including the values at each end of the scale. The patient is advised to rate their total amount of exertion and fatigue combining all sensations including physical stress, effort, and fatigue and to avoid focusing on one aspect such as leg pain. The therapist should confirm the patient’s self-report or level of exertion by repeating the number back to the patient. The use of either of

Borg’s RPE scales is especially helpful when heart-rate measurements are difficult or when a patient is on medications that impact heart rate responses to physical activity.<sup>29,195,248</sup>

**Determining amount of resistance.** Another approach to selecting the correct intensity is to teach the correct exercise performance at a lower intensity (load) and observe the performance of the exercise, noting any change in the quality of performance, such as muscle substitutions or inability to go through the entire range. (Refer to Box 6.2 in Chapter 6 for specific signs of muscle fatigue.) If the individual is able to complete 8 repetitions correctly but less than 15, the intensity is appropriate. If unable to complete 8 repetitions or shows signs of muscle fatigue, the weight should be decreased. If 15 repetitions is too easy, the weight should be increased.

Various strengthening protocol intensities are recommended for the older adult. Table 24.4 highlights several of these for comparison.

### Sets

Research by Ribeiro and colleagues<sup>210</sup> demonstrated that performing 3 sets of resistance training is more effective for strengthening muscles than performing 1 set of exercises in

**TABLE 24.4** Three Recommended Resistance Training Protocols for Older Adults

Intensity	Sets	Repetitions per Set (reps/set)	Frequency	Progression	Power
<b>Recommendations from Avers and Brown.<sup>16</sup></b>					
60% of 1 RM is the minimal exercise load necessary	1 set for untrained individuals, (more sets if possible, although risk of injury increases with multiple sets)	Set reps at desired intensity	2-3 times/week; 24 to 48 hours of rest between sessions of same muscle group	Increase load 2%-10% once able to perform 12 to 15 reps	Initiate power once 2 sets of an exercise are performed with good form and no pain at an initial load 20% of 1 RM. Gradually increase toward 60% of 1 RM.
<b>Recommendations from Haskell et al.<sup>108</sup> and Nelson et al.<sup>179</sup></b>					
Moderate to high intensity (on modified Borg 3 = moderate and 5 = strong or heavy)	1 set if goal is to increase strength; 2-3 sets are more effective	8-12 reps	≥2-times/week	Gradual increases in the amount of weight or the days/week	Not addressed
<b>Recommendations from Symons &amp; Swank.<sup>233</sup></b>					
50%-80% 1 RM	2 to 3 sets	10-15 reps	2-3 days/week	Not specified	Must include higher velocity resistance exercise incorporated into training

older women following 12 weeks of training. Thus, when advocating continuation of progressive resistance exercise training after a patient is discharged from physical therapy, if the goal is to continue to increase muscle strength, three sets are recommended.<sup>210</sup> Ratamess and colleagues<sup>205</sup> recommended a 1- to 2-minute rest between moderate velocity sets but an increase to 3 to 5 minutes of rest for high-velocity training. In lieu of a patient or client sitting on a piece of equipment for that rest period to expire, it is recommended that the person employ *active recovery* and work a different muscle group. For example, to apply active recovery to Lou, described in Case 1 in Box 24.1, he would perform his strengthening exercises by doing one set on the leg press machine, then one set on the hamstring curl machine, then one set on the rowing machine, and then one set of dips. After completing the first set of all four exercises, he would repeat the circuit for a second set and then a third set. The cycling through of different muscle groups provides the needed rest or recovery.

### Frequency of Exercise

Twenty-four to 48 hours are recommended between resistance training sessions for the same muscle groups for safe adaptation when working at an intensity of 60%.<sup>129</sup> In various practice settings, such as acute care, subacute rehabilitation, and skilled care, patients may be seen once or twice daily 5 to 7 days/week. In these circumstances, focusing on different muscle groups or varying activities such as task-specific skills, posture, balance, endurance, strengthening, and stretching should be alternated between sessions in order to allow tissues to safely adapt.<sup>16</sup> Incorporating other dimensions of rehabilitation, such as neuromuscular re-education and balance exercises, is invaluable when considering the potential need for functional interventions. The need to employ a multidimensional exercise program, as described in the next section, is recommended.<sup>129, 157</sup> A minimum frequency of performing a strengthening exercise to impact bone and muscle is two sessions/week.<sup>129</sup>

### Speed of Exercise—Power

With aging there is a preferential loss of power attributed to the loss of type II muscle fibers and a decrease in velocity of contraction.<sup>112,208,213</sup> Power training should not be implemented with the older adult until a base has been established; i.e., the ability to perform three sets of each exercise prior to adding a power component to the training.

To address power, the rapid movement of light resistance is described as most practical and widely acceptable.<sup>208</sup> Patients should perform the concentric phase of each repetition as rapidly as possible, with the combined eccentric-concentric cycle being approximately 2 to 3 seconds.<sup>110,167,208,232</sup> (Table 24.5 provides guidelines for power training with older adults.<sup>112</sup>) Similar to the guidelines for resistance training, a 48-hour recovery is recommended between power training. Mizko and colleagues<sup>167</sup> found power training to be more efficacious than strength training to improve function in community dwelling older adults (mean age 72.5 +/- 6.3 years).

**TABLE 24.5** Guidelines for Incorporating Power Into Resistance Training for Older Adults<sup>112</sup>

Set 1	8 repetitions	45% 1 RM
Set 2	8 repetitions	60% 1 RM
Set 3	≥8 repetitions	75% 1 RM
The concentric portion of each repetition should be performed as rapidly as possible. The eccentric portions should be controlled over approximately 3 seconds.		

### Progression

When progressing an exercise program, the same guidelines follow as for other populations but with continual monitoring for safety and the potential onset of injury or overwork weakness. It is essential to start at lower intensity and progress slowly.

## Functional Training for the Older Adult

Functional training is most often geared toward attaining independence or improving basic activities such as steps, raising up and lowering self in a chair, reaching items overhead or on the floor, or simply walking. Efficiency, time to perform a task, effort, and the quality of the task may be incorporated in the interventions. The tests described in Table 24.2 will help to guide the therapist in designing appropriate interventions to enhance function. Thus, if the problem is sit to stand, then the patient needs to work on the task of sit to stand. If, initially, the muscles are too weak to perform the function without substitution, then focusing on the specific weak muscles also becomes part of the exercise intervention.

## Common Disorders in Older Adults and Exercise Recommendations

With the “graying of America” and the life expectancy increasing, many diseases that affect older adults have become more prevalent. In this section, several common problems seen in older adults provide a background prior to discussing exercise interventions. One’s medical diagnosis does not define the physical therapy treatment plan, although knowledge of the medical condition alerts the therapist to special considerations, precautions, and/or contraindications to interventions. The medical diagnosis should be used in conjunction with the

clinical examination to determine the structural and functional impairments and to establish realistic goals for improving participation in functional activities. Numerous chronic conditions, as listed in ONLINE Table 24.1, and multiple other illness and injuries may threaten the older adults' independence. This section addresses common conditions and diagnoses seen in older adults, including falls, osteoporosis, sarcopenia, OA, obesity, cancer, T2DM, and incontinence. Each of these will be briefly described with cross references to other chapters within this text where additional information is presented.

## Falls in Older Adults

### Background

As people age there is an increased incidence in the number of falls. One out of every three older adults falls each year, with 20% of those falls resulting in serious injuries.<sup>17,51,90,109,116</sup> This incidence is even greater in the institutionalized elderly. Over the past decade, the number of deaths directly attributed to the injuries from falls has increased and is anticipated to increase with the aging of the Baby Boomer generation.

### Fall Risk Assessment

All older adult patients should be screened for fall risk.<sup>17,51</sup> Each patient should be asked:

1. Have you fallen in the past year?
  - If yes—how many times did you fall?
  - If yes—were you injured when you fell?
2. Do you feel unsteady when standing or walking?
3. Do you have a fear of falling?

The above three questions are from the CDC's Stopping Elderly Accidents, Deaths, and Injuries (STEAR) initiative.<sup>51</sup> Screening items 1 and 2 are also recommended by Avin and colleagues in the Clinical Guidance Statement from the Academy of Geriatric Physical Therapy on the management of falls in community-dwelling older adults.<sup>17</sup> The need to perform a multifactorial fall risk assessment is not necessary for all patients 65 and older but is essential when screening indicates a prior fall in the past 12 months, difficulty with walking or balance, or a fear of falling.<sup>17</sup>

### CLINICAL TIP

The STEADI Older Adult Fall Prevention<sup>51</sup> website from the CDC is valuable for all therapists and assistants working with older adults: <http://www.cdc.gov/steady/index.html>. The STEADI initiative provides a comprehensive tool kit with educational information for health-care providers and older adult patients. Instructional videos and a webinar are also available. An Algorithm for Fall Risk Assessment and Interventions developed by the STEADI initiative is shown in Figure 24.8 to provide guidance for screening, examination, and interventions useful for physical therapists working with the older individual at risk for falling.<sup>51</sup>

### Importance of Exercise to Reduce Fall Risks

A multidimensional program that includes resistance exercises, balance exercises, task specific training (gait, sit to stand, rising from the floor), correction of both environmental hazards, and selection of proper footwear should be included in patient interventions.<sup>17,145-227</sup> The Academy of Geriatric Physical Therapy of the APTA list these five specific recommendations based on strong level 1 evidence.<sup>17</sup>

Nonspecific exercise, low-intensity exercise, and generic group exercise programs may not meet the needs of older adults and reduce fall risk.<sup>17</sup> It is critical to recognize the need for long-term adherence: a dosage of at least 50 hours of challenging exercise (e.g. 2 hours/week for at least 6 months) is needed.<sup>17</sup> Improvements do not occur spontaneously and require more time than is generally approved by insurance companies; therefore, education on the importance of continuing the prescribed exercise program is critical.

### Resistance Training

Improvements in balance and a decrease in falls occur from strength training in older adults.<sup>137,145</sup> The causes of falls are multifactorial with weakness of the legs being an intrinsic risk factor. Strengthening the muscles of the trunk and lower extremities with resistance exercises and power training is related to reducing falls.<sup>68,137,187</sup> Strength training has been found to benefit postural control and to decrease variability of reactions during stabilization training.<sup>68</sup> In addition, strengthening the trunk muscles has been shown to improve performance of ADLs in older adults by contributing to efficiency in use of upper and lower extremities and improved balance. A systematic review by Grenacher and colleagues<sup>96</sup> supports the use of core strengthening and Pilates exercises either as an adjunct with or alternative to traditional balance and/or resistance training programs for older adults.

### Tai Chi

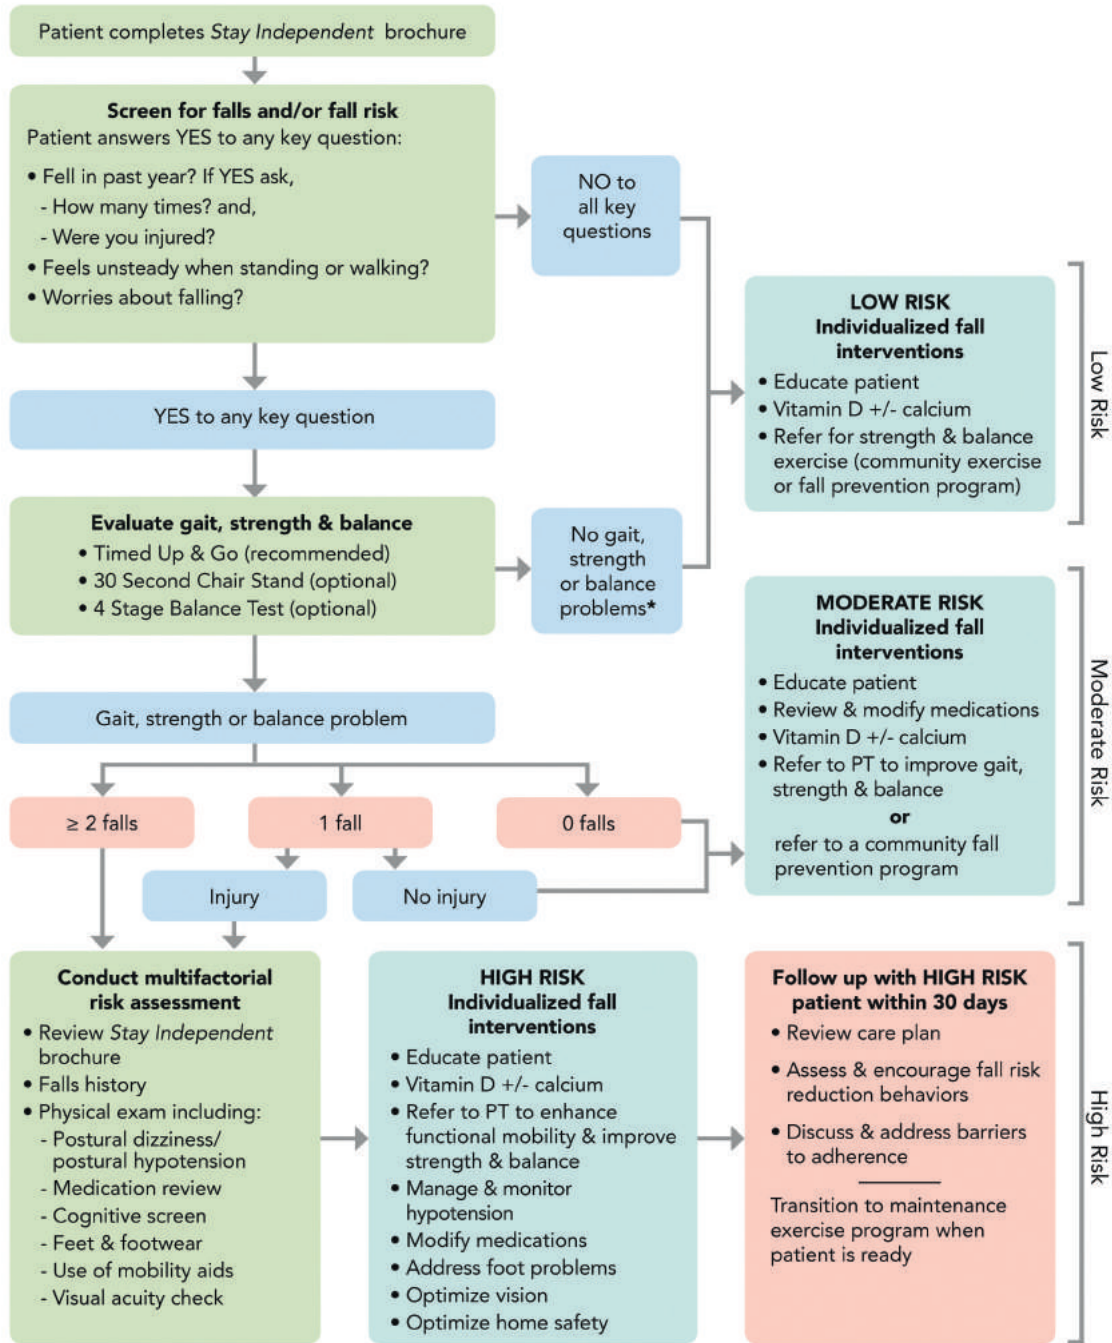

Tai chi is a mind and body practice that arose centuries ago from Asia. It incorporates postures, gentle movements, mental focus, breathing, and relaxation and has proven to be beneficial in decreasing fall risk.<sup>130,148,173</sup> When the movements are performed quickly, tai chi is considered a form of self-defense. Tai chi also benefits heart disease, cancer, and other chronic diseases such as Parkinson's, OA, and fibromyalgia. It has been reported to improve pain, sleep, and anxiety.<sup>173</sup> When performing tai chi, strength, self-awareness, deep breathing, static and dynamic balance, ROM, endurance, positioning and postural awareness, weight bearing, and relaxation are incorporated into the various movements performed.<sup>130,148,173</sup>

### Balance Training

The ability to maintain balance requires complex integration of the somatosensory, visual, and vestibular systems—all of which are affected with aging. Impairments involving balance are described in detail in Chapter 8, with a description of risk assessment (see Tables 8.2 and 8.3) and interventions (see Boxes 8.4 and 8.5, Table 8.4, and related figures in Chapter 8). Similar to progressing resistance exercises, progress balance interventions that safely challenge the patient (Fig. 24.9).

## Algorithm for Fall Risk Assessment & Interventions

\*For these patients, consider additional risk assessment (e.g., medication review, cognitive screen, syncope)

Centers for Disease Control and Prevention  
National Center for Injury Prevention and Control

**FIGURE 24.9** An example of balance exercise progression in the home setting by modifying the amount of support through the hands. **(A)** Both hands using light tactile cues, with eyes closed for greater challenge; **(B)** both hands hovering above the support surface, with eyes closed for greater challenge; **(C)** one-legged standing; and **(D)** tandem Romberg.

## Osteoporosis

### Background

Osteoporosis is considered to be the most common bony disorder resulting in risk of fractures. Peak bone mass is attained by the third decade of a woman's life with approximately 30%

loss by age 80. The morbidity and mortality of hip fractures is one of the three most common fractures associated with osteoporosis. Hip fractures result in up to a 25% increase in mortality within 1 year following the fracture, with another 25% of patients requiring long-term care and the remaining 50% not attaining their pre-hip fracture status.<sup>184</sup> (Refer to

Chapter 6 and Box 6.13 for a discussion of pathological fractures and precautions, and to Chapter 11 for a detailed description of osteoporosis and recommendations for exercise interventions.)

### Considerations for Interventions

Strength training, weight-bearing exercises, and postural extension exercises are hallmark interventions for older adults for primary, secondary, and tertiary prevention associated with osteoporosis or osteopenia. Generally this is coupled with a well-balanced diet, adequate calcium and vitamin D, smoking cessation, minimal alcohol consumption, fall prevention strategies, and possible pharmacological interventions.<sup>184,265</sup> Box 24.5 summarizes considerations and recommendations when working with the older adult with or at risk for osteoporosis. (See also Box 6.13 in Chapter 6 for precautions that should be taken with resistance exercise.)

### Importance of Exercise in Managing Osteoporosis

#### Postural Training

The employment of spinal extension and postural exercises is critical when considering the incidence of compression fractures in individuals with or at risk of osteoporosis. Schultz and colleagues<sup>215</sup> found that with the trunk at 30° of flexion, the compression load on the third lumbar vertebra is 1,800 N with the arms at the chest and 2,610 N when holding 2 kg

(4.4 lb) of weight in each hand. This is significantly greater than the 300 to 1,200 N of force necessary to fracture an osteoporotic vertebra.<sup>77</sup>

#### Resistance Training and Weight-Bearing Exercises

Muscle contractions and mechanical loading of the spine and extremities utilizing resistance training and weight-bearing exercises stimulate osteoblastic activity for improving bone density and reducing fracture risk.<sup>27,118,200</sup> Weight-bearing and endurance activities (three to five times/week) and resistance exercise (two to three times/week) are recommended for bone health.<sup>134</sup> A systematic review on the effectiveness of resistance exercise for older adults with decreased bone density concluded that resistance training was beneficial on the self-reported physical function and ADLs.<sup>265</sup>

Weight-bearing exercises such as walking, jogging, and stair climbing also have the benefit of improving cardiopulmonary fitness. These interventions for primary, secondary, and tertiary osteoporosis are summarized in Table 24.6.

#### Weighted Vests

Another less commonly used option but one that shows positive results is the use of a weighted vest in the management of osteoporosis (Fig. 24.10).<sup>110,218,224,267</sup> Weighted vests are also used for power training, walking, and other activities. Weighted vests increase resistance and body weight while exercising, walking, and performing ADLs. Increasing an individual's weight via the vest serves as a stimulus for increasing bone density while the wearer is physically active.

**Recommended guidelines for use of weighted vests.** It is essential that the vest is adjustable, that the majority of the weight be on the pelvis, and that there are no areas causing pain. Similar to the use of orthotics, when initiating the use

#### BOX 24.5 Considerations and Recommendations for Management of Patients With Osteoporosis

##### Considerations

- Height loss of >1.5" (3.8 cm) increases the likelihood of a vertebral fracture being present<sup>184</sup>
- At high risk for fragility fractures
- When trunk is in flexion, there is greater compressive loads on the vertebra
- Only 20% of individuals with osteoporotic compression fractures receive treatment

##### Recommendations

- Screen all patients for fall risk.
- Utilize the FRAX to screen all patients for fracture risk.<sup>193,269</sup>
- Educate on risks and importance of exercise.
- Have the patient:
  - Perform weight-bearing, strengthening exercises and resistance exercise that emphasize postural extension two to three times/week.
  - Perform endurance, weight-bearing activities three to five times/week.
  - Perform core and abdominal strengthening in a nonflexed position.
  - Employ good body mechanics with spine in neutral.
- Make appropriate referrals for bone density screening and nutritional consult.

**FIGURE 24.10** (A) Anterior and (B) posterior images of a weighted vest used in the management of osteoporosis and/or to increase body weight for resistance exercises.

**TABLE 24.6** Management of Primary, Secondary, and Tertiary Osteoporosis

	Description	Clinical Examples	Interview, Tests, and Measures	Interventions
Primary	Prevention of osteoporosis or osteopenia in someone susceptible to the problem or disease through strategies to promote general health	56-year-old female being seen for DeQuervain's of her hand. Family history of osteoporosis; cessation of menses 2-years ago. On inspection, patient is thin but muscular in nature.	Have you experienced height loss? Have you had any fractures as an adult? Have you taken steroids? Do you smoke or have alcohol regularly? Ask if willing to look at total patient, consider measuring height, objective posture measurement like tragus to wall; employ the FRAX.	Focus on education, postural and weight-bearing exercises, resistance training, body mechanics, and nutrition.
Secondary	Early diagnosis of osteoporosis or osteopenia made through screening; early diagnosis enables initiation of intervention	60-year-old female with a diagnosis of osteoporosis. She is referred to PT for spinal stenosis and disc herniation at C4-5, C5-6, and C6-7, neck pain, and radicular symptoms. She is being managed conservatively and has begun taking calcium and osteoporosis medications to increase bone density prior to surgical interventions and fusion of the spine.	Assess for myelopathic changes, bowel and bladder involvement, loss of balance, weakness of legs, and hyperreflexia. Query regarding the Physical Activity Vital Signs (PAVS); what type of exercise is performed by the patient and willingness to modify or make changes. Assess deep tendon reflexes, Babinski Hoffman's, and clonus.	Interventions are same as primary prevention interventions but emphasize progressive ambulation and weight-bearing exercises.
Tertiary	Clinical diagnosis of osteoporosis and presence of fragility fractures, interventions designed to limit the degree of disability, promote recovery of function, and minimize the disease progression	75-year-old female who is being seen 10-weeks post fragility fracture of the femoral neck secondary to a fall while walking on level surface. Patient has a history of 2 spinal compression fractures and a height loss of 3". Patient is being seen through home health care (recently returned home from skilled care). She is ambulating with a standard cane, weight bearing as tolerated.	Ask if patient experiences pain at rest or with activity. Ask about current level of function and prior level of function. Does the patient have a fear of falling or any self-restriction of activities? Use objective measures such as gait speed, TUG, 30s-STs, grip, and posture.	Focus on function. Progressively challenge the patient as the status improves. Employ task-specific training and weight-bearing exercises.

of weighted vests, start slowly and progress gradually. Shaw and Stone<sup>218</sup> used a beginning vest weight of 5% of body weight with a 1% to 2% increase until 10% of body weight was achieved. This was followed by a more gradual 0.5% to 1% increase in weight every 2 weeks until 20% of body weight was attained. It is recommended that the vest be worn 3 days/week for resistance power exercises such as jumping or for several hours daily while being active.<sup>85,218,224,267</sup> A website selling the vests advocates 1 hour/day, 5 days/week, with a maximum vest weight of 16 pounds.<sup>85</sup> Because there is a

paucity of clinically based evidence related to usage, the authors of this chapter recommend monitoring patients for their ability to maintain good posture and the absence of pain with a gradual, monitored increase in vest weight until attaining a desired weight. Similarly, the time spent wearing the vest is to start low and gradually progress usage. The use of the weighted vest for low-weight individuals should be used as long as the individual is ambulatory and able to tolerate it. If necessary or in response to medical changes, the amount of weight should be adjusted appropriately. Guidelines for their

use in pediatric physical therapy and sensory processing disorders are not applicable for the older adult.

It is known that a body mass index (BMI)  $<21 \text{ kg/m}^2$  is a risk factor for low bone mass density. For those with a low BMI, by determining a weight for a BMI  $>21 \text{ kg/m}^2$ , a goal for a reasonable maximum load with the vest can be attained.

**PRECAUTION:** Some patients may not tolerate the weighted vest due to clinical fragility, pain, or weakness.<sup>224,267</sup>

### FOCUS ON EVIDENCE

A 6-month study with 1-year follow-up of 42 individuals with osteopenia consisting of a progressive exercise and education program was designed to establish the feasibility and adherence to the intervention, identify any adverse events, and document changes in lower extremity function. The resistance portion of the program included use of weight vests to increase resistance during the group exercise sessions, which were conducted two times/week under supervision of a therapist and 1 time/week at home. Data for 31 participants that were available at the 1-year follow-up showed that the program was feasible, had sufficient progression of training, and had high adherence with no adverse events. There were significant improvements in femoral trochanter bone mineral density, as well as quadriceps strength and dynamic balance, with overall improvement in lower extremity function.<sup>102</sup>

## Sarcopenia/Frailty

### Background

The etymology of *sarcopenia* has a Greek origin from *sarx* (flesh) and *penia* (poverty).<sup>240</sup> It is more than the age-associated loss of muscle mass. Sarcopenia causes a cascade of responses leading to frailty impacting balance, gait, and function.<sup>63</sup> This disease is a progressive 3% to 8% loss of lean muscle mass each decade beginning with the third decade, and it is believed to affect 30% of adults greater than 60 years old and 50% of older adults greater than 80 years (see Fig. 24.2).<sup>70,73,117,155,203,22,230,240</sup> The importance of regular resistance exercise coupled with protein intake is necessary in order to minimize the loss of muscle mass. Marcell<sup>155</sup> reports, “the only agreed-upon intervention ... (for sarcopenia) was regular physical exercise, stressing weight-training for elderly men and women.”

**Sarcopenic obesity.** An individual who has both sarcopenia and obesity is described as having sarcopenic obesity (Fig. 24.11). The concept of sarcopenic obesity is when skeletal muscle mass is deficient relative to fat tissue.<sup>63</sup> This diagnosis is based on a measure of fat mass and skeletal muscle mass of the thigh using dual-energy X-ray absorptiometry (DXA) or magnetic resonance imaging (MRI). It is estimated that 4% to 12% of individuals over 60 years of age have sarcopenic obesity. This disease is managed with loss of fat, increased protein intake, and performance of resistance training.<sup>63,70</sup>

**FIGURE 24.11** An older individual with sarcopenic obesity; (A) side view showing posture and (B) front view showing atrophy in legs greater than arms.

### Considerations for Interventions

When working with the frail elderly population, it is critical to consider the risk of a fatigue fracture, the potential for loss of balance and falls, the nutrition of the patient, and whether the demands of an exercise program exceeds nutritional intake.

(Refer to Chapter 6 and Box 6.13 for a discussion of pathological fractures and precautions and to Chapter 8 for information on balance and falls.)

### Importance of Exercise in Managing Sarcopenia

The multifactorial nature of sarcopenia has many facets partially attributed to inactivity and atrophy of fast-twitch (type II) muscle fibers that are recruited during high-intensity, anaerobic exercise. Physical inactivity coupled with motor unit remodeling, decreased hormone levels, and decreased protein synthesis may contribute to sarcopenia. Fortunately, with resistance exercise, sarcopenia may be partially reversed or progression of the loss slowed.<sup>53,63,70,117,155,189,203,220,229,230,240</sup>

## Osteoarthritis

### Background

Osteoarthritis is a common chronic disease affecting 30% to 50% of adults over age 65.<sup>147</sup> Among older adults, OA is the most common form of arthritis, with the greatest incidence in the knees followed by the hips.<sup>159</sup> This wear and tear degenerative disease is reported in at least one joint in 80% of older adults. Involvement of the hands occurs frequently, but the involvement of the knees and hips is reported to be more disabling. (Refer to Chapter 11 for a detailed description of OA and management guidelines for treatment. Also refer to Chapters 15 and 17 through 22 for specific guidelines for the treatment of OA in the spine and each of the extremity joints.)

### Considerations for Interventions

When initially greeting an older adult patient, the therapist may take note of the patient's hands and the presence of Heberden or Bouchard nodes at the distal interphalangeal and proximal interphalangeal joints, respectively. The patient may also have genu varum, genu valgum, calcaneal valgum, or other deformities associated with OA.

Patients with OA must learn to value the importance of exercise; how to self-manage during painful exacerbations; and how to work on strengthening, stretching, balance, and aerobics during less painful times. Integrating the knowledge of biomechanics with observations of the patient performing exercises is critical in guiding the patient in correct exercise performance. For the patient to attain the ability to self-manage their disease, the patient must be aware of the impact of alignment and what to expect when performing exercises rather than adopting the adage "no pain, no gain."

When working with patients with OA:

- Avoid vigorous, repetitive movements on unstable joints.
- Be cautious if there is pain in the hands impacting grip when working with free weights or elastic bands.
- Observe the alignment, performance, and response to exercise and modify when indicated.
- Modify the program when a patient has increased pain, fatigue, weakness, or joint swelling to decrease stress on the joint.

- Avoid stretching, strengthening, and aerobic exercise that exacerbate symptoms during acute joint flare-ups, but continue to do ROM to the involved joint(s) and balance activities if symptoms allow.
- Emphasize moving all joints through their full ROMs at least one time each day to prevent loss in ROM.

Weight loss or maintenance of ideal weight may decrease compressive forces but must be considered in relationship to worsening the osteoporosis risk of fracture.

### Importance of Exercise in Managing OA

Despite having OA, older adults should strive to be physically active by exercising to minimize their risk of developing other chronic diseases and lower their body weight. In addition, the lack of activity can further compound the problem of OA and subsequently contribute to falls, osteoporosis, and sarcopenia. Unfortunately, many patients with OA who are experiencing pain refrain from exercise and physical activity. Mat and colleagues<sup>159</sup> reported that OA of the knee is a risk factor for falls in older adults and that strength training, tai chi, and aerobic exercises improve balance and reduce fall risk in older adults. The benefits of regular exercise for individuals with OA are many. Exercise has been shown to reduce pain while enhancing physical function, quality of life, and mental health in individuals with OA.<sup>197</sup> For example, the performance of 130 to 150 minutes/week of moderate-intensity, low-impact aerobics helps to manage pain, improve the ability to perform daily activities, improve the quality of life, decrease the level of fatigue, and improve ROM. This is complimented by better weight control and less metabolic abnormalities.<sup>141</sup>

Aquatic physical therapy is highlighted in Chapter 9 of this book. The benefits of a 12-week aquatic program in people with hip and knee OA has been demonstrated for pain reduction. In addition, it may improve self-reports of disability and improve quality of life.<sup>19,113</sup>

## Obesity

### Background

The obesity epidemic that plagues the US is becoming a global problem. The US no longer leads the world in the incidence of obesity.<sup>225</sup> For all age groups, including older adults, the obesity epidemic is increasing.<sup>251</sup> From 1980 to 2013, the estimated number of overweight or obese individuals worldwide increased to 36.9% in men and 38% in women.<sup>181</sup> More than 33% of people over 65 years of age in the US are obese; the incidence is greatest for the young old and least for the old-old.<sup>80</sup> The co-morbidity of obesity may compound other problems that impact older adults. Excessive abdominal adiposity is associated with increased risk of morbidity and mortality.<sup>270</sup>

### Changes in Body Composition

As people age, there are changes in the body composition with a decrease in the fat-free mass, an increase in fat mass, and

height loss from vertebral body compression and scoliosis. Abdominal adiposity, which is assessed by measuring the circumference of the waist, provides the clinician with insight into an individual's health status.<sup>61,123,174,176,177,198,253,271</sup> According to the National Institutes of Health, "Although waist circumference and BMI are interrelated, waist circumference provides an independent prediction of risk over and above that of BMI."<sup>176</sup> The American Heart Association, National Heart, Lung, and Blood Institute establishes >88 cm (35") for women and >102 cm (40") for men as the criteria for abdominal adiposity. The International Diabetes Federation<sup>236</sup> uses different cut-points for individuals of different ethnic groups with cut-points as low as >80 cm (31.5") for women and >90 cm (35.5") for men. In individuals of very short or very tall stature, waist circumference should be less than half of their height. For example, if a female patient is 1.44 m (4'9") in height, their waist circumference should be <72 cm (28.5"). This is more appropriate than using the cut-point of >88 cm (35").

In addition to measuring waist circumference, neck circumference may shed light into the potential of obstructive sleep apnea. A neck circumference  $\geq 16$ " (40.6 cm) in women and  $\geq 17$ " (43.2 cm) in men plus being overweight or obese are both risk factors for obstructive sleep apnea (OSA).<sup>4</sup> The prevalence of OSA increases between middle and older age. Neck size correlates with adiposity in non-athletic patients. When a large neck is noted on the inspection, the patient should be asked if they snore when sleeping, if sleep is interrupted, if they feel fatigued or unrefreshed in the morning, or if they feel irritable or forgetful.

### Impact on the Metabolic System

Individuals with visceral adiposity have increased risk of metabolic abnormalities, including decreased glucose tolerance, reduced insulin sensitivity, and abnormal lipid profiles, which increased the risk for T2DM and CV disease.<sup>123,132</sup> Other health risks associated with being overweight and obese include OA, sleep apnea, and hypertension.<sup>123</sup>

### Impact on the Respiratory System

The impact of obesity on the respiratory system is underappreciated.<sup>275</sup> Weight gain and increased body mass index are directly related with decreased lung volumes characteristic of restrictive lung dysfunction. Abdominal adiposity directly impacts diaphragmatic excursion, decreased inspiratory volume, and an increased work in breathing. Obesity hypoventilation syndrome may occur with clinical obesity when the body mass index is  $>30$  kg/m<sup>2</sup>. Secondary problems impairing respiration, such as hypercapnia, may occur in obese patients. When evaluating and treating an older adult with obesity, these comorbidities will have an effect on any exercise program and may require modification to maintain safe parameters.

## Considerations for Interventions

Health-care providers in a multitude of settings assess obesity through various measures, including BMI, waist-hip ratio, or simple waist circumference. To determine BMI, use a table,

smartphone app, or a person's weight in kilograms divided by height in meters squared. The formula for BMI is:

$$BMI = \text{weight (kg)} / [\text{height (m)}]^2$$

(in pounds and inches,  $BMI = \text{weight (lb)} / [\text{height (in)}]^2 \times 703$ )

In athletes and individuals who are muscular, BMI may overestimate body fat, and in older persons, BMI may underestimate body fat.<sup>45,49,174</sup> The WHO reports that it is unclear which measurement is most indicative of CV disease risk, while other references recommend use of waist to hip ratio due to the direct relationship of CV risk with central adiposity.<sup>40,59,198,253</sup>

Because of the relationship of obesity with restrictive lung dysfunction, it is critical to observe the older adult during any physical activity. Is breathing labored, noted by the use of accessory muscles of respiration? Does phonation decrease? Can the patient talk without shortness of breath at rest or with activity (talk test)? Does the patient limit their speech to take a breath (phonation)? If a patient has shortness of breath at rest, dyspnea on exertion, or a pulmonary problem such as emphysema, it may be appropriate to determine the patient's oxygen saturation. Does it decrease then with activity initiation and quickly return to baseline with activity cessation? What is the respiratory rate? Is the patient on supplemental oxygen? If not, is it necessary? Should it be titrated to a higher flow rate when performing exercise? Are sitting activities preferred over being recumbent due to orthopnea?

Looking at the whole patient is paramount. An obese patient who complains of knee pain must be counseled on the impact of obesity and the benefits of healthy eating and physical activity. To increase activity while decreasing the impact of ground reaction forces on the weight-bearing joints, utilize a pool for their exercise program (see Chapter 9) or have the patient exercise while sitting on a chair, mat, or large exercise ball. It is well established that patients who receive counseling will lose weight and exercise more than patients who do not receive counseling.<sup>246</sup> When working with overweight and obese patients, it is critical to avoid stigmatizing and stereotyping them.<sup>202,217</sup> Box 24.6 highlights key points when discussing weight loss with your patient.

## Importance of Exercise in Managing Obesity

Incorporating physical activity is essential for a successful weight loss program and in maintaining weight loss.<sup>74,121,132</sup> Weight loss through diet may result in loss of fat-free mass and lean body mass, while exercise combined with calorie restriction may prevent the loss of muscle. With the loss of muscle mass associated with aging, it is critical to optimize lean body mass by addressing obesity through a program that increases energy expenditure and decreases energy intake.<sup>49,74,32,251</sup>

## Cancer

### Background

Cancer falls behind heart disease as the second most common cause of death in the US. Aging is the greatest risk factor for developing cancer; it is referred to as a disease of the elderly,

### BOX 24.6 Considerations for Discussing Weight Loss<sup>202,217,246</sup>

- During the examination, address the patient's main physical therapy need first.
- If indicated, measure abdominal circumference at the midpoint between lower margin of last palpable rib and top of iliac crest in the standing position with a stretch resistant tape. Record "obesity" as a precaution.
- Perform secondary tests and measures as indicated including vital signs at rest, immediately post activity, and recovery.
- Explain findings to the patient in a nonjudgmental manner. For example, "Your body weight or waist size may increase your risk for health problems. Can we talk about my concerns?" Open discussion about weight respectfully using terms such as weight and unhealthy body weight. What is the patient's readiness to change?
- Employ the "teach back" method to ensure patient understands implications of obesity on their health status. The "teach back" method is when the patient (or family member) is asked to explain in their own words what was taught by the therapist to check for understanding.<sup>1,3</sup>
- Provide valuable resources, including possible referrals to dietitians, specialty clinics, and support groups.
- Document patient education.

with the median age for occurrence of all types of cancer being 68 years.<sup>78</sup> The lifetime probability of developing cancer is one in two for males and one in three for females. The likelihood of dying from cancer is one in four for males and one in five for females. It is estimated that nutrition, inactivity, and excess weight may account for 25% to 33% of cancers in high-income countries like the US.<sup>21</sup>

### Considerations for Interventions

Years after treatment has ended, the cancer survivor remains at risk for recurrence of the primary cancer, development of metastases, and/or development of new cancers. Metastasis may occur at any time; primary tumors may metastasize to secondary tumors in bone, lymph nodes, lung, liver, and brain. Cancers of the breast, lung, and prostate are more likely to metastasize to bone. The development of bone pain in a cancer survivor should be considered suspicious and a red flag. Initially the bone pain may cycle and increase with activity and then become continuous (ACS, bone metastasis). The pain may change and become aching or sharp in nature; skeletal pain should be considered as potential metastasis until proven otherwise.<sup>5,22</sup> When the spine is involved, spinal cord compression may occur.<sup>5</sup>

If there is metastasis to the bone, the patient is at risk for pathological fracture.<sup>5,22</sup> For example, an 80-year-old female patient who was cancer-free for 10 years presented with an acute spiral fracture of the humerus from lifting a toaster. Originally, this patient was screened for abuse and later found to have stage IV cancer with metastasis to the bone, lungs, and liver from her primary site of breast cancer. Thus, it is critical

to regularly screen patients despite a remote history of cancer. Because of the increased risk of pathologic fracture, modify the intensity as well as application site of resistance when designing strengthening programs.

A therapist working with a patient undergoing cancer treatment or a cancer survivor must consider the patient's laboratory values. However this information may not be readily accessible for therapists practicing in a free-standing practice setting. Consequently, it is essential to screen the patient for changes in health status. For example, increased fatigue when performing an exercise program may be indicative of a low hemoglobin level. Electronic medical records may allow access to important information such as platelets, white blood cell count, neutrophils, International Normalized Ratio (INR), red blood cell count, hemoglobin, and hematocrit. The reader is referred to Billek-Sawhney and Wells<sup>22</sup> for in-depth information on laboratory values of specific importance in the patient with cancer.

Hospitals may have specific criteria for when to hold therapy or proceed based on laboratory values. It is critical to consider in the goals for physical therapy. In hospitals, nursing homes, and home health therapy, ensuring the patient is safe to access the bathroom and perform ADLs is essential. This differs greatly from the performance of aerobic or resistance exercise for wellness. For example, a patient with a hemoglobin of 8.1 g/dL could be evaluated for their ability to walk around their home or room to perform basic ADLs but not for performance of resistance exercises.

When the neutrophils, a type of white blood cell, become critically low the patient is described as being neutropenic. This means that the patient is at high risk for bacterial infections. Therapists always need to adhere to infection control through proper hand washing and cleaning of equipment, as well as the wearing of a mask when experiencing cold-like symptoms. In addition, when working with patients at increased risk of infection, consider the benefit of treating them in a private treatment room or an area where there is less exposure to bacteria and other contaminants, or have them wear a mask to minimize risk of an airborne infection.

### Importance of Exercise With Cancer

The adoption of a physically active lifestyle (150 minutes of moderate-intensity aerobic activity each week) has been shown to be beneficial in preventing cancer, during cancer treatment, and during survivorship. This has been well documented for many forms of cancer.<sup>6</sup> The relationship between exercise and physical activity and maintaining an ideal body weight is related to a lower risk of colon, breast, lung, and prostate cancer. Regular physical activity has preventive benefits for cancer survivors and can reduce the risk of new chronic disease. In survivors with breast or colon cancer, the likelihood of recurrence or premature death is lessened in those who exercise.<sup>197</sup>

The deleterious effects of cancer and the treatments for it can be lessened through physical activity and exercise.<sup>22,222</sup> Rehabilitation may reduce the adverse effects of pain, fatigue,

strength loss, decreased CV capacity, lymphedema, depression, anxiety, osteoporosis or osteopenia, nausea, and numerous other side effects of treatment. Cancer-related fatigue is the most common complaint during cancer treatments. It affects 70% to 100% of individuals during and after cancer treatment and has been shown to be responsive to exercise. The benefits of exercise have been demonstrated with aerobic exercise and resistance exercise. Silver and Gilchrist<sup>222</sup> report a 40% to 50% lower fatigue level in cancer survivors who exercise.

## Type 2 Diabetes Mellitus

### Background

The incidence of T2DM is estimated to be 9.3% of the US population and is now in epidemic proportions. This percentage increases to 25.9% of individuals 65 years or older. Ninety percent to 95% of the cases of diabetes mellitus are T2DM.<sup>57</sup>

### Considerations for Interventions

#### Exercise Risks in T2DM

Considering the risk of coronary artery disease and other comorbidities of T2DM, it may be necessary for patients to have medical clearance prior to participating in an exercise program.<sup>164,195</sup> Uncontrolled metabolic disease, including T2DM, is considered a relative contraindication and a relative risk factor to exercise participation. The position statement by ACSM and the ADA state “exercise stress testing is advised primarily for sedentary individuals with diabetes who want to undertake activity more intense than brisk walking.”<sup>57</sup> Brisk walking, at 3 miles per hour or faster, falls into the category of moderate intensity exercise. The recommended RPE level of 12 to 13, or “somewhat hard,” on the original Borg RPE scale (see Box 25.4 in Chapter 25), is the corresponding description.<sup>9</sup>

#### Medical Monitoring

Electrocardiogram (ECG) stress testing is recommended for individuals who are:<sup>12,57</sup>

- Older than age 40 with or without CV disease risk factors not including T2DM
- Older than age 30 with one of the following: T2DM for more than 10 years, hypertension, cigarette smoking, dyslipidemia, retinopathy, or nephropathy
- Has known or suspected CAD, cerebrovascular disease, and/or peripheral neuropathy
- Has autonomic neuropathy
- Has advanced nephropathy with concomitant renal failure

In many PT practice settings, patients are commonly seen who have a known diagnosis of T2DM, are hypertensive, have CAD, neuropathy, nephropathy, retinopathy, and smoke. These characteristics may be commonly reported in the patient with T2DM following an amputation. Thus, if ECG results and/or testing has not been done or is not available, it is critical to initiate patients at a low-level exercise program and monitor responses.

### CLINICAL TIP

According to Curtis and colleagues,<sup>64</sup> normally with exercise there is an increase in heart rate that quickly returns to baseline. When this recovery is slowed in patients (i.e., the patients’ recovery is <22 beats/min at 2 minutes following exercise when measured in supine), it is considered an abnormal hemodynamic response; the physician should be notified and an ECG recommended.

### Hypoglycemia and Insulin

Hypoglycemia is reported as the “most serious problem” for people with diabetes.<sup>195</sup> The risk of hypoglycemia (low BG level) is less common in individuals with T2DM who do not take insulin or insulin-releasing medications, also known as secretagogues. Those individuals who do use insulin or secretagogues should supplement their exercise with carbohydrates to prevent hypoglycemia. Exercise should not be initiated if the BG is too low or too high. Exercise guidelines based on BG levels are described in Table 24.7. If these guidelines are impractical in some practice settings, the recommendation of using 100 to 300 mg/dL is employed for exercise.<sup>12,191</sup>

**PRECAUTIONS:** When working with individuals with T2DM who use insulin:<sup>191,244</sup>

- Avoid exercise when insulin is peaking.
- Advise the patient to exercise the same time each day.
- Consider the timing of the last meal, regularly assess the blood sugar level; if it is low, have the patient eat and delay exercise; if it is high, be cautious and carefully monitor the patient when exercising.
- Use caution when exercising the muscles where the insulin was just injected to avoid speeding up the pharmacodynamics.
- Maintain hydration.
- Recognize that hypoglycemia may occur for up to 48 hours post exercise.
- Assess feet for absence of protective sensation.

With the advent of insulin pumps, also known as continuous subcutaneous insulin infusion (CSII), individuals with diabetes have continuous subcutaneous insulin delivery to attain a tighter glucose control and less BG excursions. The safety guidelines for insulin pumps are commonly provided by the pump manufacturer.<sup>33,99,142</sup> In general, with exercise the amount of insulin from the pump should be less due to the exercise-induced BG drop. This can be programmed into the pump by the patient. Thus, it is recommended that patients check their blood sugar level before, during, or after exercise, especially when new to exercise or having recently received an insulin pump. The above guidelines should be employed and, in general, if exercise is greater than 30 minutes additional carbohydrates are suggested. In addition, the amount of insulin may need to be decreased after exercise. Caution should be used to avoid friction from exercise around the infusion site.<sup>15</sup>

**TABLE 24.7** Exercise Guidelines Based on Blood Glucose Levels (Modified from Partridge et al<sup>191</sup> with permission)

Blood Glucose Level	What To Do	Comments
<70 mg/dL	Exercise should not be initiated	Immediately provide carbohydrates (fruit juice, hard candy, glucose table or gel) and recheck blood glucose; seek emergent medical attention if symptoms worsen
70–100 mg/dL	Snack	15 g carbohydrate every hour of mild-moderately intense activity; 25-50 g with moderate or greater intensity; hydrate
100–300 mg/dL	Proceed with exercise program	Strenuous activity or activity of long duration (1-2 hr) requires increased carbohydrate intake; hydrate well
>300 mg/dL and on oral medications	Trial of activity 10-15 min and recheck	If blood glucose rises, stop activity; if blood glucose drops, continue checking every 10-15 min
>300 mg/dL and on insulin	Check for ketosis (urine dipstick or glucometer that measures ketosis)	If (+) ketones, avoid activity; if (-) ketones, participate with close blood glucose monitoring every 10-15 min

### Other Complications

The presence of underlying microvascular complications such as retinopathy, nephropathy, and peripheral and/or autonomic neuropathy provides the clinician with insight into the severity of T2DM and the patient's ability to exercise. In these individuals caution must be employed to avoid high-intensity exercises due to the risk of potentially worsening the microvascular complications.<sup>57,95,191</sup> In addition, it is critical to perform a comprehensive foot examination and assess shoe wear due to the potential of insensitve feet, Charcot joint, neuropathy, and/or neuropathic ulcers.

### Importance of Exercise in Managing T2DM

The management of T2DM is described as a three-pronged approach that includes exercise, diet, and medication.<sup>57,91,191</sup> These three prongs should be grounded on a solid base of patient education. Education is critical for self-management in regard to exercise, diet, and pharmacotherapy. It is essential to realize that improvements can be made in the systemic insulin action through exercise. Moderate aerobic exercise improves blood sugar levels and insulin action. Furthermore, combining aerobic and resistance exercise is more effective than either intervention alone.<sup>57</sup> A 12-week resistance exercise program was found to improve muscle strength and function in older adults who were either healthy, prediabetic, or diagnosed with T2DM. Regular exercise and physical activity for individuals with T2DM can reduce the risk of other diseases and help improve body weight. There are greater benefits with increased time and greater intensity of exercise.<sup>197</sup>

## Urinary Incontinence

### Background

Urinary incontinence affects from 26% to 46% of older adults.<sup>32,94,266</sup> It is associated with advancing age, impaired cognition, and decreased mobility. In men it may follow

treatment of prostate cancer, and in women it may occur after menopause due to the decrease in estrogen levels. Despite this, it is not considered a normal occurrence of primary aging. In stress urinary incontinence (SUI), the muscles that help with micturition may become weak from loss of muscle mass and disuse so that urine may escape with little pressure. Depending on the resource, there are four to five types of incontinence; Box 24.7 highlights the most common forms.<sup>32,94,247,266</sup> SUI occurs when coughing, laughing, sneezing, jogging, or jumping cause pressure on the bladder that is not stopped by muscular contraction. Urge, overactive bladder, functional incontinence, or overflow incontinence may occur in isolation or in combination with each other.

### BOX 24.7 Common Forms of Urinary Incontinence

#### Stress Urinary Incontinence

- Most common form of incontinence
- Weak pelvic floor muscles that allow urine to escape when exercising, sneezing, lifting, or even laughing

#### Urge Urinary Incontinence (aka Overactive Bladder)

- The bladder muscles contract and pass urine before the bladder is full causing a need to urinate, described as "key in the door" syndrome in which leakage begins prior to accessing the toilet

#### Mixed Incontinence

- When the patient experiences both SUI and urge incontinence

#### Functional Incontinence (aka Insensible Urinary Incontinence)

- The person may be unaware of the need to go to the toilet (insensible) or may not get to the toilet in time due to functional mobility limitations (functional)

## Considerations for Interventions

In addition to medication and/or surgery, the management of SUI may include referral to physical therapy for the pelvic floor exercises, as well as lifestyle, and behavioral changes.<sup>32,94,266</sup> The basics of this specialty area of practice are valuable for all physical therapists and assistants working with older adults in every practice setting. Pelvic floor musculature exercises can be taught in various ways to increase strength and develop bladder control.<sup>82</sup> Within 3 to 6 weeks of daily muscular strengthening exercise, bladder control may improve. Similar to traditional strengthening, changes may occur initially from neural adaptations but may take as long as 3 months, and overexercising may result in overwork weakness. If improvements are not noted, the patient should be referred to a physical therapist who specializes in treatment of the pelvic floor.

## Importance of Exercise in Managing Incontinence

Pelvic floor exercises are an effective approach of conservative management of incontinence.<sup>76</sup> These exercises are described in Chapter 25. The treatment of pelvic organ prolapse, painful intercourse, and other pelvic floor issues are beyond the scope of this text. For additional information the reader is referred to the APTA's Section on Women's Health.<sup>28,34</sup>

## Summary

Contrary to the ageism stereotype that an older adult cannot learn new things, the older adult, most assuredly, can learn. "Because it may take older adults more time to encode, store, and retrieve information, the rate at which new information is learned can be slower, and older adults have a greater need for repetition of new information."<sup>13</sup> This may be the case with exercise. Changes associated with aging can be combated with exercise and physical activity but require a long-term commitment. Physical activity through exercise is a viable option to pharmacological interventions for both disease prevention and management of disease.<sup>129,164</sup>

There are many stereotypes associated with aging, one being that once you are "old" you cannot get stronger! That is a myth that must change through patient education, appropriate interventions, and role modeling. It is critical to

become the change agent and create this paradigm shift away from underdosed strengthening, flexibility, endurance, and balance activities to examining the patient's status, prescribing appropriate interventions, and modifying and adjusting the patient's exercise program as the patient's status changes. Physical therapists must look at the total patient and incorporate wellness and walk the talk! A summary of practice considerations to promote physical activity in the older adult are presented in Box 24.8.

### BOX 24.8 Physical Therapy Practice Considerations to Promote Physical Activity in the Older Adult

#### "Walk the Talk"

- Encourage older adults and role model a paradigm shift from being sedentary to becoming active after retirement.
- Be visible and excited with exercise and physical activity ideas.
- Create an environment for patient socialization.
- Encourage adherence to a routine.
- Demonstrate an interest in patients' activity level.
- Encourage other members of your department or clinic in the process.
- Promote physical activity by having flyers on display, sponsoring programs, and being visible in the community.
- Assess and promote physical activity with EVERY patient.
- Prescribe the appropriate level of physical activity after determining readiness to change.
- Provide the appropriate exercise prescription that addresses the patient's level and allows for continued improvement, and modify the interventions as the patient's status changes.
- Ensure that the interventions meet the interests and abilities of the older adult.
- Serve as a resource following discharge from physical therapy.
- Consider having an onsite wellness program for patients at a nominal cost.
- Provide a resource list of local community programs and professionals that can be recommended to patients.
- Develop a network for exercise referrals.
- Be available to the patients and referral sources for consultation, guidance, and collaboration.

## Independent Learning Activities

### Critical Thinking and Discussion

- Review the subpopulations of older, young-old, mid-old, and old-old adults. In small groups, discuss various older adults that you know who are in each subpopulation in each of these categories that reflect healthy aging and non-healthy aging. Describe their physical presentation and functional mobility.
- Reflect on the “Choosing Wisely” initiative between the APTA and the American Board of Internal Medicine Foundation and underdosed strength training programs in older adults. How does this compare to your observations and practice as a student or therapist? What could be done to change the following interventions to “dose-appropriate” strengthening? Change the following three exercises to be dose appropriate: (a) full arc knee extension, leg kicks with a 2-lb weight, (b) rowing with elastic resistance band while in a sitting position against back support, and (c) performing standing mini-squats with a walker.
- Apply the WAMI-3 to the following scenarios to explain to a patient the need to participate in resistance exercise: (a) a patient with knee OA who has pain and difficulty descending stairs, (b) a patient with peripheral vascular insufficiency, and (c) a patient who had a femoral neck fracture and open reduction with internal fixation.
- Differentiate the primary and secondary aging process for the patients in Box 24.1.
- Develop an in-service instructional presentation that addresses changes with aging and the importance of physical activity and resistance exercise.
- How does a lifestyle of sedentary behavior negatively impact older adults? How is this reflected on the WAMI-3 Model?
- Why is it critical to perform standardized tests when examining older adult patients? What tests would be most appropriate to perform in a home health setting where there is not a clear path to assess gait? What tests would be most appropriate for the older adult patient being seen in an inpatient physical therapy setting?
- An older adult patient with a new diagnosis of osteoporosis is being seen bedside in an acute care hospital following a spinal compression fracture of T10; the patient does not want to participate in physical therapy. Discuss strategies that can be used to educate and motivate the patient to address the benefits of therapy and deleterious effects of immobility.
- A 78-year-old male patient is being seen in an acute care hospital secondary to sepsis following a pacemaker replacement. He is able to ambulate at 0.3 m/s. Document the assessment or professional interpretation of this test to qualify him for skilled physical therapy in a nursing home following acute discharge.
- Similar to Question 9, this patient performs the FTSTS but requires the use of his hands to perform five repetitions in 25 seconds. Document the test results and the professional interpretation of the performance on the test.
- Why is it essential to include power exercises in a strength training program of older adults?
- A 68-year-old female patient who is obese experiences an increase in her OA hip pain following the initiation of a resistance training program. What may have caused this pain? What should be done to address the pain?
- What techniques can be employed to initiate the conversation of weight loss with older adult patients?
- What questions should be incorporated into the patient interview of a 65-year-old patient with T1DM or T2DM to ensure the patient can tolerate resistance exercise? What strategies can be employed to ensure that the patient continues resistance training after discharge from physical therapy?
- You observe that your new 72-year-old female patient uses accessory muscles when breathing and has decreased phonation, a blue tinge to lips, and clubbing of the digits. What special precautions will you need to employ when working with this patient?

### Laboratory Practice

- Develop and perform a comprehensive/multidimensional program of exercises for each of the patients in Box 24.1.
- Develop and perform interventions for primary, secondary, and tertiary osteoporosis for the patients in Table 24.6.
- A 91-year-old female who lives independently at home is interested in “getting stronger.” Her past medical history includes a transient ischemic attack, osteoporosis, myocardial infarction, breast cancer, and pelvic sling surgery for incontinence. She has a history of three falls in the past year. She has a wheeled walker that she is willing to use outside her home. Develop a comprehensive program—including education—that can be done using the following: the counter at her kitchen sink, the flight of steps to her second floor with one railing, and a standard kitchen chair with arm rests. Explain how “getting stronger” includes balance and aerobic capacity.
- A 65-year-old male travels frequently for his work. He would like to use elastic resistance bands and/or his own body weight for strengthening. Develop a comprehensive program working 8 to 10 major muscle groups including his core.
- Perform each of the tests and measures described in this chapter, including TUG, gait speed, 30s-STs, FTSTS, and the tragus-to-wall measure.

## Case Studies

1. Using Case Study 1 described in Box 24.1, answer the following questions:
  - a. On examination of Lou for his left knee pain, it is apparent that he has restricted ankle dorsiflexion with tightness of his gastrocnemius tighter than his soleus muscle. What specific stretches are recommended for Lou? What specific instructions should be given to Lou? Develop written instructions.
  - b. Lou demonstrates hip internal rotation and increased knee pain on reciprocal stair descent. Demonstrate and perform specific interventions that can be performed without equipment.
  - c. Address the above muscle weakness problem again, but employ weight lifting equipment.
2. Using Case Study 2 described in Box 24.1 the following is observed as you walk Mary Jane back to the examining room:
  - a. Mary Jane appears to be frail and has a very kyphotic posture, causing her to be bent and look down toward the floor. While ambulating toward the examination room, you note she has an effective gait speed but has two episodes where she demonstrates a deviation in her path. From this brief introduction, what critical questions should you ask this patient? What tests should you perform to further assess balance?
  - b. What measurements should be taken as a result of the observation of flexed posture? Are there any red flags that warrant safety precautions and possible referral for bone density testing? If so, what are they?
- c. Mary Jane frequently has episodes of dizziness that may be caused by her cardiac medications. Also, her prescription for beta blockers may blunt her heart rate response to exercise. What precautions will be necessary while she exercises?
- d. Based on Mary Jane's vertical height loss, document the assessment and the need to rule out osteoporosis and propose appropriate recommendations.
3. Using Case Study 3 described in Box 24.1, answer the following questions:
  - a. How have the neuromuscular and musculoskeletal complaints affected Juan's functional independence and ability to participate in social activities outside his home?
  - b. Juan is not willing to attend outpatient physical therapy and states he will perform only three exercises. What exercises would you recommend that he perform and why those three exercises?
  - c. Write "1" objective and measurable goal for Juan related to educating him on the importance of physical activity and exercise that meets documentation guidelines for reimbursement.
  - d. What specific tests and measures would best measure the decline in Juan's functional mobility?
  - e. Document Juan's performance on the 30s-STS test, the interpretation of these findings, and an appropriate goal. When performing STS, Juan requires use of his arms. He is only able to perform four repetitions.

Throughout a woman's life cycle, specific gender differences need to be recognized for their relevance to rehabilitation. Recent research has shown repeatedly that women have specific and distinct physiological processes that extend beyond the obvious considerations of anatomy and hormones, including differences in symptoms of heart attacks and in metabolism of medications.<sup>77</sup> Clearly, the pregnant or postpartum patient presents a unique gender-based clinical challenge for the physical therapist. Although pregnancy is a time of tremendous musculoskeletal, physiological, and emotional change, it is nonetheless a state of wellness. Pregnant women are typically well motivated, willing to learn, and highly responsive to treatment suggestions. For

many women, the therapist is able to assess and monitor the physical changes with the primary focus on maintaining wellness. The ability to educate women about the role of exercise and health promotion during this key life transition provides a significant professional opportunity and responsibility.

In cases of musculoskeletal impairment related to pregnancy, the therapist is able to examine and treat the patient by incorporating knowledge of injury and tissue healing with knowledge of the changes during pregnancy. By considering a broader, lifespan perspective, all female patients can benefit from education regarding the role of the pelvic floor muscles in musculoskeletal health, specifically in

trunk stabilization. Evidence is growing regarding prevention of pelvic floor impairments; when women receive individualized interventions, improvement is seen in pelvic floor awareness and activation and in symptom reduction.<sup>17,53,86,87</sup> Specialized treatment of pelvic floor dysfunction is critical to quality of life (QOL) for women experiencing incontinence, pelvic organ prolapse (POP), and a variety of pelvic pain syndromes. As a natural progression of expertise in pelvic floor interventions, physical therapists are also treating males with urinary incontinence and other pelvic floor impairments. Although all physical therapists can easily incorporate activation of the pelvic floor muscles as a key component of trunk stabilization and training in body mechanics, true proficiency can come only with further training and mentoring. Advanced study of pelvic floor anatomy, evaluation, and treatment is highly recommended for therapists who wish to specialize in this area. Clinical Specialization in Women's Health (WCS), available through the American Physical Therapy Association since 2010, is another option for postgraduate training.

This chapter provides readers with basic information about the systemic changes of pregnancy as a foundation for the development of safe and effective exercise programs. In addition, a review of pelvic floor anatomy, function, and dysfunction serves as an introduction to the treatment of pelvic floor disorders. The chapter emphasizes modification of general exercises to meet the needs of the obstetric patient and provides information to assist in the development of an exercise program for an uncomplicated pregnancy. Cesarean delivery, high-risk pregnancy, and the special needs of patients with these conditions are also discussed.

## Overview of Pregnancy, Labor, and Related Conditions

### Characteristics of Pregnancy and Labor

#### Pregnancy

Pregnancy, which spans 40 weeks from conception to delivery, is divided into three trimesters, with characteristic changes during each.<sup>78,102</sup>

#### First Trimester Changes

During the first trimester (weeks 0 through 12), the following occur:

- Implantation of the fertilized ovum in the uterus occurs 7 to 10 days after fertilization.
- The mother is very fatigued, urinates more frequently, and may experience nausea and/or vomiting ("morning" sickness).
- Breast size may increase.
- There is a relatively small weight gain of 0 to 1,455 g (0 to 3 lb is normal).
- Emotional changes may occur.
- By the end of the 12th week, the fetus is 6- to 7-cm long and weighs approximately 20 g (2 oz). The fetus now can kick, turn its head, and swallow and has a beating heart, but these movements are not yet felt by the mother.

#### Second Trimester Changes

During the second trimester (weeks 13 through 26), the following occur:

- The pregnancy becomes visible to others.
- The mother begins to feel movement at around 20 weeks.
- Most women now feel very good. Nausea and fatigue have usually disappeared.
- By the end of the second trimester, the fetus is 19 to 23 cm (14 in.) in length and weighs approximately 600 g (1 to 2 lb).
- The fetus now has eyebrows, eyelashes, and fingernails.

#### Third Trimester Changes

During the third trimester (weeks 27 through 40), the following occur:

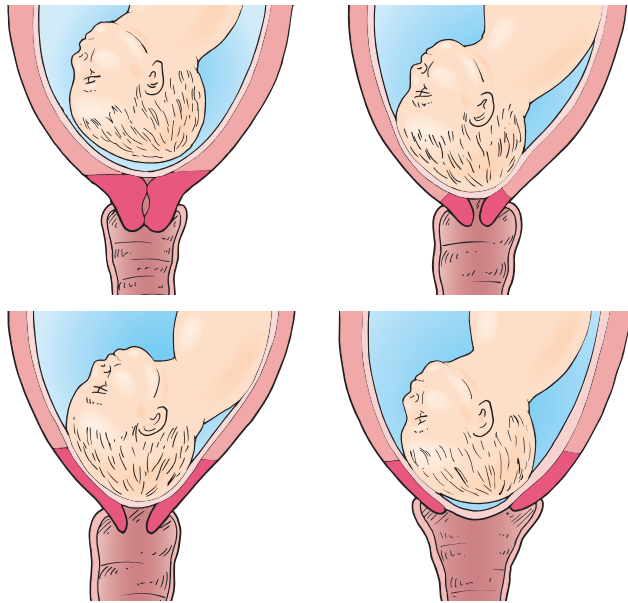

- The uterus is now very large and has regular contractions, although these may be felt only occasionally.
- Common complaints during the third trimester are frequent urination, back pain, leg edema and fatigue, round ligament pain, shortness of breath, and constipation.
- By the time of birth, the baby will be 33- to 39-cm long (16 to 19 in.) and will weigh approximately 3,400 g (7 lb, although a range of 5 to 10 lb is normal).

**NOTE:** Although pregnancy typically lasts 40 weeks, the range of 38 to 42 weeks is considered full term.

#### Labor

Labor is divided into three stages, each containing specific events.<sup>22,78</sup> While the exact mechanism that initiates labor is not known, continued study reveals the complexity of the hormonal triggers from both the maternal and fetal circulation.<sup>95</sup> Regular and strong involuntary contractions of the smooth muscles of the uterus are the primary symptom of labor. True labor produces palpable changes in the cervix, which are known as effacement and dilation (Fig. 25.1).

- **Effacement** is the shortening or thinning of the cervix from a thickness of 5 cm (2 in.) before onset of labor to the thickness of a piece of paper.
- **Dilation** is the opening of the cervix from the diameter of a fingertip to approximately 10 cm (4 in.).

**FIGURE 25.1** Effacement and dilation of the cervix. (Adapted from Ward, S, and Hisley, S: *Maternal-Child Nursing Care*. Philadelphia: F.A. Davis, 2009, with permission.)

### Labor: Stage 1

Some women experience initial cervical dilation and effacement before they are in true labor. However, by the end of this stage, the cervix is fully dilated, and there is no doubt that a baby is about to be delivered. Stage 1 of labor is divided into three major phases.

**Cervical dilation phase.** The cervix dilates from 0 to 3 cm (0 to 1 in.) and will almost completely efface. Uterine contractions occur from the top down, causing the cervix to open and pushing the fetus downward.

**Middle phase.** The cervix dilates from 4 to 7 cm (1 to 3 in.). Contractions are stronger and more regular.

**Transition phase.** The cervix dilates from 8 to 10 cm (3 to 4 in.), and dilation is complete. Uterine contractions are very strong and close together.

### Labor: Stage 2

Stage 2 involves “pushing” and expulsion of the fetus. Intra-abdominal pressure is the primary force expelling the fetus; it is produced by voluntary contraction of the abdominal muscles and diaphragm. Relaxation and stretching of the pelvic floor during stage 2 are also necessary for successful vaginal delivery. Uterine contractions may last as long as 90 seconds during this stage.

**Fetal descent.** Position changes (cardinal movements) by the fetus allow it to pass through the pelvis and be born (Fig. 25.2).<sup>78</sup> The position changes are described as:

- **Engagement.** The greatest transverse diameter of the fetal head passes through the pelvic inlet (the superior opening of the minor pelvis).
- **Descent.** Continued downward progression of the fetus occurs.

- **Flexion.** The fetal chin is brought closer to its thorax; this occurs when the descending head meets resistance from the walls and floor of the pelvis and the cervix.
- **Internal rotation.** The fetus turns its occiput toward the mother’s symphysis pubis when the fetal head reaches the level of the ischial spines.
- **Extension.** The flexed fetal head reaches the introitus; the fetus extends its head, bringing the base of the occiput in direct contact with the inferior margin of the maternal symphysis pubis; this phase ends when the fetal head is delivered.
- **External rotation.** The fetus rotates its occiput toward the mother’s sacrum to allow the fetal shoulders to pass through the pelvis.

**Expulsion** The fetal anterior shoulder passes under the symphysis pubis, and the rest of the body follows.

### Labor: Stage 3

**Placental stage (expulsion of the placenta).** After delivery, the uterus continues to contract and shrink, causing the placenta to detach and be expelled.

- As the uterus decreases in size, the placenta detaches from the uterine wall, blood vessels are constricted, and bleeding slows. This can occur 5 to 30 minutes after the baby is delivered.
- A hematoma forms over the uterine placental site to prevent further significant blood loss; mild bleeding persists for 3 to 6 weeks after delivery.

**Uterine involution.** The uterus continues to contract and decrease in size for 3 to 6 weeks after delivery; the uterus always remains slightly enlarged over its prepregnant size.

## Anatomical and Physiological Changes of Pregnancy

Considerable changes occur in the woman’s body as the pregnancy progresses.<sup>7,22,67,78,</sup>

### Weight Gain During Pregnancy

Current recommendations for weight gain during a singleton pregnancy are an average of 25 to 35 lb<sup>71,78</sup> with a distribution as shown in Box 25.1.

### Changes in Organ Systems

#### Uterus and Related Connective Tissue

**Uterus.** The uterus increases from a prepregnant size of 5 by 10 cm (2 by 4 in.) to 25 by 36 cm (10 by 14 in.). It increases five to six times in size, 3,000 to 4,000 times in capacity, and 20 times in weight by the end of pregnancy. By the end of pregnancy, each muscle cell in the uterus has increased approximately 10 times over its prepregnancy

**FIGURE 25.2** Principal movements in the mechanism of labor and delivery, left occiput anterior position. (From Ward, S, and Hisley, S: Maternal-Child Nursing Care. Philadelphia: F.A. Davis, 2009, with permission.)

### BOX 25.1 Total Weight Gain (Ranges) for Single Fetus

■ Baby	3.36–3.88 kg	(7–8 lb)
■ Placenta	0.48–0.72 kg	(2–3 lb)
■ Amniotic fluid	0.72–0.97 kg	(2–3 lb)
■ Uterus and breasts	2.42–2.66 kg	(4–8 lb)
■ Blood and fluid	1.94–3.99 kg	(4 lb)
■ Fat stores	0.48–2.91 kg	(5–9 lb)
■ Total:	9.70–14.55 kg	(25–35 lb)

length.<sup>125</sup> Once the uterus expands upward and leaves the pelvis, it becomes an abdominal rather than a pelvic organ.

**Connective tissues.** Ligaments connected to the pelvic organs are more fibroelastic than ligaments supporting joint structures. The fascial tissues, which surround and enclose

the organs in a continuous sheet, also include a significant amount of smooth muscle fibers.<sup>38</sup> The round and broad ligaments, as well as the cardinal-uterosacral complex, all provide suspensory support for the uterus.

### Urinary System

**Kidneys.** The kidneys increase in length by 1 cm (0.5 in.).

**Ureters.** The ureters enter the bladder at a perpendicular angle because of uterine enlargement. This may result in a reflux of urine out of the bladder and back into the ureter; therefore, during pregnancy, there is an increased chance of developing urinary tract infections because of urinary stasis.

### Pulmonary System

**Hormonal influences.** Hormone changes affect pulmonary secretions and rib cage position.

- Edema and tissue congestion of the upper respiratory tract begin early in pregnancy because of hormonal changes.

Hormonally stimulated upper respiratory hypersecretion also occurs.

- Changes in rib position are hormonally stimulated and occur prior to uterine enlargement. The subcostal angle progressively increases; the ribs flare up and out. The anteroposterior and transverse chest diameters each increase by 2 cm (1 in.). Total chest circumference increases by 5 to 7 cm (2 to 3 in.) and does not always return to the prepregnant state.
- The diaphragm is elevated by 4 cm (1.5 in.); this is a passive change caused by the change in rib position.

**Respiration.** Respiration rate is unchanged, but depth of respiration increases.<sup>78</sup>

- Tidal volume and minute ventilation increase, but total lung capacity is unchanged or slightly decreased.<sup>78,125</sup>
- There is a 15% to 20% increase in oxygen consumption; a natural state of hyperventilation exists throughout pregnancy to meet the oxygen demands of pregnancy.<sup>78,125</sup>
- The work of breathing increases because of hyperventilation; dyspnea is present with mild exercise as early as 20 weeks into the pregnancy.<sup>78,125</sup>

## Cardiovascular System

**Blood volume and pressure.** Blood volume progressively increases 35% to 50% (1.5 to 2 L) throughout pregnancy and returns to normal by 6 to 8 weeks after delivery.

- Plasma increase is greater than red blood cell increase, leading to the “physiologic anemia” of pregnancy, which is not a true anemia but is representative of the greater increase of plasma volume. The increase in plasma volume occurs as a result of hormonal stimulation to meet the oxygen demands of pregnancy.
- Venous pressure in the lower extremities increases during standing as a result of increased uterine size and increased venous distensibility.
- Pressure in the inferior vena cava rises in late pregnancy, especially in the supine position, because of compression by the uterus just below the diaphragm. In some women, the decline in venous return and resulting decrease in cardiac output may lead to symptomatic supine hypotensive syndrome. The aorta is partially occluded in the supine position.
- Blood pressure decreases early in the first trimester. There is a slight decrease of systolic pressure and a greater decrease of diastolic pressure. Blood pressure reaches its lowest level approximately midway through pregnancy and then rises gradually from midpregnancy to reach the prepregnant level approximately 6 weeks after delivery. Although cardiac output increases, blood pressure decreases because of venous distensibility.

**Heart.** Heart size increases, and the heart is elevated because of the movement of the diaphragm.

- Heart rhythm disturbances are more common during pregnancy.

- Heart rate usually increases 10 to 20 beats per minute by full term and returns to normal levels within 6 weeks after delivery.
- Cardiac output increases 30% to 60% during pregnancy and is most significantly increased when a woman is in the left side-lying position, in which the uterus places the least pressure on the aorta.

## Musculoskeletal System

**Abdominal muscles.** The abdominal muscles, particularly both sides of the rectus, as well as the linea alba, are all subjected to significant biomechanical changes and become stretched to the point of their elastic limit by the end of pregnancy. This greatly decreases the muscles’ ability to generate a strong contraction and thus decreases their efficiency of contraction. The shift in the center of gravity as the baby grows also decreases the mechanical advantage of the abdominal muscles.<sup>68,125</sup>

**Pelvic floor muscles.** The pelvic floor muscles, in their anti-gravity position, must withstand the total change in weight; the pelvic floor drops as much as 2.5 cm (1 in.) as a result of pregnancy.<sup>120</sup>

**Connective tissues and joints.** The hormonal influence on the ligaments is profound, producing a systemic decrease in ligamentous tensile strength. Joint laxity has been measured in multiple joints during pregnancy and postpartum, with attempts to correlate hormonal levels with changes in joint stability and also to determine the connection between musculoskeletal impairments related to childbearing with levels of estradiol, progesterone, relaxin, and cortisol. A longitudinal study of 35 pregnant women that measured wrist laxity showed increases in each of the above serum levels with significant correlation found only between cortisol levels and increased laxity. The authors propose that individual differences in hormonal receptors could account for the mixed findings over many years of studies. Better understanding of these hormonal influences is pertinent as it relates to persistent pelvic pain or risk of POP.<sup>84</sup>

- Clinically, it appears that these physiological changes lead to increased vulnerability to injury in weight-bearing joints of the back, pelvis, and lower extremities during pregnancy.

## Thermoregulatory System

**Metabolic rate.** During pregnancy, basal metabolic rate and heat production increase.<sup>4</sup>

- An additional intake of 300 calories per day is needed to meet the basic metabolic needs of pregnancy.
- In pregnant women, normal fasting blood glucose levels are lower than in nonpregnant women.<sup>4</sup>

## Changes in Posture and Balance

### Center of Gravity

The center of gravity shifts upward and forward because of the enlargement of the uterus and breasts. This requires

postural compensations to maintain balance and stability (Fig. 25.3).<sup>7,67,125</sup>

- The *lumbar and cervical lordoses* increase to compensate for the shift in the center of gravity.
- The *shoulder girdle and upper back* become rounded with scapular protraction and upper extremity internal rotation because of breast enlargement; this postural tendency persists in the postpartum period due to infant care demands. Tightness of the pectoralis muscles and weakness of the scapular stabilizers may be preexisting to or induced by the pregnancy postural changes.
- The *suboccipital muscles* respond in an effort to maintain appropriate eye level (optical righting reflex) and to moderate forward head posture along with the change in shoulder alignment.
- A tendency toward genu recurvatum will shift weight toward the heels in an attempt to counteract the anterior pull of the growing fetus.
- Changes in posture do not automatically correct after childbirth, and the pregnant posture may become habitual. In addition, many childcare activities contribute to persistent postural faults and asymmetry.

**FIGURE 25.3** Change in posture as pregnancy progresses: (A) 23 weeks, (B) 34 weeks.

### Balance

With the increased weight and redistribution of body mass, there are compensations to maintain balance.<sup>7,125</sup>

- The pregnant woman usually walks with a wider base of support and increased external rotation at the hips.

- This change in stance, along with growth of the baby, makes some activities such as walking, stooping, stair climbing, lifting, reaching, and other activities of daily living (ADLs) progressively more challenging.
- Activities requiring fine balance and rapid changes in direction, such as aerobic dancing and bicycle riding, may become difficult to do, especially during the third trimester, so added caution is necessary in order to avoid falling.<sup>4</sup>

## Overview of Pelvic Floor Anatomy, Function, and Dysfunction

Treatment of pelvic floor impairments has become more visible and available in the physical therapy community over the past 15 to 20 years. As a result, both male and female clients with pelvic floor dysfunction are now seeking, and being referred for, rehabilitation in larger numbers. Advanced and in-depth study of anatomy, including internal pelvic floor muscle assessment, physiology, evaluation, and treatment, continues to be highly recommended for therapists who specialize in this area. Physicians and consumers, particularly with the increase of social media use, are also more aware of the need for expert practitioners when seeking treatment for pelvic floor dysfunction. As an example, a closed Facebook support group for women experiencing POP attracted over 3,000 members in less than 4 years (from 2011 to 2015), representing all 50 states in the United States and 38 countries, with ages ranging from teens to mid-80s.<sup>101</sup>

### Pelvic Floor Musculature

The pelvic floor musculature is composed of multiple elements in a funnel-shaped orientation, with bony attachments to the pubic bone and the coccyx. Laterally, the tissues blend into a fascial layer overlying the obturator internus. The prime mover of the pelvic floor is the levator ani. The levator ani, in combination with the coccygeus, forms the pelvic diaphragm. The most superficial muscles of the pelvic floor include the superficial transverse perineal muscles, the ischiocavernosus, the bulbocavernosus (called bulbospongiosus in men), and the external anal sphincter. Both the right and left sides of the pelvic floor complex contribute fibers to the perineal body located superficially between the vagina/scrotum and external anal sphincter (Fig. 25.4). The structure and action of the muscles of each layer are summarized in Table 25.1. The combined action of these muscles creates a superior force toward the heart and a puckering or drawstring motion around the sphincters.<sup>112</sup>

**FIGURE 25.4** Pelvic floor muscles. (A) Sagittal section—note sling/hammock orientation; (B) viewed from below—note figure-eight orientation of the muscles around the orifice of the urethra/vagina and the anal sphincter; and (C) posterior view—note the funnel shape of the pelvic muscles.

### Female Pelvic Floor

The female pelvic floor allows for passage of the urethra, vagina, and rectum. This automatically results in less intrinsic stability and pelvic organ support when compared to the male anatomy. The urogenital hiatus is the opening through which the urethra and vagina pass; measurement of this opening is being used as an objective measure in research design.<sup>119</sup>

### Innervation

Recent cadaveric studies have uncovered many variations in configuration of the nerves to the pelvic floor complex.<sup>11,59,124</sup> The nerve supply to the perineal tissues includes the pudendal nerve (with its three terminal branches, the dorsal, perineal and rectal), the levator ani nerve, and direct branches from the sacral nerve roots, with conflicting findings as to sacral levels. These dual and variable innervations provide a safeguard in particular against damage during labor and vaginal delivery, which would be more likely with a single-nerve arrangement.

### Function

The pelvic floor musculature has the following essential roles:

- Provide support for the pelvic organs and their contents
- Withstand increases in intra-abdominal pressure —“shock absorber”
- Contribute to stabilization of the spine/pelvis for postural stability<sup>109</sup>
- Sphincteric closure of urethra, vagina, and anus
- Sexual response

### Effect of Childbirth on the Pelvic Floor

#### Neurological Compromise

Stretch and compression of the pudendal and levator ani nerves occur during labor as the baby’s head travels through the birth canal. This stretch can be 20% to 35% of the total

**TABLE 25.1** Female and Male Pelvic Floor Anatomy: From Superficial to Deep

Muscle Layer	Structure	Action
<b>Superficial (outlet: primarily sexual function)</b>		
	Ischiocavernosus	Maintains erection of clitoris or penis
	Bulbocavernosus in females; bulbospongiosus in males	Vaginal “sphincter” closure, erection of clitoris or penis, empties urethra in males
	Superficial transverse perineal	Fixes perineal body
	External anal sphincter	Closure of anus

*Continued*

**TABLE 25.1** Female and Male Pelvic Floor Anatomy: From Superficial to Deep—cont'd

Muscle Layer	Structure	Action
<b>Perineal membrane (formerly urogenital diaphragm)</b>		
	Deep transverse perineal	Compression of urethra and ventral wall of vagina
	Compressor urethrae Urethrovaginal sphincter	Support of the perineal body and introitus
<b>Pelvic diaphragm (primary muscular support)</b>		
	Levator ani ■ Pubococcygeus ■ Puborectalis ■ Iliococcygeus Coccygeus (Ischiococcygeus)	Prime mover of the pelvic floor, puborectalis aids in closure of the rectum
		Flexes coccyx

length of the nerve structures and has been found to be more significant in the posterior portion of the perineum.<sup>80,114</sup> This compromise to the nerve tissue is most intense during pushing (the second stage of labor), through the completion of vaginal delivery.

### Muscular Impairment

Extreme stretching of all pelvic floor tissues is inherent in the process of labor and vaginal delivery. Recent computerized simulations of the biomechanics of childbirth are adding to the understanding of these impairments.<sup>80</sup> Muscle and/or ligamentous injury during labor and delivery diminishes the maximal closure pressure of the pelvic floor complex, which makes the entire system more vulnerable to increased intra-abdominal pressure and changes force transmission to the distal vagina, possibly contributing to prolapse of the bladder, urethra, vagina, uterus, small intestine, and rectum.<sup>9</sup>

The pelvic floor musculature may also be torn or incised during the birth process. Additional soft tissue lacerations can occur as a result of forceps use, necessitating suturing throughout the musculature and into the vaginal vault.

### Episiotomy

An episiotomy is an incision made in the perineal body (see Fig. 25.4B). It is automatically considered a second-degree laceration according to the following classification of perineal lacerations.<sup>78</sup>

- First degree—only skin
- Second degree—includes underlying superficial muscle layer
- Third degree—extends to anal sphincter
- Fourth degree—tears through the sphincter and into the rectum, possibly into the deeper muscular layer of the pelvic floor (see Fig. 25.4 A)

Although episiotomy is common, occurring in 33% to 54% of vaginal deliveries, there is no strong medical evidence supporting its use. In fact, outcomes with episiotomy are worse in some cases, including pain with intercourse and extension into the external and internal anal sphincter or rectum. Pelvic floor dysfunctions such as incontinence and organ prolapse need further study relative to history of episiotomy.<sup>76</sup> Anal sphincter defects were linked with fecal incontinence in the postpartum period as far as 6 months after delivery in a study done by the Pelvic Floor Disorders Network.<sup>20</sup> Long-term follow up (beyond 1 year postpartum) is very limited.

Differences in recovery of pelvic floor strength in women with and without episiotomy have been documented with continued lack of consensus as to benefit of this procedure.<sup>76</sup> There is consistent agreement in the literature that episiotomy is closely associated with forceps-assisted delivery; additionally, if epidural anesthesia, forceps, and episiotomy are all utilized during labor and delivery, the risk of anal sphincter tear is even greater.<sup>1,20,47,64,74</sup> Pregnant women have many questions about labor in general and episiotomy in particular; the clinician is able to provide education and support for the patient as she explores birthing options with her physician.

### FOCUS ON EVIDENCE

A randomized, controlled trial of 459 Canadian women during their first pregnancy found a significant protective effect against third- and fourth-degree tears (extensions following episiotomy) in women who participated in “strenuous” exercise three or more times per week. The researchers defined “strenuous” exercise as bicycling, jogging, tennis, skiing, and weight training, as opposed to “nonstrenuous” exercise such as walking, swimming, prenatal classes, and yoga. Data were collected regarding type, frequency, and duration of exercise

for a 12-month period including prepregnancy and postpartum time frames. In the “strenuous” exercise group, 200 of the women did *not* have third- or fourth-degree tears compared with only 25 women who did experience this tearing. In addition, this study helped dispel the theory that serious exercisers may have overdeveloped perineal musculature; these women were not at increased risk for episiotomy when compared to casual exercisers.<sup>74</sup>

## Classification of Pelvic Floor Dysfunction

This is a very broad category that encompasses bladder, bowel, and sexual symptoms in males and females in a variety of combinations. Some patients present with pelvic floor disuse atrophy, weakness, or nerve damage; others will have overactive pelvic floor musculature. Pelvic pain is another far-reaching, nonspecific diagnosis; many of these patients will be seen by multiple doctors prior to musculo-skeletal etiology being considered.

### Pelvic Organ Prolapse

A prolapse is a supportive impairment that results in vaginal protrusion. It refers to the descent of any of the pelvic viscera out of their normal alignment because of muscular, fascial, and/or ligamentous deficits and because of increased abdominal pressure (Fig. 25.5). A prolapse often worsens over time and with subsequent pregnancies. Other contributing factors include chronic increases in intra-abdominal pressure (such as constipation or increased BMI), menopause, and possibly significant lifting or exertion.<sup>96</sup>

- A cross-sectional study found stage I prolapse in 33% of the subjects and stage II descent in 62.9%. The sample included 270 women with a mean age of 68.3 years and median parity of three vaginal births.<sup>96</sup> In another study, over 1,900 U.S. women were assessed for symptomatic prolapse and other pelvic floor dysfunctions with findings of prevalence in up to 49.7% of the sample correlated with increased age, increased parity, and increased weight.<sup>98</sup> This is critically important information for all clinicians prescribing trunk stabilization programs for female patients regardless of diagnosis.

**FIGURE 25.5** (A) Good pelvic floor support with a firm base, organs in normal position. (B) Inadequate support, pelvic organs descend.

- From a biomechanical aspect, activation of the pelvic floor is necessary in coordination with deep segmental muscle activation of the multifidus and transversus abdominis (see Chapters 13 and 15) to prevent excessive downward forces during all daily activities.

### FOCUS ON EVIDENCE

Creating an “ideal” program to achieve motor learning of the pelvic floor is complicated by differing study results. A landmark study done by Dr. Bump showed that brief verbal instruction alone was not effective in teaching correct pelvic floor contraction technique in 50% of women and, in fact, caused increased downward pressures to the bladder in 25% of their sample rather than producing an appropriate superiorly directed force.<sup>26</sup> Other studies have confirmed repeatedly that skilled individualized intervention is needed as many women perform pelvic floor contractions incorrectly.<sup>15</sup> Studies in normal individuals promote the use of a transverse abdominis contraction as a way to facilitate a synergistic contraction of the pelvic floor.<sup>109,110</sup> However, coordinated recruitment of the trunk muscles and the pelvic floor cannot be assumed across the board in a standard rehabilitation setting. Ideally, co-contraction of the pelvic floor with the deep segmental muscles would be confirmed internally prior to prescribing more challenging positions and activities.

- As prolapse progresses, functional changes occur as a result of perineal pressure and heaviness, including low back pain, abdominal pressure or pain, and difficulties with bladder and bowel elimination.<sup>23</sup> These symptoms can interfere with exercise; recreation; household responsibilities, including yard work; and occasionally the ability to work outside the home.<sup>96</sup>

### FOCUS ON EVIDENCE

A 2011 Cochran review highlighted rigorous trials to support pelvic floor muscle exercise in the treatment of prolapse with specific recommendations for longer follow-up and varied combinations of interventions.<sup>61</sup>

### Urinary or Fecal Incontinence

Involuntary loss of bladder or bowel contents, frequently a result of both neuromuscular and musculoskeletal impairments, may occur in combination with prolapse. A conservative estimate of people affected with urinary or fecal incontinence is 25 million in the United States alone.<sup>90</sup> Women are twice as likely to have these symptoms as men.<sup>43</sup> In a recent prevalence study of noninstitutionalized persons over the age of 65, over 25% of men and 50% of women reported urinary incontinence.<sup>58</sup> These patients often have significant social discomfort, anxiety regarding leakage, and hygiene concerns. Significant financial implications exist for

both the individual and the larger society. In a systematic review, analysis of costs for women in the United States, including both conservative and surgical interventions, totaled over \$12 billion per year.<sup>32</sup> Types of incontinence are summarized in Box 25.2.

### FOCUS ON EVIDENCE

Multiple studies have shown statistically significant improvement in urinary leakage as a result of a program of pelvic floor strengthening.<sup>46,81,87,88,108,122</sup> Decrease in postprostatectomy leakage in men has also been documented after pelvic floor exercise, at times in combination with biofeedback.<sup>57, 81,125</sup>

Functional improvements (decreased urinary incontinence and improved pelvic floor strength) have been noted in late pregnancy and from 3 to 12 months postpartum in a number of studies.<sup>87,88,108</sup>

There is strong evidence in support of skilled intervention for pelvic floor dysfunction. The inclusion of physical therapists in the first line of treatment allows integration of exercise physiology and progressive strengthening principles to treatment protocols along with proper instruction and close follow-up.<sup>15</sup> Bø<sup>16</sup> summarized current findings in support of pelvic floor rehabilitation in the treatment of stress urinary incontinence:

- Strength training of the pelvic floor (using principles of exercise physiology) improves structural support of the organs and connective tissue in addition to facilitating more effective recruitment of motor units and more consistent, proficient contractions.
- Counterbracing with the pelvic floor musculature, done intentionally and habitually prior to increases in intra-abdominal pressure, becomes a form of behavioral modification with “trigger” activities such as lifting and coughing.

#### BOX 25.2 Types of Lower Urinary Tract Impairments<sup>1</sup>

- **Stress urinary incontinence:** loss of urine with increased abdominal pressure (exertion, cough, sneeze) may present in isolation or combined with urge incontinence
- **Urgency:** sudden desire to void, hard to ignore, may be called overactive bladder
- **Urge urinary incontinence:** loss of urine associated with a strong sense of urgency
- **Detrusor overactivity:** bladder contractions during filling phase, seen on urodynamics
- **Retention incontinence:** hypotonic or acontractile bladder leads to dribbling of urine or interrupted flow (previously called overflow)
- **Functional incontinence:** related to other impairments such as arthritis, Parkinson's, dementia, medications

### Pain and Overactivity of the Pelvic Floor and Surrounding Musculature

Pain and overactivity may be related to delayed healing of perineal lacerations, trauma to the soft tissues and/or the pelvic girdle joints during delivery, pelvic obliquity, multiple gynecologic/visceral diagnoses, cauda equina involvement, and scar tissue restrictions, as well as high incidence clinically of protective muscle spasm, guarding, and anxiety regarding movement in general. Central sensitization and pain education are key factors in treatment planning.<sup>29</sup>

- One study described “nonmenstrual” pelvic pain as being most commonly caused by endometriosis, adhesions, interstitial cystitis, or irritable bowel syndrome, occurring in as much as 20% of women aged 15 to 50.<sup>18</sup> In another study with a total sample of 581 women (aged 18 to 45), the following prevalence was found: pelvic pain, 39%; dyspareunia (pain with intercourse), 46%; and dysmenorrhea, 90%.<sup>68</sup>
- Functional impairments may include pain with ADLs, decreased sitting tolerance, dyspareunia, and difficulty with elimination of bladder and bowel contents. In patients with pelvic pain impairments, often referred to as chronic pelvic pain (CPP), persistent tightness of the lumbar paraspinals and hip flexors is typically present.<sup>10</sup>
- Because of the breadth of this topic, treatment recommendations are conflicting. Attention is being given to the correlation of pelvic pain with a history of sexual abuse, which highlights the need for multidisciplinary assessment in order to address all potential causative factors. Sexual abuse continues to be underreported, yet recent studies cite rates of 20% to 25% of women who report childhood sexual trauma.<sup>69,102,105</sup>

### Risk Factors for Dysfunction in the Female Population

#### Childbirth

Childbirth is clearly the most significant risk factor for female pelvic floor impairments. The process of labor, particularly with vaginal delivery and current medical management, can produce significant trauma to the structures of the pelvic floor.

- A longitudinal cohort study with follow-up 15 years after delivery (n = 55) showed that stress incontinence during the first pregnancy doubled the risk of recurrence 15 years later.<sup>41</sup> With respect to risk of future POP, in a cohort study of over 17,000 women, those with one delivery were four times more likely, and those with two children were over eight times more likely to have a subsequent hospital admission for POP. However, this study did not distinguish mode of delivery.<sup>82</sup>
- Other potential obstetric risk factors include mothers older than 30 years of age, multiple deliveries, prolonged second stage (over 1-2 hours) of labor, forced pushing, use of forceps, vacuum extraction or oxytocin, third- or fourth-degree perineal tears, and birth weight greater than 8 lb.<sup>56,68,75,97,116,123</sup>

## Other Causes

Women who have never been pregnant may also present with pelvic floor dysfunction. Excessive straining because of chronic constipation, smoking, chronic cough, obesity, and hysterectomy can contribute to these impairments in any woman.<sup>5,13,43,123</sup> More recent studies are uncovering a connection between high impact exercise and urinary leakage, even in young athletes.<sup>40</sup> The role of estrogen in the development of incontinence is still unclear, with some studies citing estrogen depletion as a risk factor,<sup>43</sup> and others finding a connection between incontinence and oral estrogen-replacement therapy.<sup>66,123</sup> High caffeine intake has been cited as a specific risk factor for urge incontinence,<sup>25,66</sup> and reduction of caffeine, combined with dietary modifications and pelvic floor exercises, has led to improved continence.<sup>25</sup>

## Considerations for Treatment of Pelvic Floor Dysfunction in the Male Population

As physical therapists become more knowledgeable and proficient in female pelvic floor impairments, it may be an “easy” and natural transition to add services for male (and possibly

pediatric clients). Continued training for therapists is imperative and available. Teaching of pelvic floor awareness and correct exercise technique is similar as for women in terms of explaining the anatomy and function of the musculature. However, men can see movement of the base of the penis and scrotum, which gives them more immediate feedback regarding accurate identification of the pelvic floor muscles. The primary contributing factor for pelvic floor dysfunction in men is prostate enlargement or prostate cancer treatment; otherwise, many of the same topics of discussion apply (i.e., increases in intra-abdominal pressure, caffeine) when educating these clients. Evidence is growing for this population as well in terms of optimal rehabilitation approaches.<sup>57,85,91,106,122</sup>

## Interventions for Pelvic Floor Impairments

Management of both women and men with pelvic floor impairments involves a comprehensive approach. Management guidelines for pelvic floor impairments are summarized in Box 25.3. Exercises for the pelvic floor are described in the exercise section of this chapter.

### BOX 25.3 MANAGEMENT GUIDELINES— Pelvic Floor Impairments

#### Potential Impairments of Structure and Function, Activity Limitations, and Participation Restrictions

- Pelvic floor muscle weakness, soft tissue disruption
- Lack of sphincter control resulting in urinary or fecal incontinence
- Organ prolapse
- Poor proprioceptive awareness and disuse atrophy of the pelvic floor muscles
- Lack of knowledge of pelvic floor muscle function
- Over activity of pelvic floor muscles along with pain and/or voiding dysfunction
- Limited participation in work, social, and community activities related to:
  - frequent urges/poor sphincter control/pain and discomfort
  - potential skin breakdown, hygiene concerns

#### Plan of Care

#### Interventions

- | Plan of Care  | Interventions   |
|---|---|
| 1. Educate the patient                              | 1. Explain the anatomy and function of the pelvic floor.<br>Explain intervention approach for specific impairments.<br>Increase awareness of risk factors for pelvic floor impairments (weight gain, constipation, etc.).<br>Educate regarding skin care as needed. |
| 2. Coordinate intervention with other professionals | 2. Consult with physician regarding medications, further diagnostic testing.<br>Consult with dietitian regarding diet.<br>Refer for internal pelvic floor musculoskeletal assessment as needed.   |
| 3. Develop self-management strategies               | 3. Increase awareness of bladder irritants, impact of bowel function on bladder symptoms, and recommended fluid/fiber intake.<br>Use voiding diary to record baseline information and monitor improvements in leakage and urgency.                                  |

**BOX 25.3** MANAGEMENT GUIDELINES—  
**Pelvic Floor Impairments—cont'd**

Plan of Care	Interventions
	Use exercise log. Teach urge suppression techniques. Incorporate pain management and self-care strategies.
4. Screen for unresolved postpartum impairments	4. Assess strength/integrity of abdominal wall, postural asymmetries, history of other musculoskeletal issues.
5. Develop awareness and control of the pelvic floor musculature for life-long daily functional use	5. Increase implementation of pelvic floor activation and relaxation as appropriate for retention of motor patterns and integration with ADLs.

### Patient Education

#### **Teach the patient about pelvic floor anatomy and function.**

Place emphasis on appreciating all three dimensions of the muscle complex: the sling/hammock fibers, the figure-eight orientation of the musculature, and the “funnel” configuration extending inferiorly to the outlet (see Fig. 25.4). Use visual aids to help the patient visualize the fibers that run anterior-posterior as well as superior-inferior (to create a “lifting” motion toward the heart), as well as the circumferential fibers (which produce a drawstring or “pucker” effect). Verbal cues that seem to be effective include “tighten your muscles as if to hold back gas and urine” along with visualizing the lift and pucker motions. Be specific with gender differences, mentioning the image of tightening around the vaginal opening and movement of the penis and scrotum as appropriate.

#### **Provide individual instruction in exercise performance.**

Detailed, individual exercise instruction is linked to significant proprioceptive improvement and meets the criteria for skilled care. Successful strengthening is unlikely without this individualized educational component along with later confirmation of correct exercise performance.<sup>15</sup>

**Teach bladder and bowel management.** Regardless of primary symptoms, it is important to educate all clients on behavioral management specifically concerning bladder irritants and fiber intake. Most clients are motivated to apply tools that will improve continence; however, cutting back on caffeinated beverages and improving fiber intake can be very challenging. Help the patient develop a routine for keeping track of and then modifying the daily habits that affect the impairments. Suggestions include:

- **Voiding diary.** Have the client record all voids, any time there is an “accident,” and cause of leakage if known (cough, sneeze). Also have the patient record amount/frequency/type of all fluids, and food intake if monitoring fiber. If protective garments are used, record type and number per day. Many sample diaries can be found on the Internet.

- **Exercise log.** Have the patient record, or check off, when pelvic floor exercises are performed as well as any general fitness exercises.
- **Urge suppression techniques.** With urge incontinence have the patient practice techniques to calm the sudden strong urge to urinate or leak urine.<sup>43</sup> Suggestions include:
  - Remaining calm (panic makes the urge worse)
  - Use pelvic floor contractions<sup>27,113</sup>
  - Standing still or sitting down until the urge disappears—usually 1 minute
  - Thinking of something else as a distraction
  - Trying not to rush to the toilet
  - Continue with normal activity or visit the toilet after the urge disappears. To help retrain the bladder, try a 5-minute delay then calmly walking to the bathroom.

Review the diary and exercise log periodically with the patient to note progress and provide additional education as needed.

### Neuromuscular Re-education

**Facilitate pelvic floor muscular activation.** Neuromuscular re-education is essential because many women have significant disuse atrophy and proprioceptive deficits of the pelvic floor muscles. Internal techniques of assessment and treatment may be indicated for optimal patient outcomes. For example, manual stretch facilitation (a proprioceptive neuromuscular facilitation technique) to the levator ani at the vaginal or anal orifice can be an effective treatment option for clinicians with appropriate training.

Initially, emphasize correct identification of the pelvic floor musculature, with the goal of the patient learning isolated contractions of the pelvic floor. Many patients exhibit excessive accessory muscle recruitment (such as the gluteals, hip adductors, and abdominals) or the tendency to breath hold during attempts to recruit the pelvic floor muscles. Monitor for these substitutions during early treatment sessions to eliminate their use. Palpate the pelvic floor muscles

at the perineal body over thin layers of fabric to verify correct activation, and then teach this palpation technique to the patient for use at home to assist in the re-education process. Once the patient learns to isolate and improve coordination of the pelvic floor contractions progress the instruction to integration of pelvic floor activity with ADLs, lumbar stabilization, and other functional strengthening exercises.

### Biofeedback

**Use biofeedback with instrumentation.** The definition of biofeedback is “the technique of using monitoring devices to furnish information regarding ... bodily function ... in an attempt to gain some voluntary control over that function” (www.thefreedictionary.com). This can be accomplished by a creative physical therapist in a number of ways. There are multiple types of instruments that can be used to provide sensory feedback as the pelvic floor muscles contract around the device. Some are pressurized objects that allow for isotonic strengthening. Traditional surface electromyography (SEMG) sensors are solid and provide isometric resistance to the muscular contraction. SEMG can also be applied through peri-anal sensors for patients who are not candidates for internal assessment or treatment. SEMG provides immediate visual and/or auditory feedback regarding pelvic floor activity, which improves patient comprehension, appropriate recruitment patterns, and proprioceptive awareness. It is particularly invaluable for pelvic floor re-education and retention of motor learning pathways owing to generalized lack of knowledge of the muscles’ existence, let alone their function and importance. Motor learning, which is facilitated through the “real-time” capabilities of the equipment, is greatly enhanced when compared to exercise without this intervention.

**Combine biofeedback with exercises.** Specific exercises to address pelvic floor impairments are listed in the exercise section of the chapter. The use of exercise and biofeedback, including SEMG for treatment of pelvic floor dysfunction in both male and female populations, has been studied with mixed results.<sup>27,43,57,103,106,126</sup> The need for further research is great.

### Manual Treatment and Modalities

Manual treatment and modalities, including intravaginal and intrarectal techniques, also play a role in the treatment of all pelvic floor disorders. Advanced training is necessary for true expertise with internal techniques.

### FOCUS ON EVIDENCE

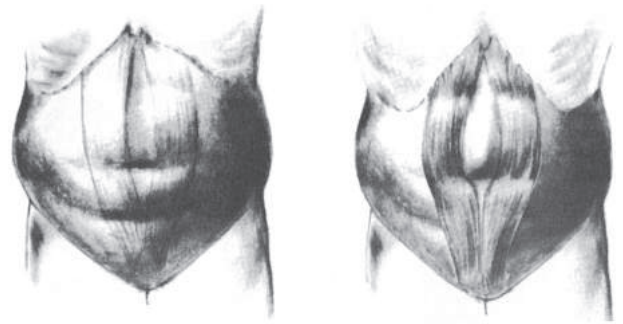

FitzGerald<sup>48</sup> analyzed improvement in pelvic pain and urinary urgency and frequency comparing specific pelvic floor myofascial release techniques to “global therapeutic massage.” A significantly higher proportion of the 81 women in the study improved with the direct physical therapy interventions versus massage ( $p = 0.0012$ ).

## Pregnancy-Induced Pathology

The combined influence of hormones, weight gain, and postural changes of pregnancy contributes to a variety of impairments (in addition to pelvic floor dysfunction that was described in the previous section) that can be addressed with physical therapy.

### Diastasis Recti

Diastasis rectus abdominis (DRA) is separation of the rectus abdominis muscles in the midline at the linea alba. Elizabeth Noble was the first physical therapist to describe rehabilitation for this condition.<sup>93</sup> The etiology of this separation is unknown; however, the continuity and integrity of the abdominal musculature are disrupted (Fig. 25.6). Any separation larger than two finger widths is considered significant.<sup>19,28,93</sup> Currently other methods of assessment and treatment are being explored (for example, rehabilitative ultrasound or calipers versus manual palpation to measure separation) in order to determine best practice.<sup>73</sup>

**FIGURE 25.6** Diagrammatic representations of diastasis recti. (From Boissonnault, JS, and Kotarinos, RK: *Diastasis recti*. In Wilder, E [ed]: *Obstetric and Gynecologic Physical Therapy*, Vol. 20, ed. 1. New York: Churchill Livingstone, 1988, p 91, with permission.)

### Incidence

This condition is frequently seen in the childbearing woman, although it is not exclusive to this population. In one study, Boissonnault and Blaschak<sup>19</sup> tested 89 women for separation of the rectus abdominis muscles. The sample included one group of women who were not pregnant, one group for each trimester of pregnancy, and two postpartum groups. The incidence in this study ranged from none in the nonpregnant and first trimester women, to 27% in the second trimester, to a high of 66% in the third trimester. Also of interest is that 36% of the women between 5 weeks and 3 months postpartum continued to display a separation. A study by Bursch<sup>28</sup> found a significant diastasis in 62.5% of postpartum women tested within 92 hours of delivery. In a population of 547 women seen in a urogynecology practice, 52% of the primarily menopausal women had persistent diastasis recti; 66% of

those with DRA also had various combinations of stress or fecal incontinence and POP.<sup>118</sup>

- Diastasis recti may occur in pregnancy as a result of hormonal effects on the connective tissue and the biomechanical changes of pregnancy; it may also develop during labor, especially with excessive breath holding during the second stage.<sup>120</sup> It causes no discomfort.
- It can occur above, below, or at the level of the umbilicus but appears to be less common below the umbilicus.
- It appears to be less common in women with good abdominal tone before pregnancy.<sup>19</sup>
- Clinically, a diastasis may be found in women well past their childbearing years<sup>118</sup> (Fig. 25.7 A) and also in men (Fig. 25.7 B). Routine assessment for this condition is highly recommended in all clients and can easily be done in conjunction with abdominal strength testing.

**FIGURE 25.7** (A) Diastasis recti abdominis (DRA) of an 82-year-old woman who currently has urinary incontinence and emphysema. The DRA began with earlier pregnancies and is now exacerbated with coughing. Note the umbilical hernia. (B) DRA in a 54-year-old male truck driver with low back pain and significant deconditioning.

### Significance

The condition of diastasis recti may produce musculoskeletal complaints, such as low back pain, possibly as a result of

decreased ability of the abdominal musculature and thoracolumbar fascia to stabilize the pelvis and lumbar spine.

**Activity limitations.** Activity limitations can also occur, such as inability to perform independent supine-to-sitting transitions because of extreme loss of the mechanical alignment and function of the rectus muscle. Again, this finding is not exclusive to women in the childbearing years.

**Decreased fetal protection.** In severe separations, the remaining midline layers of abdominal wall tissue are skin, fascia, subcutaneous fat, and peritoneum.<sup>19,28,120</sup> The lack of muscular support provides less protection for the fetus.

**Potential for herniation.** Severe cases of diastasis recti may progress to herniation of the abdominal viscera through the separation at the linea alba. This degree of separation requires surgical repair. Rehabilitation following this type of repair may include components of C-section rehabilitation, with specific precautions and input from the referring surgeon. There may be a need for very slow progression depending on the severity of the diastasis and type of repair.

### Examination for Diastasis Recti

Test all patients for the presence of diastasis recti before prescribing any abdominal exercises. Repeat this test throughout pregnancy and rehabilitation, and make appropriate modifications to existing exercises. This is a very quick assessment to incorporate with other trunk testing procedures.

Instruct female patients to perform a self-test on or after the third postpartum day for optimal accuracy. Until 3 days after delivery, the abdominal musculature has inadequate tone for valid test results.<sup>93,120</sup>

**Patient position and procedure:** Hook-lying. Have the patient slowly raise his/her head and shoulders off the floor, reaching hands toward the knees, until the spines of the scapulae leave the floor. Place the fingers of one hand horizontally across the midline of the abdomen at the umbilicus (Fig. 25.8); also test above and below the umbilicus. If a

**FIGURE 25.8** Diastasis recti test.

separation exists, the fingers will sink into the gap between the rectus muscles, or a visible bulge between the rectus bellies may be appreciated. Document the number of fingers that can be placed between the muscle bellies and identify if the separation is above, below, or at the level of the umbilicus.<sup>93</sup>

### Intervention for Diastasis Recti

Teach the patient to perform the corrective exercise for diastasis recti (see Fig. 25.11 and accompanying text later in this chapter) until the separation is decreased to 2 cm or less prior to resuming more strenuous abdominal strengthening that increases intra-abdominal pressure.<sup>93,120</sup> Transverse abdominis exercises may be incorporated with the caution against breath holding. Once correction has been obtained, strengthening of the obliques and more advanced abdominal work can be resumed.<sup>67</sup>

## Posture-Related Back Pain

Back pain commonly occurs because of the postural changes of pregnancy, increased ligamentous laxity, hormonal influences, and decreased abdominal muscle function.<sup>5,7,39,67,93,100,,108,125</sup>

### Incidence

Back pain is reported by 50% to 80% of pregnant women at some point during pregnancy.<sup>51,92</sup> This condition contributes to lost work days, decreased functional ability, and QOL scores. In addition, symptoms may continue in the postpartum period, with prevalence in as many as 68% of women, for as long as 12 months after delivery.<sup>92,99</sup> Women who are physically fit generally have less back pain during pregnancy.<sup>103</sup>

### Characteristics

The symptoms of low back pain usually worsen with muscle fatigue from static postures or as the day progresses; symptoms are usually relieved with rest or change of position.

### Interventions

Low back pain symptoms can be treated effectively with many traditional low back exercises, proper body mechanics, posture instructions, and improvement in work techniques, along with superficial modality application.<sup>93,120</sup> The use of deep heating agents, electrical stimulation, and traction is generally contraindicated during pregnancy.

## FOCUS ON EVIDENCE

Garshasbi and Faghieh Zadeh<sup>51</sup> studied more than 200 primigravid women (pregnant for the first time) in a prospective randomized study on the effect of exercise and the intensity of low back pain during pregnancy. Subjects were excluded if they had a history of exercise before pregnancy or history of orthopedic conditions. The exercise group was in a supervised exercise program for 3 hr/wk for 12 weeks in the second and early third trimesters; the control group was women who were homemakers and had no significant change in activity level. The groups were statistically equal in maternal and neonatal weight gain, as well as length of pregnancy. The exercise group

experienced significant decrease in intensity of low back pain by the end of the study, whereas intensity was increased in the control group. The study did not describe the nature of the symptoms or differentiate between postural pain and sacroiliac pain. Interestingly, there was no significant difference in the change in lordosis between the two groups.

A 2007 Cochrane review found pregnancy specific exercises—including “water gymnastics”—to provide relief of back or pelvic pain more than typical prenatal care alone, although the effect was small due to potential bias in the studies.<sup>104</sup> In 2015 this subject was revisited with a larger number of studies in the review. Moderate- to low-quality evidence documented that land exercise for low back pain reduces functional disability and sick days more than standard prenatal care. There are continued questions due to heterogeneity in study design and small numbers of subjects.<sup>79</sup>

## Sacroiliac/Pelvic Girdle Pain

### Characteristics

Sacroiliac pain is localized to the posterior pelvis and is described as stabbing deep into the buttocks distal and lateral to L5/S1. Pain may radiate into the posterior thigh or knee but not into the foot. Symptoms include pain with prolonged sitting, standing or walking, climbing stairs, turning in bed, unilateral standing, or torsion activities. Symptoms may not be relieved by rest and frequently worsen with activity. Pubic symphysis dysfunction may occur alone or in combination with sacroiliac symptoms and includes significant tenderness to palpation at the symphysis, radiating pain into the groin and medial thigh, and pain with weight bearing. In addition, excessive separation and translation at the joint may occur.<sup>39,120</sup> One study reported a four times greater incidence of posterior pelvic pain than low back pain in pregnant women.<sup>100</sup>

### Interventions

Treat pelvic girdle and sacroiliac symptoms via modification or elimination of activities that may further aggravate sensitive tissue, stabilization exercises, and the use of belts and corsets to provide external support to the pelvis.

**Activity modification.** Help the patient adapt her daily activities to minimize asymmetrical forces acting on the trunk and pelvis. For example, teach:

- getting into a car by sitting down first, then pivoting both legs and the trunk into the car, keeping the knees together
- log rolling for transitions in bed
- side-lying symmetry by placing a pillow between the knees and under the abdomen
- modifying sexual positions to avoid full range of hip abduction
- avoiding single-leg weight bearing, excessive abduction, and sitting on very soft surfaces
- avoiding climbing more than one step at a time, swinging one leg out of bed at a time when getting up, or crossing the legs when sitting<sup>39,120</sup>

**Exercise modification.** Modify exercises so as not to aggravate the condition. Avoid exercises that require single-leg weight bearing and excessive hip abduction or hyperextension. Teach the patient to activate the pelvic floor and transverse abdominals when transitioning from one position to another and with any lifting in order to stabilize the trunk and pelvis.

### FOCUS ON EVIDENCE

A randomized, clinical trial with 2-year follow-up looked at long-term effects of physical therapy for pelvic girdle pain in the postpartum period.<sup>121</sup> Each group had 20 weeks of treatment, with the control group focusing on modalities, manual therapy, and general exercises. In addition, the second group had specific focus on trunk/hip stabilizing exercises, with particular attention to the transverse abdominals. All participants received individual instruction from an experienced physical therapist. Outcome measures included the Oswestry Disability Questionnaire, pain scales, and a health-related QOL tool that measured eight subscales. At 1 year postpartum, the group with specific stabilizing exercises showed significantly better scores on all measures of those three tools, except for the social functioning subscale of the QOL tool. The same measurements were collected at 2 years' post-delivery, and the benefit for the stabilization group persisted, with significant differences in functional status and morning and evening pain. The specific exercise group had scores on QOL comparable to those of a representative group of the general population.

**External stabilization.** Use of external stabilization such as belts or corsets designed for use during pregnancy helps reduce posterior pelvic pain, especially when walking.

### FOCUS ON EVIDENCE

Ostgaard and colleagues<sup>100</sup> found that the use of nonelastic external stabilization designed for use during pregnancy helped reduce posterior pelvic pain in 82% of women. This was a large, randomized, controlled study (n = 407). More recent studies have validated the use of external stabilization for pelvic girdle pain (n = 118)<sup>92</sup> but found no effect with a support belt in cases of pubic symphysis pain (n = 87).<sup>39</sup>

The *Clinical Practice Guidelines (CPGs) for Pelvic Girdle Pain in the Antepartum Population* recommend using support belts for the antepartum patient with pelvic girdle pain and also state there is need for further research to clarify initial application, duration, and specific patient classifications because of conflicting evidence.<sup>37</sup>

## Varicose Veins

Varicosities are aggravated in pregnancy by the increased uterine weight, venous stasis in the legs, and increased venous distensibility.

## Characteristics

Varicosities can present in the first trimester and are more prevalent with repeated pregnancies. They can occur in the lower extremities, the rectum (hemorrhoids), or vulva. Symptoms usually include heaviness or aching discomfort, especially with dependent leg positions; intensity may become severe as the pregnancy progresses. In addition, pregnant women are more susceptible to deep vein thrombosis.<sup>120</sup>

## Interventions

**Exercise modification.** If there is discomfort, modify exercises so that minimal dependent positioning of the legs occurs.

**External support.** Encourage the patient to wear elastic support stockings to provide an external pressure gradient against the distended veins, to perform lower extremity exercises, and to elevate the lower extremities as often as possible. Vulvar varicosities may benefit from use of external support to provide counter-pressure and support to the tissues.<sup>93</sup>

## Joint Laxity

### Significance

All joint structures are at increased risk of injury during pregnancy and during the immediate postpartum period.<sup>84</sup> The tensile quality of the ligamentous support is decreased, and therefore injury can occur if women are not educated regarding joint protection. There is much controversy regarding the impact of postpartum hormone levels; however, elevated levels have been found 3 to 5 months after delivery.<sup>120</sup> This elevation may persist even longer if the woman is nursing. Many patients are aware of persistent symptoms in conjunction with the menstrual cycle, and this correlation is certainly seen clinically.

## Interventions

**Exercise modification.** Teach the woman safe exercises to perform during the childbearing year, including modification of exercises to decrease excessive joint stress (see exercises described in the management section of this chapter).

**Aerobic exercise.** Suggest non-weight bearing or less stressful aerobic activities such as swimming, walking, or stationary biking, particularly for women who were relatively sedentary before pregnancy. Other activities that may be initiated in pregnancy include modified yoga or Pilates and strength training.<sup>4</sup>

## Nerve Compression Syndromes

### Causes

Impairments from conditions such as thoracic outlet syndrome (TOS) or carpal tunnel syndrome (CTS) may be caused by one or more of the following in pregnancy: postural changes in the neck and upper quarter, fluid retention, hormonal changes, or circulatory compromise. Overall, women are three times as likely as men to experience CTS. Occurrence

in pregnancy can be as high as 41%.<sup>103</sup> (See Chapter 13 for a discussion of CTS and TOS and Chapter 14 for a discussion of posture.)

Nerve compression syndromes (for example, of the lateral femoral cutaneous nerve) may also occur in the lower extremities because of the weight of the fetus, fluid retention, hormonal changes, or circulatory compromise.

### Interventions

Typical protocols include postural correction exercises, manual techniques, ergonomic assessment, and modalities (see Chapter 13 for management of nerve compression syndromes). A static wrist orthosis may be used in the treatment of CTS. Carpal tunnel surgery in the pregnant population is rare because symptoms generally resolve soon after delivery; a longer course of the problem has been noted in women who breastfeed.<sup>120</sup>

## Exercise Interventions for Pelvic Floor Impairments, Pregnancy, Labor, and Related Conditions

### Exercise for the Pelvic Floor

Pelvic floor muscle training is a valuable modality regardless of a patient's presentation or cause of symptoms.<sup>13,16,26,31,45,47,49,50,66,67,87,88,93,103,108,120,125</sup> Although this chapter is geared toward women's health, men with pelvic floor impairments may benefit from exercise interventions and are therefore included in this material. Many men and women are unfamiliar with the presence of the pelvic floor muscles and are even less aware of their function and role in daily activities. For women, symptoms are often linked with the childbearing years owing to the stress of pregnancy, labor, and delivery on the pelvic floor. For men, bladder and/or bowel impairments or sexual dysfunction may co-exist with prostate enlargement, cancer, surgery, or cancer related treatment.<sup>57,85,91,106,122</sup> The management guidelines outlined in Box 25.3 and exercises presented in this section are therefore used when treating the range of impairments described in this chapter in both female and male clients.

### Pelvic Floor Awareness and Training

Begin pelvic floor exercises with an empty bladder. Gravity-assisted positioning (hips higher than the heart, such as supported bridge or elbows/knees position) may be indicated initially for some clients with extreme weakness and proprioceptive deficits. Explore various positions to maximize patient awareness and motor learning with progression into more challenging activities/positions as functional application becomes feasible.

### Contract-Relax

Instruct the client to tighten the pelvic floor as if attempting to stop urine flow or hold back gas. Hold for 3 to 5 seconds, and relax for at least the same length of time. Repeat as many as 10 times (if performed with proper technique). As pelvic floor muscle fibers fatigue, substitution with the gluteals, abdominals, or hip adductors may occur. To maximize proprioception and motor learning, it is important initially to emphasize identification and isolation of the pelvic floor and avoid the substitute muscle actions.<sup>115</sup> In addition, watch for Valsalva's maneuver; if necessary, have the client count out loud to encourage normal breathing patterns.

### Quick Contractions

Have the client perform quick, repeated contractions of the pelvic floor muscles while maintaining a normal breathing rate and keeping accessory muscles relaxed. Try for 15 to 20 repetitions per set. This type II fiber response is important to develop in order to withstand pressure from above, especially with coughing or sneezing.

### "Elevator" Exercise

Instruct the client to imagine riding in an elevator. As the elevator goes up from one floor to the next, she contracts the pelvic floor muscles a little "higher." As strength and awareness improve, add more "floors" to the sequence of the contraction. Another way to increase difficulty is to ask for relaxation of the muscles gradually, as if the elevator were descending one floor at a time. This component requires an eccentric contraction and is very challenging.

### Pelvic Floor Relaxation

- Instruct the client to contract the pelvic floor as in the strengthening exercise, then allow total voluntary release and relaxation of the pelvic floor. Emphasize use of the "elevator" imagery, with particular attention to taking the elevator to the "basement."
- Pelvic floor relaxation is closely linked with effective breathing and relaxation of the facial muscles. Emphasize slow, deep breath and allow the pelvic floor to completely relax and soften. For a woman, relaxation of the pelvic floor is extremely important during stage 2 of labor and vaginal delivery.<sup>50,93,120</sup>
- Chronic inability to relax the pelvic floor muscles may lead to impairments such as pelvic floor overactivity, pain with intercourse (dyspareunia), or voiding dysfunction. (Please refer to the earlier information on pelvic pain syndromes.) If the patient presents with these symptoms, only prescribe submaximal, quick contractions in order not to increase tension; in addition, increase the rest time between pelvic floor contractions and sets. Use of surface EMG for downtraining, and muscle reeducation is invaluable with these impairments for increasing awareness of holding patterns, pain inhibition, and resting levels.

### CLINICAL TIP

For optimal outcomes, pelvic floor contractions should be incorporated into routine ADLs, particularly activities that are “triggers” for leakage due to increased intra-abdominal pressure; used for stabilization prior to coughing or sneezing; and continued for life-long health benefits.<sup>16,66</sup> From a neurophysiology standpoint, voluntary pelvic floor contractions create reflex inhibition through Bradley's Loop 3, which inhibits internal urethral sphincter relaxation and relaxes the detrusor muscle, leading to less urinary urgency and improved voiding intervals.<sup>113</sup>

## Related Exercises for Pelvic Floor Stabilization

### Hip Rotation<sup>72</sup>

**Patient position:** To recruit greater pelvic floor muscle activity, instruct the patient to sit tall (avoid slouching), with feet on the floor.<sup>111</sup>

- Have the client first perform active internal and external rotation by moving each leg outward and inward
- For *resisted hip external rotation*, place a resistance band around the distal thighs and instruct the client to roll their knees out against the band (the feet remain on the floor with heels touching and toes pointed outward to form a V), and hold the contraction for 5 seconds (Fig. 25.9 A).
- For *resisted hip internal rotation*, place an inflatable ball (approximately 9") between the knees and instruct the

**FIGURE 25.9** Hip rotation exercises to recruit pelvic floor muscle activity. (A) Resisted external rotation using a resistance band (note feet remain on floor in V position with heels touching), and (B) resisted internal rotation squeezing a ball between the knees (feet remain on floor and heels slide outward).

client to squeeze the ball by rolling their knees inward (the feet remain on the floor with the toes touching and heels sliding apart), and hold the contraction for 5 seconds (Fig. 25.9 B).

### Stabilization Exercises

Ideally, pelvic floor muscles contract in synchrony with the deep segmental muscles of the spine (multifidus and transverses abdominis); stabilization exercises may be helpful to facilitate contraction of the pelvic floor as a component of pelvic floor motor learning.<sup>14,109,110</sup> These exercises are described in Chapter 16. When used during pregnancy, specific precautions are identified later in this chapter.

## Aerobic Exercise During Pregnancy

Many women who have been doing aerobic exercises choose to continue exercising during pregnancy to maintain their cardiopulmonary fitness. Maternal<sup>4,8,33,35,70,125</sup> and fetal<sup>4,33,31,36,50,70,117,125</sup> responses have been well studied; therefore, this information is used to guide both the therapist and the patient in determining necessary modifications to an existing exercise program. The physiological effects of aerobic exercise to both the mother as well as fetus are described, followed by recommendations for fitness exercise.

### Maternal Response to Aerobic Exercise

#### Blood Flow

Aerobic exercise does not reduce blood flow to the brain and heart. It does, however, cause a redistribution of blood flow away from the internal organs (and possibly the uterus) and toward the working muscles. This raises two concerns: that the reduction in blood flow may decrease the oxygen and nutrient availability to the fetus and that uterine contractions and preterm labor may be stimulated.<sup>33</sup> Stroke volume and cardiac output both increase with steady-state exercise. This, coupled with increased blood volume and reduction in systemic vascular resistance during pregnancy, may help offset the effects of the vascular shunting.

#### Respiratory Rate

The maternal respiration rate appears to adapt to mild exercise but does not increase proportionately with moderate and severe exercise when compared with a nonpregnant state. The pregnant woman reaches a maximum exercise capacity at a lower work level than a nonpregnant woman because of the increased oxygen requirements of exercise.

#### Hematocrit Level

The maternal hematocrit level during pregnancy is lowered; however, it rises as many as 10 percentage points within

15 minutes of beginning vigorous exercise. This condition continues for as many as 4 weeks postpartum. As a result, cardiac reserve is decreased during exercise.

### Inferior Vena Cava Compression

Compression of the inferior vena cava by the uterus can occur after the fourth month of pregnancy, with relative obstruction of venous return. This leads to decreased cardiac output and orthostatic hypotension. It occurs most often in supine or static standing positions, and therefore prolonged time in these positions should be avoided.<sup>4</sup>

### Energy Needs

Hypoglycemia occurs more readily during pregnancy; therefore, adequate carbohydrate intake is important for the pregnant woman who exercises.<sup>31</sup> A caloric intake of an additional 500 calories per day is suggested to support the energy needs of pregnancy and exercise, dependent on the intensity and duration of the exercise. In comparison, a sedentary pregnant woman requires a 300 calorie per day increase.<sup>6</sup>

### Core Temperature

Vigorous physical activity and dehydration through perspiration lead to increased core temperature in anyone who exercises. Concern has been expressed over this occurring in the pregnant woman because of the relationship of elevated core temperature to neural tube defects of the fetus. Studies report that during pregnancy the core temperature of physically fit women actually decreases during exercise. These women appeared to be more efficient in regulating their core temperature, and thus the thermal stress on the embryo and fetus is reduced.<sup>31,35</sup>

### Uterine Contractions

Norepinephrine and epinephrine levels increase with exercise. Norepinephrine increases the strength and frequency of uterine contractions. This may pose a problem for the woman at risk of premature labor, although the association is small.<sup>4</sup>

### Responses of Healthy Women

Regular physical activity is beneficial for most pregnant women in terms of both physical and psychological wellness, and it also aids in weight management. Moderate-intensity aerobic activities are generally recommended in healthy pregnancy and the postpartum period for at least 150 min/wk.<sup>4</sup> Additionally, studies have shown that healthy women who continue to run throughout pregnancy deliver an average of 5 to 7 days sooner compared with controls.<sup>33,34</sup> Clapp<sup>33-35</sup> found that exercise, including weight bearing (even with ballistic motions such as during aerobic dancing), can be performed in midpregnancy and late pregnancy without risk of preterm labor or premature rupture of the membranes. Women who wish to continue strenuous

or competitive exercise or participate in specific athletic training require close supervision by a specialist during pregnancy.<sup>4,117</sup>

## Fetal Response to Maternal Aerobic Exercise

No human research has conclusively proven a detrimental fetal response to mild- or moderate-intensity maternal exercise. Recent studies suggest that even vigorous exercise does not have the detrimental effects on the fetus that once were feared, and therefore restrictions on exercise because of concerns for the effects on the embryo and fetus have been lessened. In fact, fit women who maintained their volume of exercise after 20 weeks' gestation delivered babies with lower fat mass than those who decreased exercise intensity midway through the pregnancy.<sup>33-35</sup> Given the epidemic of obesity in the United States, the need for future research to define further the connections between fetal nutrition and adult disease is imperative.<sup>36</sup>

### Blood Flow

A 50% or greater reduction of uterine blood flow is necessary before fetal well-being is affected (based on animal research). No studies have documented such decreases in pregnant women who exercise, even vigorously. It is suggested that the cardiovascular adaptations in exercising women offset any redistribution of blood to muscles during exercise.<sup>33</sup>

### Fetal Heart Rate

Brief submaximal maternal exercise (as much as 70% maternal aerobic power) does not adversely affect fetal heart rate (FHR).<sup>4</sup> The FHR usually increases 10 to 30 beats/minute at the onset of maternal exercise. After mild to moderate maternal exercise, the FHR usually returns to normal levels within 15 minutes, but in some cases of strenuous maternal exercise, the FHR may remain elevated as long as 30 min. Fetal bradycardia (indicating fetal asphyxia) during maternal exercise has been reported in the literature with the return to pre-exercise FHR levels within 3 minutes after maternal exercise, followed by a brief period of fetal tachycardia.<sup>50</sup> The healthy fetus appears to be able to tolerate brief episodes of asphyxia with no detrimental results.

### Heat Dissipation

The fetus has no mechanism such as perspiration or respiration by which to dissipate heat. However, physically fit women are able to dissipate heat and regulate their core temperature more efficiently, thus reducing risk.<sup>33</sup>

### Newborn Status

Newborn children of women who continue endurance exercises into the third trimester of pregnancy are reported to have an average decrease in birth weight of 310 g. There is no change in head circumference or heel-crown length. Further study of these children (as old as 5 years of age) has shown

slightly better neurodevelopmental status in addition to higher percentage of lean body mass.<sup>35</sup>

## Recommendations for Aerobic Training

**NOTE:** These recommendations are for pregnant women with no maternal or fetal risk factors.\*

- It is strongly recommended that all women participate in mild to moderate exercise, for both strength and cardiopulmonary benefits, for at least 15- to 30-minutes most days of the week. Individualized programs based on prepregnancy fitness levels are preferable.<sup>4,117</sup>
- Currently, there are no data in humans suggesting that pregnant women need to decrease their intensity of exercise or lower their target heart rates, but because of decreased oxygen supply, it is advisable to modify exercise intensity according to their tolerance.
  - Conventional (age-based) target heart rate zones may be too aggressive for the average pregnant patient.
  - Use of the Borg scale of perceived exertion (Box 25.4) is more appropriate in this population, with exertion between 12 and 14 suggested during uncomplicated pregnancy.<sup>4,21,117</sup>
  - When fatigued, a woman should stop exercising, and she should never exercise to exhaustion.
- Activities to avoid include contact sports, anything with a high risk of abdominal trauma or falling, “hot” yoga or “hot” Pilates, high-altitude activities (greater than 6,000 ft), and scuba diving. The fetus is at increased risk of decompression sickness during scuba diving.<sup>4,117</sup>
- Nonweight-bearing aerobic exercises, such as stationary cycling, swimming, or water aerobics, will minimize the risk of injury throughout pregnancy and the postpartum period.
- If the woman cannot safely maintain balance because of the shifting and increasing weight, have her modify exercises that could result in falling and injuring herself or the fetus. An example would be the need to modify or eliminate racquet sports as pregnancy progresses.<sup>4</sup>
- Adequate caloric intake for nutrition, adequate fluid intake, and appropriate clothing for heat dissipation are critical.
- Resumption of prepregnancy exercise routines during the postpartum period should be gradual. However, initiation of pelvic floor exercises immediately postpartum may reduce or possibly prevent symptoms and duration of incontinence.<sup>4,86-88</sup>
- Physiological and morphological changes of pregnancy continue for a minimum of 4 to 6 weeks postpartum—longer if the woman is breastfeeding. Encourage continued joint protection.

### BOX 25.4 Borg Rating Scale for Perceived Exertion (RPE)<sup>21</sup>

6—Very, very light
7
8
9—Very light
10
11—Fairly light
12
13—Moderately hard
14
15—Hard
16
17—Very hard
18
19—Very, very hard
20—Exhaustion

- Breastfeeding women can be reassured that moderate exercise does not impair quantity or quality of breast milk or infant growth.
  - Rate of weight loss in the postpartum period is variable in women who are lactating; an additional 500 calories/day are needed to support production of breast milk.<sup>67</sup>
  - Water intake continues to be important; 12 or more glasses per day are recommended.
  - There may be a short-term increase in lactic acid secreted in breast milk after high-intensity exercise; if the baby appears to eat less after an exercise session, this can easily be remedied by nursing before exercise. In addition, feeding the baby prior to exercise will reduce discomfort from any breast engorgement.<sup>4,67,117</sup>

### ABSOLUTE CONTRAINDICATIONS TO AEROBIC EXERCISE DURING PREGNANCY:

- Hemodynamically significant heart disease
- Restrictive lung disease
- Incompetent cervix: early dilation of the cervix before full term, or cerclage
- Vaginal bleeding, especially second or third trimester
- Placenta previa after 26 weeks gestation: placenta is located on the uterus in a position in which it may detach before the baby is delivered
- Multiple gestation with risk of premature labor<sup>4,67,94</sup>
- Preeclampsia or pregnancy-induced hypertension
- Rupture of membranes: loss of amniotic fluid before the onset of labor
- Premature labor: labor beginning before the 37th week of pregnancy
- Maternal type 1 diabetes
- Severe anemia

**NOTE:** See also precautions and relative contraindications to exercise in general in the following section.

\*4,7,8,21,33-36,44,51,67,70,87,88,93,103,108,114,117,120,125

## Exercise for the Uncomplicated Pregnancy and Postpartum

Exercise classes during pregnancy and after childbirth are designed to minimize impairments and help the woman maintain or regain function while she is preparing for the arrival of the baby and then caring for the infant.\* The potential structural and functional impairments and the management guidelines related to uncomplicated pregnancies are summarized in Box 25.5, and a suggested sequence for teaching an exercise class is listed in Box 25.6.<sup>4,7,8,120,125</sup>

\*4,7,8,44,51,52,67,70,87,88,92,93,100,103,104,108,114,117,120,121,125

Guidelines and techniques for exercise class instruction are included in this section.<sup>4,7,8,67,93, 117,120,125</sup> In addition, interventions for women receiving individualized care for specific impairments are noted throughout this section. Interventions for special situations such as cesarean childbirth and high-risk pregnancy are described in the following sections.

### Guidelines for Managing the Pregnant Woman

Suggest that your patients discuss with their physicians any guidelines or restrictions to exercise before engaging in an exercise program, either in a class or on a one-to-one basis. As always, follow your state practice act for physical therapy regarding referral, evaluation, and treatment.

#### BOX 25.5 MANAGEMENT GUIDELINES— Pregnancy and Postpartum

##### Potential Impairments of Structure and Function

- Musculoskeletal pain and muscle imbalances from faulty postures
- Poor body mechanics related to lack of knowledge, changing body size, and physical demands of child care
- Lower extremity edema and discomfort from altered circulation and varicose veins
- Pelvic floor impairments, including:
  - Urinary or fecal incontinence
  - Organ prolapse
  - Overactivity
  - Poor episiotomy healing
  - Poor proprioceptive awareness and disuse atrophy
  - Pain throughout the pelvic girdle/trunk
- Abdominal muscle stretch, trauma, and diastasis recti
- Potential decrease in cardiovascular fitness
- Lack of knowledge of body changes and safe exercises to use during and after pregnancy
- Changing body image
- Lack of physical preparation (strength, endurance, relaxation) necessary for labor and delivery
- Lack of knowledge of appropriate positioning for optimal comfort in labor and delivery
- Lack of adequate postpartum rehabilitation
- Anxiety regarding childbirth due to history of abuse

##### Plan of Care

##### Interventions

- | Plan of Care  | Interventions  |
|---|--|
| 1. Develop awareness and control of posture during and after pregnancy. | 1. Stretch, train, and strengthen postural muscles. Posture awareness.   |
| 2. Learn safe body mechanics.   | 2. Body mechanics in sitting, standing, lifting, and lying, as well as transitions from one position to another. Body mechanics with baby equipment and childcare activities. Position options for labor and delivery. |
| 3. Develop upper extremity strength for the demands of infant care.     | 3. Resistive exercises to appropriate muscles.   |

**BOX 25.5 MANAGEMENT GUIDELINES—  
Pregnancy and Postpartum—cont'd**

Plan of Care	Interventions
4. Promote increased body awareness and a positive body image.	4. Body awareness and proprioception activities. Reinforce posture.
5. Prepare the lower extremities for the demands of increased weight bearing and circulatory compromise.	5. Elastic support stockings. Safe stretching exercises. Toning and resistive exercises to appropriate muscles.
6. Develop awareness and control of the pelvic floor musculature.	6. Isolate pelvic floor muscle contraction and relaxation. Muscle control and integration with ADLs.
7. Maintain abdominal function and prevent or correct diastasis recti.	7. Monitor diastasis recti. Diastasis recti exercises. Safe abdominal-strengthening exercises with diastasis recti protection/correction.
8. Promote or maintain safe cardiovascular fitness.	8. Safe progression of aerobic exercises.
9. Teach about the changes of pregnancy and birth.	9. Patient/family instruction. Refer to other disciplines as indicated.
10. Develop relaxation skills.	10. Relaxation and breathing techniques
11. Prevent impairments associated with pregnancy.	11. Education about potential problems of pregnancy, prevention techniques, and appropriate exercises.
12. Prepare physically for labor, delivery, and postpartum activities.	12. Strengthen muscles needed in labor and delivery, and train responses. Comfort measures and relaxation techniques for labor and delivery.
13. Provide education on safe postpartum exercise progression.	13. Postpartum exercise instruction.
14. Develop awareness of treatment options for pelvic floor dysfunction.	14. Comprehensive approach for prolapse, incontinence, or overactivity.

**BOX 25.6 Suggested Sequence for Exercises Classes**

1. General rhythmic activities to “warm-up”
2. Gentle selective stretching for postural alignment and for perineum and adductor flexibility
3. Aerobic activity for cardiovascular conditioning (duration/intensity may need to be individualized)
4. Postural exercises; upper/lower extremity strengthening and individualized abdominal exercises
5. Cool-down activities
6. Pelvic floor exercises
7. Relaxation techniques
8. Labor and delivery techniques/positions
9. Educational information
10. Postpartum exercise instruction (e.g., when to begin exercises, how to safely progress, precautions) because the patient may not be attending a postpartum class. Include education regarding body mechanics relative to childcare.

**Examination.** Individually examine each woman before participation to screen for preexisting musculoskeletal problems, posture, and fitness level.

**Education.** Educate your patients that increased uterine cramping *may* occur with moderate activity; this is acceptable as long as the cramping stops when the activity is completed. Teach your patient all exercise guidelines and precautions so that exercises may be carried out safely at home. Include the following:

- Do not exceed 5 minutes of supine positioning at any one time after the first trimester of pregnancy to avoid vena cava compression by the uterus. Educate your patients that compression of the vena cava also occurs with motionless standing. For supine exercise, place a small wedge or rolled towel under the right hip to lessen the effects of uterine compression on abdominal vessels and to improve cardiac output. The wedge turns the patient slightly toward the left (Fig. 25.10).<sup>8</sup> This modification is also helpful during physical therapy evaluation and treatment when the patient is positioned supine.

**FIGURE 25.10** To prevent inferior vena cava compression when the patient is lying supine, a folded towel can be placed under the right side of the pelvis so the patient is tipped slightly to the left.

- To avoid the effects of orthostatic hypotension, instruct the woman to always rise slowly when moving from lying down or sitting to standing positions.
- Discourage breath holding and avoid activities that tend to elicit Valsalva's maneuver because this may lead to undesirable downward forces on the uterus and pelvic floor. In addition, breath holding causes stress to the cardiovascular system in terms of cardiac output, blood pressure, and heart rate.
- Break frequently for fluid replenishment. The risk of dehydration during exercise is increased in pregnancy. Avoid exercising in high temperature or humidity. Increase water intake in proportion to time spent exercising and as environmental temperature increases.
- Encourage complete bladder emptying before exercise. A full bladder places increased stress on an already vulnerable pelvic floor.
- Include appropriate warm-up and cool-down activities.
- Modify or discontinue any exercise that causes pain.
- Limit activities in which single-leg weight bearing is required, such as standing leg kicks. In addition to possible loss of balance, these activities can promote sacroiliac or pubic symphysis discomfort.

**Stretching/flexibility.** Choose stretching exercises that are specific to a single muscle or muscle group; do not involve several groups at once. Asymmetrical stretching or stretching multiple muscle groups can promote joint instability.

- Avoid ballistic movements.
- Do not allow any joint to be taken beyond its normal physiological range.
- Use caution with hamstring and adductor stretches. Overstretching of these muscle groups can increase pelvic instability or hypermobility.

### CLINICAL TIP

Consider use of muscle energy techniques using light resistance for a client with pelvic instability and one whose pelvic bony landmarks are out of alignment. (See Chapter 15 for description of techniques.)

**Muscle performance and aerobic fitness.** In addition to pelvic floor training and aerobic exercising that have already been presented in this chapter, specific areas to emphasize and selected exercise techniques for the woman during pregnancy and to prepare for labor and delivery are described in the following sections.

### FOCUS ON EVIDENCE

The *CPGs* from the Section on Women's Health and the Orthopaedic Sections of the American Physical Therapy Association recommend the use of exercise in the antepartum population with pelvic girdle pain. The guidelines also recommend exercise for pelvic girdle and low back pain but are not conclusive as to type due to conflicting evidence in varied populations and variety of exercise interventions.<sup>37</sup>

## Precautions and Contraindications to Exercise during Pregnancy

There are some circumstances in which exercise is contraindicated or requires very specific restrictions and precautions.<sup>4,6,7,24,37,52,54,30,67,93,94,103,114,117,120,125</sup> Discussion of interventions for patients with high-risk pregnancy are described later in this chapter.

**PRECAUTIONS:** Observe participants closely for signs of overexertion or complications. The following signs are reasons to *discontinue exercise* and *contact a physician*.<sup>4,117</sup>

- Vaginal bleeding
- Persistent pain, especially in the chest, pelvic girdle, or low back
- Leakage of amniotic fluid

- Regular painful uterine contractions that persist beyond the exercise session
- Decreased fetal movements
- Persistent shortness of breath, especially before exertion
- Irregular heartbeat
- Tachycardia
- Headache
- Dizziness/faintness
- Swelling/pain in the calf (rule out phlebitis)
- Difficulty in walking or maintaining balance

### CLINICAL TIP

Keep in mind when developing intervention programs, whether providing advice to a class or providing individual therapy, that most physical agents are *contraindicated* in pregnancy. Superficial heat or ice may be beneficial to relieve pain/spasm and improve circulation.

- Electric stimulation may be added postpartum to modulate pain and to stimulate muscle contractions, respectively.
- Ultrasound may be helpful in cases of poor episiotomy healing and persistent painful scar tissue, including reports of dyspareunia.<sup>65</sup>

**RELATIVE CONTRAINDICATIONS:** The woman with one or more of the following conditions may participate in an exercise program under close observation by a physician and a therapist as long as no further complications arise.<sup>4,6,8,24,67,93</sup> Exercises often require modification.<sup>4,117</sup> Discuss with referring practitioner.

- Poorly controlled type 1 diabetes, hypertension, seizure disorder or hyperthyroidism
- History of extremely sedentary lifestyle
- Musculoskeletal complaints and/or pain presenting with orthopedic limitations
- Overheating
- Extreme morbid obesity or extreme underweight (BMI below 12) or eating disorder
- Diastasis recti
- Heavy smoker
- Unevaluated maternal cardiac arrhythmia
- Chronic bronchitis
- Intrauterine growth retardation in current pregnancy

**NOTE:** Refer to the absolute contraindications to aerobic exercise identified in the aerobic section.

## Critical Areas of Emphasis and Selected Exercise Techniques

### Pelvic Floor Exercises

Pelvic floor exercises were described earlier in this section since they are useful for treating multiple conditions. It is worth emphasizing here the importance of including pelvic floor exercises when managing the pregnant woman.

### Posture Exercises

The growing fetus places added stress on postural muscles as the center of gravity shifts forward and upward and the spine shifts to compensate and maintain stability. In addition, after delivery, activities involving holding and caring for the baby stress postural muscles. Muscles that require emphasis are listed in Box 25.7 with reference to respective chapters where the exercises are described. Adaptations of specific exercises for the pregnant woman are described in this section.

Use caution when implementing flexibility and stretching exercises. Remember that connective tissues and supporting joint structures are more vulnerable during pregnancy and the immediate postpartum period because of hormonal changes. Resistance exercises are performed at a low intensity.

### Corrective Exercises for Diastasis Recti

Always check for diastasis recti before initiating abdominal exercises. Use only the corrective exercises (head lift or head lift with pelvic tilt) until the separation is 2 cm (two finger widths) or less.<sup>93</sup>

#### Head Lift

**Patient position and procedure:** Hook-lying with hands crossed over midline at the level of the diastasis for support. Have the client exhale and lift only the head off the floor while at the same time, using her hands to gently approximate the rectus muscles toward midline (Fig. 25.11), then lower the head slowly and relax. This exercise emphasizes the rectus abdominis muscle and minimizes the obliques. If a client cannot successfully reach across her abdomen, use a sheet

### BOX 25.7 Selected Stretching and Resistance Exercises During Pregnancy

#### Stretching (With Caution)

- Upper neck extensors and scalenes (Chapter 16)
- Scapular protractors, shoulder internal rotators, and levator scapulae (Chapter 17)
- Low back extensors (Chapter 16)
- Hip flexors, adductors, and hamstrings (Chapter 20)  
CAUTION: women with pelvic instabilities should not overstretch these muscles
- Ankle plantarflexors (Chapter 22)

#### Strengthening (Low Intensity With Modifications Described in This Chapter)

- Upper neck flexors and lower neck and upper thoracic extensors (Chapter 16)
- Scapular retractors and depressors (Chapter 17)
- Shoulder external rotators (Chapter 17)
- Trunk stabilizers with precautions if diastasis recti present (Chapter 16)
- Hip extensors (Chapter 20)
- Knee extensors (Chapter 21)
- Ankle dorsiflexors (Chapter 22)

**FIGURE 25.11** Corrective exercise for diastasis recti. The patient gently approximates the rectus muscle toward the midline by pulling with the crossed arms.

wrapped around the trunk at the level of the separation to provide support and approximation.<sup>93</sup>

### Head Lift With Pelvic Tilt

**Patient position and procedure:** Hook-lying. The arms are crossed over the diastasis for support as described in the “head lift” exercise. Have the patient slowly lift only the head off the floor while approximating the rectus muscles and performing a posterior pelvic tilt, then slowly lower the head and relax. Perform all abdominal contractions with an exhalation to minimize intra-abdominal pressure.

### Stabilization Exercises

Exercises for activating the abdominal and low back muscles and developing control of their stabilizing function in the lumbar spine and pelvis are described in Chapter 16 (see Table 16.4 and Figs. 16.47 and 16.48 [Level 3 A–C]; see also Table 16.5 and Fig. 16.49 A–D). Initiate and progress the exercises at the intensity that the woman is able to safely control. Emphasize slow, controlled breathing while developing the stabilizing function of the muscles. As pregnancy progresses, the abdominals will undergo extreme overstretching, and the pelvic floor complex will be progressively challenged by increased weight. These biomechanical changes make it even more challenging to teach pelvic floor activation in pregnancy without confirmation of internal assessment. As a result, core exercise prescription in particular must be adapted to meet the needs of each individual, and periodic reassessment must be done (approximately every 4 weeks during pregnancy).

### PRECAUTIONS:

- Because the trunk muscles are contracting isometrically in many of the stabilization exercises, there is a tendency to hold the breath; this is detrimental to the blood pressure and heart rate. Caution the woman to maintain a relaxed breathing pattern and exhale during the exertion phase of each exercise.
- If diastasis recti is present, adapt the stabilization exercises to protect the linea alba as described in the Corrective Exercises for Diastasis Recti section. Any progression of postpartum abdominal strengthening exercises should be postponed until the diastasis has been corrected to two finger widths or less.

- Keep in mind the 5-minute time limit for supine positioning when prescribing abdominal exercises after 13 weeks’ gestation.

### FOCUS ON EVIDENCE

An evidence based review of studies dealing with low-back pain and pelvic girdle pain reported statistical significance for the relief of pain and improved function during advancing pregnancy utilizing stability ball exercises and progressive core stabilization exercises.<sup>12</sup>

### Dynamic Trunk Exercises

#### Pelvic Motion Training

These exercises are helpful in cases of posture-related back pain; they are beneficial for improving proprioceptive awareness, as well as lumbar, pelvic, and hip mobility.

**Pelvic tilt exercises.** Begin in quadruped (on hands and knees). Instruct the patient to perform a posterior pelvic tilt. While the patient keeps her back straight, have her isometrically tighten (imagine drawing in) the lower abdominals and hold, then release and perform an anterior tilt through very small range.

- For additional exercise, while holding the abdominals in and the back straight, have the woman laterally flex the trunk to the right (side-bend to the right), looking at the right hip, then reverse to the left.
- Have the woman practice pelvic tilt exercises in a variety of positions, including side-lying and standing.

**Pelvic clock.**<sup>44</sup> With the woman hook-lying, ask her to visualize the face of a clock on her lower abdomen. The umbilicus is 12 o’clock and the pubic symphysis is 6 o’clock. The patient’s legs may move slightly while performing this exercise.

- Have her begin with gentle movements back and forth between 12 and 6 o’clock (the basic pelvic tilt exercise).
- Then ask her to move back and forth between 3 o’clock (weight shifted to left hip) and 9 o’clock (weight shifted to the right hip).
- Then move slowly and smoothly (in a clockwise manner) from 12 to 3 to 6 to 9 and then back to 12 o’clock. With repetition, the movement can become somewhat faster.

Eventually, these will become automatic, rhythmical movements and will not require such concentration on each number of the clock. Continue relaxed breathing throughout the exercise, and do not force any part of the movement. If the patient has difficulty with the motion, make the clock “smaller” until coordination improves.

**Pelvic clock progressions.** Use the visual imagery of cutting the face of the clock in half so that there is a right side and a left side or a top half and a bottom half. Have the woman move her pelvis through the arc on the one side and back through the middle of the clock, and then move the pelvis

through the opposite side and back through the middle. Initially, the woman may notice asymmetry when comparing the halves; this will improve with time.

- Once the patient understands and is able to perform the clockwise pattern, have her do counterclockwise motions with all of the activities mentioned previously, and then progress the exercises to the sitting position.

### Trunk Curls

- Curl-ups and curl-downs are classic abdominal exercises but should not be used during pregnancy. If a woman chooses to continue with trunk curls, they should only be used in the early stages of pregnancy *if tolerated and if no diastasis recti is present*. Have a pregnant patient protect the linea alba with crossed hands (see Fig. 25.11) while performing trunk curls.
- This precaution should also be followed when performing diagonal curls (carried out to emphasize the oblique muscles). Have the woman lift one shoulder toward the outside of the opposite knee as she curls up and down while protecting the linea alba with crossed hands.

## Modified Upper and Lower Extremity Strengthening

As the abdomen enlarges, it becomes impossible to comfortably assume the prone position. Exercises that are usually performed in the prone position must be modified.

### Standing Push-Ups

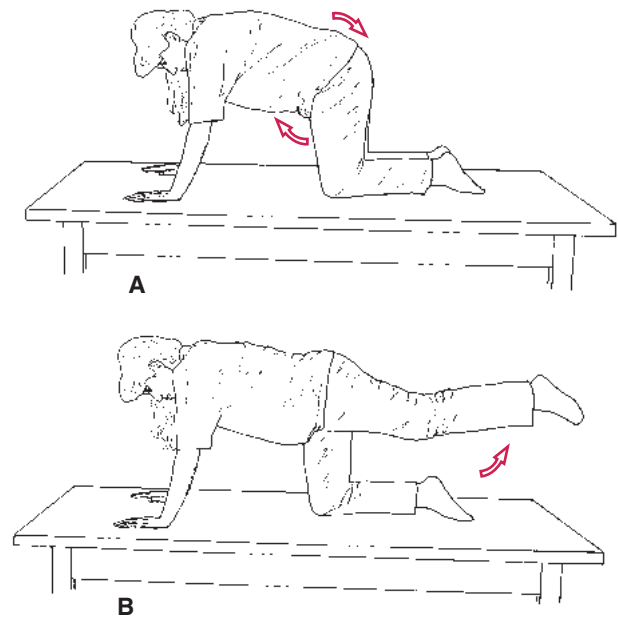

**Patient position and procedure:** Standing, facing a wall, feet pointing straight forward, shoulder width apart, and approximately an arm-length away from the wall. The palms are placed on the wall at shoulder height. Have the woman slowly bend the elbows, bringing her upper body close to the wall, maintaining a stable trunk and pelvic position, and keeping the heels on the floor. Her elbows should be shoulder height. She then slowly pushes with her arms, bringing the body back to the original position.

### Supine Bridging

**Patient position and procedure:** Supine in the hook-lying position. Have the woman perform a posterior pelvic tilt and then lift her pelvis off the floor. She can do repetitive bridges or hold the bridge position and alternately flex and extend her upper extremities to emphasize the stabilization function of the hip extensors and trunk musculature (see Fig. 20.28).

### Quadruped Hip Extension

**Patient position and procedure:** On hands and knees (hands may be in fists or palms may be open and flat). Instruct the woman to first perform a posterior pelvic tilt and then slowly lift one leg, extending the hip to a level no higher than the pelvis while maintaining the posterior pelvic tilt (Fig. 25.12). She then slowly lowers the leg and repeats with the opposite side. The knee may remain flexed or extended during the exercise. Monitor this exercise, and discontinue if there is stress on the sacroiliac joints or ligaments. If the

**FIGURE 25.12** All-fours leg-raising. (A) Patient assumes quadruped position with posterior pelvic tilt. (B) Leg is raised only until it is in line with the trunk.

woman cannot stabilize the pelvis while lifting the leg, have her just slide one leg posteriorly along the floor and return (see Fig. 16.50 A).

### Modified Squatting

Wall slides and supported squatting exercises are used to strengthen the hip and knee extensors for good body mechanics and to help stretch the perineal area for flexibility during the delivery process. In addition, if the woman wishes to use squatting for labor and delivery, the muscles must be strengthened and endurance trained in advance.

- **Patient position and procedure:** Standing with back against a wall and her feet shoulder width apart. Have the woman slide her back down the wall as her hips and knees flex only as far as is comfortable, then slide back up (see Fig. 20.29).
- **Patient position and procedure:** Standing with feet shoulder width apart or wider, facing a counter, chair, or wall on which the woman can rest her hands and/or forearms for support. Have the woman slowly squat as far as is comfortable, keeping knees apart and over the feet and keeping the back straight. To protect her feet, she should wear shoes with good arch support. A woman with knee problems should perform only partial range of the squat. For optimal success with squatting during stage 2 of labor (pushing), increase the duration of the squat gradually to 60 to 90 seconds as tolerated.

### Scapular Retraction

When scapular retraction exercises become difficult in the prone position, the woman should continue strengthening in the sitting or standing position (see Figs. 17.46 and 17.47.)

## Perineum and Adductor Flexibility

In addition to modified squatting previously described, these flexibility exercises prepare the legs and pelvis for childbirth.<sup>7,93,120</sup> Discontinue if any irritation or pain occurs at the pubic symphysis.

### Self-Stretching

- *Patient position and procedure:* Supine or side-lying. Instruct the woman to abduct the hips and pull the knees toward the sides of her chest and hold the position for as long as is comfortable (at least to the count of 10).
- *Patient position and procedure:* Sitting on a short stool with the hips abducted as far as comfortable and feet flat on the floor. Have her flex forward slightly at the hips (keeping the lumbar spine in neutral), or have her gently press her knees outward with her hands for an additional stretch.

## Relaxation and Breathing Exercises for Use During Labor

Developing the ability to relax requires awareness of stress and muscle tension. Techniques of conscious relaxation allow the individual to manage and respond to a variety of imposed stresses by being mentally alert to the task at hand while relaxing tense muscles that are superfluous to the activity (see Chapter 4). This is particularly important during labor and delivery when there are times that the woman should relax and allow the physiologic processes to occur without excessive tension in unrelated muscles.<sup>93</sup> Additional relaxation techniques for managing stress are described in Chapter 14. The following guidelines are most effective for the pregnant woman if consistently practiced in preparation for labor and delivery.

### Visual Imagery

Use instrumental music and verbal guidance. Instruct the woman to concentrate on a relaxing image such as the beach, mountains, or a favorite vacation spot. Suggest that she focus on the same image throughout the pregnancy so that the image can be called up to the conscious level when recognizing the need to relax during labor. These techniques have been found to be helpful in various pain conditions as well as for anxiety.<sup>89</sup>

### Muscle Setting

- Have the woman lie in a comfortable position.
- Have her begin with the lower body. Instruct her to gently contract and then relax first the muscles in the feet, then legs, thighs, pelvic floor, and buttocks.
- Next, progress to the upper extremities and trunk, then to the neck and facial muscles.
- Reinforce the importance of remaining awake and aware of the contrasting sensations of the muscles. Emphasize “softening” of the muscles as the session continues.
- Add deep, slow, relaxed breathing to the routine.

## Selective Tension

Progress the training by emphasizing awareness of muscles contracting in one part of the body while remaining relaxed in other parts. For example, while she is tensing the fist and upper extremity, the feet and legs should be limp. Reinforce the comparison between the two sensations and the ability to control both tension and relaxation.

### CLINICAL TIP

While practicing *selective tension*, have your client work with a partner who gently shakes the extremity that is “relaxed” to make sure there is no tension in it.

## Breathing

- Slow, deep breathing (with relaxation of the upper thorax) is the most efficient method for exchange of air to use with relaxation techniques and for controlled breathing during labor.
- Teach the woman to relax the abdomen during inspiration so that it feels as though the abdominal cavity is “filling up” and the ribs are expanding laterally. During exhalation, the abdominal cavity becomes smaller; active contraction of the abdominal muscles is not necessary with relaxed breathing.
- To prevent hyperventilation, emphasize a slow rate of breathing. Caution the woman to decrease the intensity of the breathing if she experiences dizziness or feels tingling in the lips and fingers.

## Relaxation and Breathing During Labor

### First Stage

As labor progresses, the contractions of the uterus become stronger, longer, and closer together. Relaxation during the contractions becomes more difficult. Provide the woman with suggested techniques to assist in relaxation.<sup>93</sup>

- Ensure the woman has emotional support from the father, family member, or special friend to provide encouragement and assist with overall comfort.
- Seek comfortable positions including walking, hands and knees, lying on pillows, or lying or sitting on a Swiss ball (Fig. 25.13); include gentle repeated rhythmical motions such as pelvic rocking.
- Breathe slowly with each contraction; use visual imagery, such as muscles softening like butter, and attempt to relax. Some women find it helpful to focus their attention on a specific visual object. Other suggestions include singing, talking, or moaning during each contraction to prevent breath holding and encourage slow breathing.
- During transition (near the end of the first stage), there is often an urge to push. Teach the woman to use quick blowing techniques, using the cheeks, not the abdominal muscles, to overcome the desire to push until the appropriate time.

**FIGURE 25.13** The use of a stability ball in labor can provide relief of back pain and the comfort of rhythmical, relaxing movements. The labor coach can massage the back and/or hip muscles and apply heat or ice if desired.

- Massage or apply pressure to any areas of pain or discomfort, such as the low back. Using the hands may help distract the focus from the contractions.
- Apply heat or cold for local symptoms; wipe the face with a wet washcloth.

### Second Stage

Once dilation of the cervix has occurred, the woman may become more active in the birth process by assisting in pushing the baby down the birth canal.<sup>93</sup> Teach her the following techniques:

- While bearing down, take in a breath, contract the abdominal wall, and slowly breathe out. This will cause increased pressure within the abdomen along with relaxation of the pelvic floor.

**PRECAUTION:** Tell the woman that if she holds her breath, there will be increased tension and resistance in the pelvic floor. In addition, exertion with a closed glottis, known as Valsalva's maneuver, has adverse effects on the cardiovascular system.

- For maximum efficiency, maintain relaxation in the extremities, especially the legs and perineum. Keeping the face and jaw relaxed assists with this.
- Between contractions, perform total body relaxation.
- As the baby is delivered, just "let go," and breathe with light pants or groans to relax the pelvic floor as it stretches.

## Unsafe Postures and Exercises During Pregnancy

**Bilateral straight-leg raising.** This exercise typically places more stress on the abdominal muscles and low back than they can tolerate. It can cause back injury or diastasis recti and therefore should not be attempted.

**"Fire hydrant" exercise.** This exercise is performed on hands and knees, and one hip is abducted and externally rotated at a time (the "image" of a dog at a fire hydrant). If the leg is elevated too high, the sacroiliac joint and lumbar vertebrae can be stressed. It should be avoided by any woman who has preexisting sacroiliac joint symptoms or women in whom symptoms develop.

**All-fours (quadruped) hip extension.** This exercise can be performed safely only as explained earlier in this chapter (see Fig. 25.12). It becomes unsafe and can cause low back pain when the leg is elevated beyond the physiologic range of hip extension, causing the pelvis to tilt anteriorly and the lumbar spine to hyperextend.

**Unilateral weight-bearing activities.** Weight bearing on one leg (which includes slouched standing with the majority of weight shifted to one leg and the pelvis tilted down on the opposite side) during pregnancy can cause sacroiliac joint irritation and should be avoided by women with preexisting sacroiliac joint symptoms. Unilateral weight bearing also can cause balance problems because of the increasing body weight and shifting of the center of gravity. This posture becomes a significant problem postpartum when the woman carries her growing child on one hip. Any asymmetries become accentuated, and painful compensations may develop.

## Exercise Critical to the Postpartum Period

After an uncomplicated vaginal delivery, exercise can be started as soon as the woman feels able to exercise and has been cleared by her physician or midwife.<sup>4,6, 67,87,88,93,51,108,117</sup>

**Pelvic floor strengthening.** Exercises should be resumed as soon after the birth as possible. These exercises increase circulation and aid healing of lacerations or episiotomy. Combining pelvic floor contractions with feeding or changing the baby may help them become integrated into the daily routine. When treating a postpartum client in the clinic, emphasize the life-long need for pelvic floor exercise, especially when lifting or with significant exertion, to allow the pelvic floor muscles to provide additional "shock absorption" and trunk support.

**Diastasis recti correction.** The testing procedure for diastasis recti was described earlier in this chapter. The mother should be taught this test and encouraged to perform it on the third postpartum day. Corrective exercises (see Fig. 25.11) should continue until the separation is two finger widths or less. At that time, more vigorous abdominal exercise can be resumed.

**Aerobic and strengthening exercises.** As soon as the woman feels able, resume cardiopulmonary exercise and light resistance training with gradually increasing intensity. It is suggested that a physical examination, including assessment of pelvic floor integrity be conducted before the onset of vigorous exercise or sport-specific training.

**PRECAUTIONS:** Because the woman may not be seen for exercise instruction after the delivery, inform her of the following precautions:

- If bleeding increases or turns bright red, exercise should be postponed. Tell her to rest more and allow a longer recovery time.
- Joint laxity may be present for some time after delivery, especially if breastfeeding. Precautions should be taken to protect the joints as described previously.<sup>7,120,125</sup> Adequate warm-up and cool-down time is important.

## Cesarean Childbirth

A *cesarean section* (C-section) is the delivery of a baby through an incision in the abdominal wall and uterus rather than through the pelvis and vagina.<sup>3,52, 54,60, 67</sup> General, spinal, or epidural anesthesia may be used.

### Significance to Physical Therapists

#### Surgical Risks

C-section delivery is now at an all-time high and is the most commonly performed surgical procedure in the world. In 2013, C-sections in the United States reached a record high rate of 32.7%.<sup>62</sup> This number has fluctuated in the past 3 to 4 decades, in part depending on the type of hospital and the population it served. Since the early 1990s, the American College of Obstetricians and Gynecologists (ACOG) has discouraged repeat C-sections as routine practice, and the *Healthy People 2010* goal was to reduce the primary rate to 15%, with a target rate for repeat cesareans at 63%.<sup>127</sup> The Vaginal Birth After Cesarean (VBAC) movement was a factor in reducing C-sections from 1990 to 1996; however, since then, the rates have continued to climb. The medical community is continuing to discuss the short- and long-term benefits

and harms to both mother and baby of a trial of labor following a previous C-section. Pregnant clients will have many questions regarding this evidence. Al-Zirqi and colleagues<sup>2</sup> identified specific risk factors for uterine rupture with a VBAC and determined that absolute risk was low (5/1,000 births; n= 18,794). However, the use of prostaglandin induction significantly increased the odds for rupture when compared to spontaneous labor.

Recently, the perceived “convenience” of a C-section is becoming a factor, leading to increases in not only repeat, but also elective, C-sections. In reality, there is conflicting evidence that cesarean delivery may aid in prevention of future pelvic floor dysfunction.<sup>9,55,60,116</sup> These risks and benefits will continue to be discussed as long-term maternal and fetal outcomes are detailed in the literature. Because these statistics continue to fluctuate and more changes will be inevitable as our health-care system evolves, physical therapists must stay informed in order to address these issues with all pregnant patients so each patient will know the risks and benefits when making their own decision.<sup>2,9,54,60,74,83,116,120,123</sup>

#### Interventions

**Pelvic floor rehabilitation.** Women who have had a cesarean delivery may still require pelvic floor rehabilitation. Many women experience a lengthy labor, including prolonged second stage (pushing), before a C-section is deemed necessary. Therefore, the pelvic floor musculature and the pudendal and levator ani nerves may still be compromised. Also, pregnancy itself creates significant strain on the pelvic floor musculature and other soft tissues.

**Postsurgical rehabilitation.** Postpartum intervention for the woman who has had a cesarean delivery is similar to that of the woman who has had a vaginal delivery. However, a C-section is a major abdominal surgery with all the risks and complications of such surgeries, and therefore the woman may also require general postsurgical rehabilitation.<sup>54,60,120</sup> Impairments and management guidelines are summarized in Box 25.8.

### BOX 25.8 MANAGEMENT GUIDELINES— Postcesarean Section

#### Potential Impairments of Structure and Function

- Risk of pulmonary, gastrointestinal, or vascular complications
- Postsurgical pain and discomfort
- Development of adhesions at incision site
- Faulty posture
- Pelvic floor dysfunction
  - Urinary or fecal incontinence
  - Organ prolapse
  - Overactivity
  - Poor proprioceptive awareness and disuse atrophy
  - Pain throughout the pelvic girdle/trunk
- Abdominal weakness, diastasis recti
- General functional restrictions of post delivery

**BOX 25.8** MANAGEMENT GUIDELINES—  
**Postcesarean Section—cont'd**

Plan of Care	Interventions
1. Improve pulmonary function and decrease the risk of pneumonia	1. Breathing instruction, coughing, and/or huffing
2. Decrease incisional pain with coughing, movement, or breastfeeding	2. Postoperative TENS; support incision with pillow when coughing or breastfeeding Incisional support with pillow or hands with movement education regarding incisional care and risk of injury
3. Prevent postsurgical vascular or gastrointestinal complications	3. Active leg exercises Early ambulation Teach abdominal massage to stimulate peristalsis <sup>63</sup>
4. Enhance incisional circulation and healing; prevent adhesion formation.	4. Gentle abdominal exercise with incisional support Scar mobilization and friction massage
5. Decrease postsurgical discomfort from flatulence, itching, or catheter	5. Positioning instruction, massage, and supportive exercises
6. Correct posture	6. Posture instruction, particularly regarding childcare
7. Prevent injury and reduce low back pain	7. Instruction in incisional splinting and positioning for ADLs Body mechanics instruction
8. Prevent pelvic floor dysfunction	8. Pelvic floor exercises Education regarding risk factors and types of pelvic floor dysfunction
9. Develop abdominal strength	9. Abdominal exercise progression, including corrective exercises for diastasis recti

**Emotional support.** All childbirth preparation classes do not adequately educate and prepare couples for the experience of a cesarean delivery. As a result, the woman with an unplanned C-section frequently feels as if her body has failed her, causing her to have more conflicting emotions than a woman who has experienced a “normal” vaginal delivery.

## Suggested Activities for the Patient Following a Cesarean Section

### Exercises

- Instruct the woman during her pregnancy in all appropriate exercises, with indicated precautions.
- Instruct the woman to begin preventive exercises as soon as possible during the recovery period.<sup>52,67,93,94</sup>
  - Ankle pumping, active lower extremity range of motion (ROM), and walking are used to promote circulation and prevent venous stasis.
  - Pelvic floor exercises are used to regain strength, function, and control of the muscles of the perineum.
  - Deep breathing and coughing or huffing are used to prevent pulmonary complications (see instructions that follow).
  - Progress abdominal exercises slowly. Check for diastasis recti, and protect the area of the incision to improve comfort. Initiate nonstressful muscle-setting techniques and progress as tolerated, based on the degree of separation.<sup>52,67,93,94,120</sup>
  - Teach posture correction as necessary. Retrain postural awareness and help realign posture with indicated therapeutic exercise. Develop control of the shoulder girdle muscles as they respond to the increased stress of caring for the new baby.
  - Reinforce the value of deep diaphragmatic breathing techniques for pulmonary ventilation, especially when exercising, and relaxed breathing techniques to relieve stress and promote relaxation.
  - Inform the woman that she should wait at least 6 to 8 weeks before resuming vigorous exercise. Emphasize the importance of progressing at a safe and controlled pace and not expecting to begin at her prepregnancy level.

## Coughing or Huffing

Coughing is difficult following a C-section because of incisional pain. An alternative is huffing.<sup>93</sup> A huff is an outward breath caused by the upper abdominals contracting up and in against the diaphragm to push air out of the lungs. The abdominals are pulled up and in, rather than pushed out, causing decreased pressure in the abdominal cavity and less strain on the incision. Huffing must be done quickly to generate sufficient force to expel mucus. Instruct the patient to support the incision with a pillow or the hands and say “ha” forcefully and repetitively while contracting the abdominal muscles.

## Interventions to Relieve Intestinal Gas Pains

**Abdominal massage or kneading.** Have the patient lie supine or on the left side. This is very effective and typically done with either long or circular strokes. Begin on the right side at the ascending colon, stroking upward, then stroke across the transverse colon from right to left and down the descending colon, then finish with an “S” stroke along the sigmoid colon. This can also be particularly beneficial in stimulating peristalsis and improving constipation in general.<sup>63</sup>

**Pelvic tilting and/or bridging.** These can be done in conjunction with massage.

**Bridge and twist.** Have the patient maintain a position of bridging while twisting her hips to the right and left.

## Scar Mobilization

Cross-friction massage should be initiated around the incision site as soon as sufficient healing has occurred. This will minimize adhesions that may contribute to postural problems and back pain.

# High-Risk Pregnancy

A *high-risk pregnancy* is one that is complicated by disease or problems that put the mother or fetus at risk for illness or death before, during, or after delivery. Conditions may be preexisting, induced by pregnancy, or caused by an abnormal physiologic reaction during pregnancy.<sup>54,67</sup> The goal of medical intervention is to prevent preterm delivery. Historically bed rest has been used, as well as restriction of activity and medications when appropriate. Recent guidelines from ACOG are advising against routine bed rest, however. “Although frequently prescribed, bed rest is only rarely indicated and, in most cases, allowing ambulation should be considered. Patients prescribed prolonged bed rest or restricted physical activity are at risk of venous thromboembolism, bone demineralization, and deconditioning.”<sup>74</sup> Prolonged bed rest can impact not just the musculoskeletal system, but also pulmonary, cardiovascular, and metabolic functions. Although these women may initially be seen in the home or as inpatients, the deconditioning present continues to create functional restrictions for the postpartum client in terms of strength and endurance, making this scenario ideal for further

physical therapy intervention. Here again, as with pelvic floor dysfunction, advanced education for the therapist and specialized care is required for successful outcomes.<sup>7,54,67,103,108,120</sup>

## High-Risk Conditions

**Premature onset of labor.** If cervical dilation, effacement, and/or uterine contractions begin before 37 weeks’ gestation, this is considered preterm labor. Clearly, the health of the baby is of primary concern if these signs are present. The mechanism for this condition is still unclear.<sup>67</sup>

**Preterm rupture of membranes.** If the amniotic sac breaks and amniotic fluid is lost before onset of labor, it can be dangerous to the fetus if fetal development is complete. Labor may begin spontaneously after the membranes rupture. The chance for fetal infection also increases when the protection of the amniotic sac is lost. Leakage of amniotic fluid is an indication for immediate medical attention.

**Incompetent cervix.** An incompetent cervix is the painless dilation of the cervix that occurs in the second trimester (after 16 weeks’ gestation) or early in the third trimester of pregnancy. Intervention may include cerclage (stitches in the cervix to keep it closed). If the dilation continues, it may lead to premature membrane rupture and delivery of a fetus too small to survive.

**Placenta previa.** The placenta attaches too low on the uterus, near the cervix. As the cervix dilates, the placenta begins to separate from the uterus and may present before the fetus, thus endangering fetal life. The primary symptom is intermittent, recurrent, or painless bleeding that increases in intensity.

**Pregnancy-related hypertension or preeclampsia.** Characterized by hypertension, protein in the urine, and severe fluid retention, preeclampsia can progress to maternal convulsions, coma, and death if it becomes severe (eclampsia). It usually occurs in the third trimester and disappears after birth. The cause is not understood.

**Multiple gestation.** More than one fetus develops. Complications of multiple gestations include premature onset of labor and birth, increased incidence of perinatal mortality, lower-birth-weight infants, and increased incidence of maternal complications (e.g., hypertension).

**Diabetes.** Diabetes can be present before pregnancy or may occur as a result of the physiological stress of pregnancy. Gestational diabetes mellitus (GDM), which presents or is first recognized in pregnancy, affects 7% of pregnant women and usually disappears after pregnancy; however, as many as 50% of these women may develop type 2 diabetes within 10 years.<sup>30</sup> Inactivity and excessive weight gain in pregnancy has been found to be an independent risk factor for GDM.<sup>4</sup>

Unlike many of the previously discussed high-risk conditions, women with gestational diabetes may be appropriate candidates for more traditional physical therapy interventions.<sup>4</sup> Supervised, individualized exercise programs are excellent options. Parameters for exercise in pregnancy for

women with gestational diabetes were published by the American Diabetes Association in 2006.<sup>6</sup> They support aerobic exercise with limited duration and at 50% maximum aerobic capacity; alternatively, the Borg scale may be used with a range of 11 to 13 rate of perceived exertion (RPE) as maximal activity level (see Box 25.4). With appropriate monitoring of fetal/uterine activity, maternal heart rate, and blood glucose levels, exercise duration of 15 to 30 minutes appears to be safe.<sup>67</sup> Instruct patients to monitor for any postexercise uterine activity; contractions need to be fewer than one every 15 minutes.<sup>6,67</sup>

Exercise may actually prevent gestational diabetes in obese pregnant women.<sup>4</sup> In particular, recumbent bicycling or arm ergometer exercises stabilize and lower glucose levels.<sup>103</sup>

**FOCUS ON EVIDENCE**

In a randomized study of overweight women with gestational diabetes (n=32), the control group was treated with diet alone, while the remaining women also participated in circuit resistance training. The diet-plus-exercise group was able

to postpone the use of insulin therapy until later in the pregnancy ( $p < 0.05$ ) and was also prescribed less insulin overall ( $p < 0.05$ ) than the diet-alone group.<sup>24</sup> A recent systematic review assessed both prevention and management of gestational diabetes with inconclusive results, possibly linked to compliance issues. There is some evidence that physical activity in pregnancy contributes to glycemic control and reduced use of insulin in these women.<sup>107</sup>

**Management Guidelines and Precautions for High-Risk Pregnancies**

Establish an individually designed exercise program for each woman with a high-risk pregnancy based on diagnosis, limitations, physical therapy examination, evaluation, and consultation with the physician. Activities must address patient needs but should not further complicate the condition.<sup>7,120</sup> Management guidelines for the woman who is confined to bed because of her high-risk status are summarized in Box 25.9.

**BOX 25.9 MANAGEMENT GUIDELINES—  
High-Risk Pregnancy**

**Potential Impairments of Structure and Function, and Activity Limitations**

Primary activity limitations are inability to be out of bed and move about and prolonged static positioning, contributing to the following impairments:

- Joint stiffness and muscle aches
- Muscle weakness and disuse atrophy
- Vascular complications including risk of thrombosis and decreased uterine blood flow
- Decreased proprioception in distal body parts
- Constipation caused by lack of exercise
- Postural changes
- Boredom

Emotional stress; patient may be at risk of losing the baby

Guilt from the belief that some activity caused the problem or that the patient did not take good enough care of herself

Anxiety about her home situation, older children, finances, or the impending birth

Plan of Care	Interventions
1. Decrease stiffness	1. Positioning instructions; assess for supports Facilitation of joint motion in available range
2. Maintain muscle length and bulk	2. Stretching and strengthening exercises within limits imposed by the physician
3. Maximize circulation; prevent deep-vein thrombosis	3. Ankle pumping; ROM
4. Improve proprioception	4. Movement activities for as many body parts as possible
5. Improve posture within available limits	5. Posture instruction, modified as necessary based on allowed activity level Bed mobility and transfer techniques if able (avoid Valsalva's maneuver)

Continued

**BOX 25.9** MANAGEMENT GUIDELINES—  
**High-Risk Pregnancy—cont'd**

Plan of Care	Interventions
6. Relieve boredom	6. Vary activities and positioning for exercises; encourage interaction with others on bed rest ( <a href="http://www.side-lines.org">http://www.side-lines.org</a> )
7. Enhance relaxation	7. Relaxation techniques/stress management
8. Prepare for delivery	8. Childbirth education, breathing training, and exercises to assist and prepare for labor
9. Enhance postpartum recovery	9. Exercise instruction and home program for postpartum period Body mechanics instruction, particularly related to childcare

Develop good rapport with the patient and instill trust. Closely monitor the patient during all activities; re-evaluate after each treatment, and note any changes. It is also important to teach the patient self-monitoring techniques so that she will be alert to adverse reactions and respond appropriately.

- Prolonged static positioning is a primary concern. The position of choice for the high-risk patient is left side-lying, which is optimal for reducing pressure on the inferior vena cava and for maximizing cardiac output, thereby enhancing maternal and fetal circulation.
- Some exercises, especially abdominal exercises, may stimulate uterine contractions. If this occurs, modify or discontinue them.
- Monitor and report any uterine contractions, bleeding, or amniotic fluid loss.
- Do not allow use of Valsalva’s maneuver. Avoid any activities that increase intra-abdominal pressure. Body mechanics and postural instruction may stimulate abdominal contractions, so be sure the patient does not strain and closely monitor for adverse symptoms.
- Keep the exercises simple. Have the patient do them slowly, smoothly, and with minimal exertion.
- Many high-risk pregnancies result in cesarean deliveries, so educate the woman about cesarean delivery rehabilitation.
- Incorporate maximum muscle efficiency into each movement.
- Teach the patient self-monitoring techniques.

**Exercise Suggestions With High-Risk Pregnancies**

Exercise suggestions are adaptations of interventions that have already been described that should be considered for the bed-bound patient with a high-risk pregnancy.<sup>7,103,120</sup> Exercises to include are summarized in Box 25.10.

**Positioning**

- Left side-lying to prevent vena cava compression, enhance cardiac output, and decrease lower extremity edema
- Pillows between the knees and under the abdomen when side-lying
- Supine positioning for short periods, with a wedge placed under the right hip to decrease inferior vena cava compression (see Fig. 25.10)
- Modified prone positioning (side-lying, partially rolled toward prone, with pillow under abdomen) to decrease low back discomfort and pressure

**BOX 25.10** Bed Exercises for High-Risk Pregnancy

- Patient supine (with wedge under the right hip), semireclined, or side-lying
- Cervical active ROM and chin tucks
- Backward shoulder circles (scapular retraction); reach to ceiling (protraction)
- Unilateral upper extremity diagonal patterns
- Shoulder, elbow flexion/extension; arm circles in side-lying
- Forearm pronation/supination; wrist flexion/extension, hand open/close
- Pelvic tilts
- Abdominal exercises (per physician consultation)
- Pelvic floor exercises (per physician consultation)
- Quad and gluteal isometric sets
- Unilateral hip abduction and adduction, internal/external rotation
- Unilateral hip and knee flexion/extension in side-lying
- Ankle pumping, ankle circles, ankle “alphabet”
- Toe flexion/extension

**ROM**

- Active ROM of all joints
- Motions should be slow, nonstressful, and through the full range if possible
- Teach in a gravity-neutral position if antigravity ROM is too much exertion
- Individualize the number of repetitions and frequency to the woman's condition

**Ambulation/Standing**

Historically, getting out of bed has been contraindicated with high-risk pregnancies; this will likely continue to evolve in varied health-care settings.<sup>4</sup> In the past, women would be upright only for using the bathroom or to shower. When allowed:

- Encourage good posture in ambulation
- Tip-toe or heel walking to emphasize calf muscles
- Gentle, partial-range squatting to emphasize hip and thigh muscles

**Relaxation Techniques, Bed Mobility, and Transfer Activities**

- Relaxation as in the uncomplicated pregnancy
- Moving up, down, and side-to-side in bed
- Log rolling: incorporate neck and upper and lower extremities to aid movement
- Supine-to-sitting: use log-roll technique, assisted by arms

**Preparation for Labor**

- Relaxation techniques
- Substitutions for squatting: supine, sitting, or side-lying, bringing flexed knees toward chest (hips will have to be abducted)
- Pelvic floor relaxation
- Breathing exercises: minimize forced abdominal exhalations

**Postpartum Exercise Instruction**

Instructions are the same as previously described in the uncomplicated pregnancy section.

## Independent Learning Activities

**Critical Thinking and Discussion**

1. Describe three normal changes of pregnancy that will affect exercise tolerance.
2. Explain the clinical significance of diastasis recti, the testing procedure, and the corrective exercise.
3. Differentiate between postural and sacroiliac back pain in the pregnant patient.
4. Name five risk factors for pelvic floor dysfunction.
5. What exercise guidelines are most helpful for a woman who has not exercised prior to becoming pregnant?
6. Discuss optimal positioning for an uncomplicated labor and delivery in terms of biomechanics, gravity, and energy conservation.
7. Vaginal delivery places great stretch and compression on which nerves?

**Laboratory Practice**

1. Practice giving instructions to a lab partner on how to perform the following exercises. Observe that they are being done correctly. Reverse the experience and provide feedback.
  - Diastasis recti exercises
  - Pelvic clock exercises
  - Breathing and relaxation for the different stages of labor and delivery
2. Practice giving instructions, and get verbal feedback as to the success of instructions for the pelvic floor awareness training and strengthening exercises.
3. Observe an exercise class for pregnant women. Critique the effectiveness and inclusiveness of the instruction.

**Case Studies****Case Study 1**

Ms. V is a 32-year-old pregnant woman referred with a diagnosis of “low back pain” that became severe at 24 weeks’ gestation. She reports (L) lumbar/thoracic, (R) anterior rib/pectoral, and cervical symptoms, which are worsening as the pregnancy progresses. Before her pregnancy, she wore a custom-made bra (32-MM), which is now much too small and provides inadequate support. Wearing this bra greatly increases her cervical and upper trapezius symptoms. Wearing a sports bra or standing more than 10 to 15 minutes causes increased low back symptoms. Pain is severely limiting her daily activities both at home and in the community. She has difficulty climbing stairs, grocery shopping, doing laundry, and other household chores. She is wakened at night by pain and also reports numbness in her lower extremities at night. She is a single mother of a 6-year-old son. Pertinent medical history includes a weight gain of 100 lb with her previous pregnancy, C-section delivery, and removal of fibrocystic breast tissue three times. She has no systemic medical conditions or medications other than prenatal vitamins. Current weight: 238 lb, height: 5’4”.

**Clinical Findings**

Postural assessment reveals marked forward head/shoulders with internal rotation at both shoulder joints, significant lordosis (cervical and lumbar), recurvatum bilaterally, decreased longitudinal arches, and increased base of support with excessive external rotation (ER) at both hips. All dynamic movements are pain inhibited: frequent weight shift and

asymmetrical transitions, antalgic gait pattern with increased ER of hips. Lumbar extension and (L) cervical rotation most limited by pain and spasm.

Diastasis recti of 9 cm noted above umbilicus; abdominal strength 3–/5. Pelvic landmarks difficult to assess due to adipose tissue; leg lengths appear equal. Slight tenderness over pubic symphysis with palpation.

- Identify the impairments and functional limitations.
- Identify goals that deal with impairments and functional limitations.
- Develop a treatment plan to meet the goals; identify specific interventions and parameters, number of times she will be seen, and any follow-up or referrals that you believe will be necessary.

### Case Study 2

Mrs. W is a 71-year-old woman with an 11-year history of urinary incontinence and urgency. She experiences frequent, large-volume accidents, using 8 to 10 large incontinence pads and 8 panty liners per day for garment protection. Voiding frequency is 13 to 16 times every 24 hours. She also reports constipation and straining for evacuation, which improves with increased fiber intake. Caffeine intake is two servings per day. Mrs. W is a nonsmoker. She is much less active with social and community activities as a result of this problem. Urodynamic testing revealed diminished bladder capacity at 150 cc and confirmed the diagnosis of detrusor instability.

Pertinent medical history includes nine pregnancies and seven live births (G9, P7) with one breech presentation. LBP and “sciatic nerve problems” of long standing were reported

with lumbar fusion done when she was 44 and 48 years of age. Other surgical history includes rectocele/cystocele repair when she was 36 and partial hysterectomy when she was 37. Hypertension and asthma are both well controlled with medication.

### Clinical Findings

Pelvic floor muscle assessment reveals poor sensory awareness, decreased resting tone, and an MMT of 2/5. Patient able to hold a contraction 4 seconds and repeat 10 “quick flicks” in 10 seconds. Accessory recruitment of the abdominals noted. Pressure perineometry confirms muscle weakness with 6.35 cm of water pressure generated. Levator ani contraction is enhanced with stretch facilitation to the pelvic floor (R > L).

Abdominal strength is 3/5. Diastasis recti noted above the umbilicus of 4.5 cm. Diaphragmatic breathing pattern present; no Valsalva’s with exertion. All dynamic movements of the trunk are mildly restricted because of lumbar fusion.

The patient underwent physical therapy treatments approximately 18 months ago and is independent with her low back program. (Because of insurance limitations of 10 visits, the patient requested primary attention to pelvic floor dysfunction and incontinence.)

- Identify the impairments and functional limitations.
- Identify goals that deal with the impairments and functional limitations.
- Design a treatment plan to meet the goals; identify specific interventions and parameters, number of times she will be seen, and any follow-up or referrals that you believe will be necessary.

Impairments of the lymphatic system can lead to lymphatic insufficiencies that can result in significant physical impairments and subsequent loss of function of either the upper or lower extremities. Disturbances in structure or function can lead to accumulation of lymphatic fluids in the tissue of the body that affect the physiological health of the tissue, impair joint mobility, and impact daily functioning. Lymphatic dysfunction can be a result of a congenital or hereditary abnormality or can be caused by trauma, infection, or treatment for a cancer.

To contribute to the effective management of patients with lymphatic disorders, a therapist must possess a sound understanding of the underlying pathologies and the clinical manifestations of many types of lymphatic disorders, as well as the interplay between the lymphatic and venous systems. A therapist must also be aware of the use, effectiveness, and limitations of therapeutic exercise in the comprehensive management and rehabilitation of patients with lymphatic insufficiencies.

## Disorders of the Lymphatic System

### Structure and Function of the Lymphatic System

The primary function of the lymphatic system is to collect and transport fluid from the interstitial spaces back to the venous circulation (Fig. 26.1).<sup>36,57,62,69,86,133,135</sup> This is accomplished with a series of lymph vessels and lymph nodes.<sup>36,69,135</sup> The lymphatic system also has a role in the body's immune function.<sup>36,69,86,133,135</sup> When the lymphatic system is compromised either by impairment of lymphatic structures or by an overload of lymphatic fluid, the result is swelling in the tissue spaces. Edema is a natural consequence of trauma to and subsequent healing of soft tissues. If the lymphatic system is compromised and does not function efficiently, lymphedema develops and impedes wound healing.

**FIGURE 26.1** Major vessels of the lymphatic system.

*Lymphedema* is an excessive and persistent accumulation of extravascular and extracellular fluid and proteins in tissue spaces.<sup>12,22,32,57,69,74,135</sup> It occurs when lymph volume exceeds the capacity of the lymph transport system, and it is associated with a disturbance of the water and protein balance across the capillary membrane. An increased concentration of proteins draws larger amounts of water into interstitial spaces, leading to lymphedema.<sup>32,51,69,135</sup> The accumulation of the extracellular fluid and protein causes a proliferation of adipose tissue in the affected area.<sup>14,15,86</sup> Furthermore, many disorders of the cardiopulmonary system can cause the load on lymphatic vessels to exceed their transport capacity and subsequently cause lymphedema.<sup>51,74,107</sup>

### Anatomy of the Lymphatic System

The lymphatic system is an open system.<sup>36,69,70,135</sup> The lymphatic capillaries are situated close to the blood capillaries and are responsible for pulling the fluid into the lymphatic circulation (Fig. 26.2).<sup>36,57,70,133,135</sup> Once inside the lymphatic

**FIGURE 26.2** Lymph capillary and larger lymph vessel.

vessels, the fluid is transported from lymph nodes to lymphatic trunks.<sup>36,69,70,133,135</sup> The end result is the collection of the lymphatic fluid at the venous angles. In total, the body has 600 to 700 lymph nodes with the largest grouping found in the head and neck, around the intestines, and in the axilla and groin.<sup>36,135</sup>

### Physiology of the Lymphatic System

The main components of lymphatic fluid are water and protein found in the extracellular spaces.<sup>32,36,51,69,70</sup> In a normal state, the lymphatic system transports this fluid back to the venous circulation. The amount of fluid transported is the lymphatic load, and the amount of fluid the lymphatic system can transport is the transport capacity.<sup>36,69,135</sup> When the balance in the interstitium is disrupted, whether by an increased lymphatic load or a decreased transport capacity, lymphedema can develop.<sup>32,36,51,135</sup> Lymphatic load is increased when the venous system is unable to transport the required amount of fluid, which can occur in a patient with a venous insufficiency.<sup>69</sup> Transport capacity is affected when the structures of the lymphatic system are impaired, for example, following surgery to remove lymph nodes in a patient with cancer.

### Types of Lymphedema

Lymphedema can be classified as primary, meaning there is an inherent problem with the structures of the lymphatic system, or secondary, meaning there is an injury to lymphatic structures.<sup>36,51,69,135</sup> This injury may be in the form of surgery, radiation, trauma, or infection. Lymphedema can also be caused by a combination of lymphatic-venous dysfunction commonly seen in patients with chronic venous insufficiency. Remember, lymphedema is not a disease but rather a symptom of a malfunctioning lymphatic system.

### Primary Lymphedema

Primary lymphedema, although uncommon, is the result of insufficient development (dysplasia) and congenital malformation of the lymphatic system.<sup>50,69</sup>

Primary lymphedema can be divided according to the age of presentation.<sup>36,51,69</sup>

- **Congenital:** presents at birth and is sometimes known as Milroy's disease
- **Praecox (early):** develops prior to 35 years of age
- **Tarda:** develops after 35 years of age

Primary lymphedema typically affects more females than males and presents more often in the extremities, more so in the lower than upper extremities. However, it can be seen in other areas of the body as well.<sup>36,51,70,135</sup> If not managed properly, this type of lymphedema can progress over time and present with skin changes (hyperkeratosis) and increased skin folds and skin creases.<sup>36,51,62,124,128</sup>

## Secondary Lymphedema

Most of the patients seen by health-care practitioners for management of lymphedema have secondary lymphedema.<sup>101</sup> By far, the most common causes of secondary lymphedema are related to the comprehensive management of cancers of the breast, pelvis, and abdomen.<sup>4,11,12,44,50,51,101,102</sup> Secondary lymphedema is classified by the cause of the injury to the lymphatic structures including the following:

- Surgery
- Inflammation and infection
- Obstruction or fibrosis
- Combined venous-lymphatic dysfunction (chronic venous insufficiency)

### Surgical Dissection of Lymph Nodes

Lymph nodes and vessels often are surgically removed (lymphadenectomy) as an aspect of treatment of a primary malignancy or metastatic disease. For example, lymph node sampling is performed in most types of breast cancer surgeries to determine the extent and progression of breast cancer.<sup>13,19,44,59</sup> Likewise, pelvic or inguinal lymph node excision often is necessary for the treatment of pelvic or abdominal cancers.<sup>4,101,102</sup>

### Infection and Inflammation

Inflammation of the lymph vessels (*lymphangitis*) or lymph nodes (*lymphadenitis*) and enlargement of lymph nodes (*lymphadenopathy*) can occur as the result of a systemic infection or local trauma. Any of these conditions can cause disruption of lymph circulation.<sup>50,51,69,135</sup>

### Obstruction or Fibrosis

Trauma, surgery, and neoplasms can block or impair the lymphatic circulation.<sup>51,69,123</sup> Radiation therapy associated with treatment of malignant tumors also can cause fibrosis of vessels.<sup>4,13</sup>

### Combined Venous-Lymphatic Dysfunction

Although not a primary disorder of the lymphatic system, chronic venous insufficiency and varicose veins are associated with venous stasis and accumulation of edema in the extremities.<sup>45,50,65,135</sup> Dependent, peripheral edema, occurring with long periods of standing or sitting, is a common manifestation

of chronic venous dysfunction. Edema decreases if the limb is elevated. Patients often report dull aching or tiredness in the affected extremity.<sup>27,33,45,50,65,96,135</sup> If the insufficiency is associated with varicose veins, venous distention (bulging) also is notable. When edema persists, the skin becomes less supple over time and takes on a brownish pigmentation.

With time, a continued increase in the lymphatic work load imposed by the venous system causes a combined venous-lymphatic dysfunction. The lymphatic system begins to lose efficiency with the increased workload imposed over time, and a mixed edema results.<sup>135</sup> A venous-lymphatic dysfunction has a mixture of low protein edema from the venous system and a high protein edema from the lymphatic system. This combined dysfunction is termed *phlebolymphe*ma.<sup>18,35</sup>

Several characteristics distinguish the venous component from lymphedema in phlebolymphe

ma. Skin changes, typically hyperpigmentation, are present in chronic venous insufficiency. Clinical findings typical of the lymphedema component include pitting swelling in the dorsal aspect of the foot with swelling in the toes.<sup>18,35</sup>

## Clinical Manifestations of Lymphatic Disorders

### Lymphedema

**Location.** When lymphedema develops, it is most often apparent in the distal extremities, particularly over the dorsum of the foot or hand.<sup>32,51</sup> The term *dependent edema* describes the accumulation of fluids in the peripheral aspects of the limbs, particularly when the distal segments are lower than the heart. In contrast, lymphedema can manifest more centrally, for example, in the axilla, groin, or even the trunk.<sup>32,50,69,135</sup> Thorough assessment of the entire limb and regional area is important to define the extent of swelling.

**Severity.** The severity of lymphedema may be described quantitatively or qualitatively. Lymphedema is described by the severity of changes that occur in skin and subcutaneous tissues. The three categories—pitting, brawny, and weeping edema—are described in Box 26.1. Although all three types reflect a significant degree of lymphedema, they are listed in order of severity, from least severe to most severe.<sup>19,22,50,111</sup>

### CLINICAL TIP

When skin is interrupted in a patient with lymphedema, it is common to note a seeping of clear, yellow-tinged fluid that is slightly thicker than vascular fluid in consistency. This increased viscosity comes from the high level of protein contained in the fluid transported by the lymphatic system. If the fluid is leaking out of the pores without interruption of the skin, this signals a severe nature to the condition.

Another common way to define the severity of lymphedema is through staging. Staging refers to the physical

**BOX 26.1 Severity of Lymphedema**

- **Pitting edema.** Pressure on the edematous tissues with the fingertips causes an indentation of the skin that persists for several seconds after the pressure is removed. This reflects significant but short-duration edema with little or no fibrotic changes in skin or subcutaneous tissues.
- **Brawny edema.** Pressure on the edematous areas feels hard with palpation. This reflects a more severe form of interstitial swelling with progressive, fibrotic changes in subcutaneous tissues.
- **Weeping edema.** This represents the most severe and long-duration form of lymphedema. Fluids leak from cuts or sores; wound healing is significantly impaired. Lymphedema of this severity occurs almost exclusively in the lower extremities.

condition of the limb only.<sup>62</sup> The stages are described in Box 26.2.<sup>36,62,70,135</sup> Stage 0 or the latency stage might present with the greatest possibility for reducing the onset of worsening lymphedema. This is especially true in the patient with secondary lymphedema from cancer surgery.

**Increased Size of the Limb**

As the volume of interstitial fluid in the limb increases, so does the size of the limb (weight and girth).<sup>17,51,65,135</sup> Increased volume, in turn, causes tautness of the skin and susceptibility to skin breakdown.<sup>19,69</sup>

**BOX 26.2 Stages of Lymphedema****Stage 0—Latency Stage**

- No outward swelling noted
- Essentially asymptomatic with occasional reports of heaviness in the extremity
- Despite reduced transport capacity, the body is still able to accommodate the lymphatic load

**Stage I—Reversible Stage**

- Elevation reduces swelling
- No tissue fibrosis
- Swelling is soft or pitting

**Stage II—Spontaneously Irreversible**

- Fibrosis of tissue; brawny, hard swelling
- Swelling is no longer pitting
- Positive Stemmer sign
- Frequent infections may occur

**Stage III—Lymphostatic Elephantiasis**

- Positive Stemmer sign
- Significant increase in limb volume
- Typical skin changes noted (hyperkeratosis, papillomas, deep skin folds)
- Bacterial and fungal infections of the skin and nails more common

Descriptors, such as mild, moderate, and severe, sometimes are based on how much larger the size of the edematous limb is compared to the non-involved limb.<sup>74</sup> However, there are no standard definitions associated with size and severity.

**Sensory Disturbances**

Paresthesia (tingling, itching, or numbness) or occasionally a mild, aching pain may be felt, particularly in the fingers or toes. In many instances the condition is painless, and the patient perceives only a sense of heaviness of the limb. Fine finger coordination also may be impaired as the result of the sensory disturbances.<sup>19,51,93,111</sup>

**Stiffness and Limited Range of Motion**

Range of motion (ROM) decreases in the fingers and wrist or toes and ankle or even in the more proximal joints, leading to decreased functional mobility of the involved segments.<sup>19,82</sup>

**Decreased Resistance to Infection**

Wound healing is delayed, and frequent infections (e.g., cellulitis) may occur.<sup>51,64,65,135</sup> Cellulitis is a common health condition in patients with lymphedema.<sup>86</sup> Early recognition and treatment of cellulitis has shown to be important in reducing further tissue damage.<sup>30,129</sup>

**Examination and Evaluation of Lymphatic Function**

A patient's history, a systems review, and specific tests and measures provide information to determine impairments and functional limitations that can arise from lymphatic disorders and the presence of lymphedema. Key components in the examination process that are particularly relevant when lymphatic dysfunction is suspected or lymphedema is present are summarized in this section.<sup>20,33,82,114,135</sup> Other tests and measurements, such as vital signs, ROM, strength, posture, and sensory, functional, and cardiopulmonary testing, are also appropriate.

**History and Systems Review**

Note any history of infection, trauma, surgery, or radiation therapy. If a patient has a history of cancer and received chemotherapy, a review of the treatment and duration of the chemotherapy treatment is also important. The onset and duration of lymphedema, delayed wound healing, or previous treatment of lymphedema are pertinent pieces of information. Identify the occupation or daily activities of the patient, and determine if long periods of standing or sitting are required. Specific questioning to determine a pattern to the swelling can also aid in treatment planning.

**Examination of Skin Integrity**

Visual inspection and palpation of the skin provide information about the integrity of the skin. The location of the edema should be noted. When the limb is in a dependent position, palpate the skin to determine the type and severity

of lymphedema and changes in skin and subcutaneous tissues. Describe the thickness and density of the tissue in each area of the limb. Areas of pitting, brawny, or weeping edema should be noted.

### CLINICAL TIP

When palpating the skin over lymph nodes, note any tenderness of the nodes (cervical, supraclavicular, or inguinal). Tenderness may or may not indicate ongoing infection or serious disease.<sup>46</sup> Evidence of warm, enlarged, tender, painless, or adherent nodes should be reported to the physician.

The presence of wounds or scars and the color and appearance of the skin, which is often shiny and red in the edematous limb, should be noted. Document any papillomas, hyperkeratosis, or darkening of the skin, especially in the lower extremities. Photographic documentation is convenient in the clinical or home setting and provides visual evidence of changes in skin integrity. If a wound or scar is identified, its size should be noted, as should scar mobility or the presence of inflammation or infection in a wound.

A positive Stemmer sign, an indication of stage II or III lymphedema, may be identified during palpation (Fig. 26.3). It is considered positive if the skin on the dorsal surface of the fingers or toes cannot be pinched or is difficult to pinch compared with the uninvolved limb.<sup>36,70,100,125,135</sup> A positive Stemmer sign can be indicative of a worsening condition.

**FIGURE 26.3** Stemmer sign: Objective test for lymphedema in the extremities. (From Hetrick, H: *Lymphedema complicating healing*. In McCulloch, JM, and Kloth, LC (eds): *Wound Healing: Evidence-Based Management*, ed. 4. Philadelphia: F.A. Davis, 2010, p 283, with permission.)

### Girth Measurements

Circumferential measurements of the involved limb should be taken and compared with the non-involved limb if the problem is unilateral.<sup>17,93</sup> Identify specific intervals or landmarks at which measurements are taken so measurements during subsequent examinations are reliable. Use of circumferential

measurements at anatomical landmarks has been shown to be a valid and reliable method of calculating limb volume.<sup>2,113</sup>

### Volumetric Measurements

An alternative method of measuring limb size is to immerse the limb in a tank of water to a predetermined anatomical landmark and measure the volume of water displaced.<sup>17,113</sup> Although this method also has been shown to be valid and reliable, for routine clinical use, it is more cumbersome and less practical than girth measurements.<sup>2,113</sup>

### Perometer Measurements

A perometer calculates limb volume through the use of infrared light and opto-electric sensors. The perometer scans the limb without direct contact on the skin, making this an efficient form of volumetric measurement.<sup>3</sup> However, the cost and size of the perometer make this technology unrealistic for most clinical facilities.

### Bioimpedance Measurements

Bioimpedance measurements involve the use of a low-level, alternating electrical current to measure the resistance to the flow through the extracellular fluid in the upper extremities.<sup>31,99,122</sup> The higher the resistance to flow, the more extracellular fluid present. Testing is fairly easy to perform, requiring only placement of skin electrodes.

For any bioimpedance value to be meaningful, initial testing must take place prior to surgery.<sup>38,78,108</sup> Testing can then be performed at set intervals throughout the treatment continuum. This affords the opportunity for intervention at an earlier stage in the development of lymphedema. Other factors that affect volume in the body can theoretically affect the bioimpedance reading; therefore, this must be considered.<sup>31,78,99,100,122</sup> Bioimpedance is gaining acceptance in clinical practice as an effective method of detecting early, perhaps subclinical, lymphedema.<sup>38,63,108</sup>

### Lymphedema Risk Reduction

If a patient is at risk of developing lymphedema secondary to infection, inflammation, obstruction, surgical removal of lymphatic structures, chronic venous insufficiency, or an increased body mass index (BMI), reducing the risk of lymphedema should be the priority of patient management. In some situations, such as after removal of lymph nodes or vessels, risk-reducing measures may be needed for a lifetime. Even when a patient takes every measure to reduce the risk of edema, it still may develop at some time, particularly after trauma to or surgical removal of lymph vessels. Box 26.3 summarizes precautions and measures to reduce the risk of lymphedema.\* The education of patients in the importance of risk reduction has been shown to be effective in lowering lymphedema symptoms.<sup>39,40,49,78</sup>

\*3,13,19,52,55,58,70,82,92,98,111,116,123

### BOX 26.3 Precautions, Risk Reduction, and Self-Management of Lymphedema

#### Reducing the Risk of Lymphedema

- Keep moving. Standing or sitting for long periods of time can cause pooling of fluid in the legs. Sit with both feet on the floor instead of legs crossed.
- When traveling long distances by car, stop periodically, and walk around or support an involved upper extremity on the car's window ledge or seat back.
- Elevate involved limb(s), and perform repetitive pumping exercises frequently during the day.
- Be cautious about performing vigorous, repetitive activities with the involved limb.
- Monitor the weight used with exercise. Increase weight slowly, and assess for feelings of heaviness, throbbing, or aching in the limb.
- Carry heavy loads, such as a heavy backpack or shoulder bag, over your uninvolved shoulder.
- If you have lymphedema, wear compressive garments while exercising.
- Wear clothing and jewelry that does not leave a mark or imprint on your skin when removed.
- Monitor diet to maintain an ideal weight and minimize sodium intake.
- If possible, have blood pressures, needle sticks, and blood draws performed in the uninvolved upper extremity or lower extremity.

#### Skin Care

- Keep the skin clean and supple; use moisturizers and sunscreen, but avoid perfumed lotions.
- Immediately attend to a skin abrasion or cut, an insect bite, a blister, or a burn.
- Protect hands and feet; wear socks or hose, properly fitting shoes, rubber gloves, oven mitts, etc.
- Use protective gloves when in contact with harsh detergents and chemicals.
- Use caution when cutting nails. Push back cuticles instead of trimming.
- Use an electric razor when shaving legs or underarms. If the underarm area is numb, use your eyes to ensure that good skin integrity was maintained.
- Avoid hot baths, whirlpools, and saunas that elevate the body's core temperature.
- Seek immediate medical care if infection is suspected. An infection may present with warmth, redness, tenderness, or rash on the skin. A fever may or may not be present.
- Consult your physician immediately if a new onset of swelling is noted that does not resolve in 1 to 2 days.

## Management of Lymphedema

### Background and Rationale

Comprehensive management of lymphedema involves a combination of appropriate medical management and direct therapeutic intervention by a therapist combined with self-management by the patient. Treatment also includes

appropriate pharmacological management for infection control and prevention or removal of excessive fluid and proteins.<sup>12,50,69</sup>

Because there is no cure for lymphedema, the main goal of treatment is to minimize the lymphedema as much as possible or return the lymphedema to a latency stage. In addition, the health of the tissue is important. Other goals include reducing risk of infection and softening of fibrotic tissue.<sup>36,135</sup>

The overall objective of management, when lymphedema has developed, is to improve drainage of obstructed areas and, theoretically, to channel fluids into more centrally located lymph structures that carry the fluid to the venous system. In order to affect the reduction of lymphatic and/or venous edema, the following should be considered.

- Interstitial pressure is increased by external forces. These external forces can be from manual lymphatic drainage (MLD) or compression therapy. An increased interstitial pressure causes an increased uptake of fluid. There is an increase of lymph production as more fluid enters the lymphatic system as well as an increase in the resorption of fluid by the venous system.<sup>36,78,135</sup>
- Elevation can assist fluid return in stage I lymphedema or in venous edema. If elevation produces a reduction, then a mild compression therapy (i.e., compression garment) may be indicated.<sup>32,62,69,70,123</sup>
- Dynamic pressure changes within the body can assist lymphatic flow. Pressure changes can be in the form of diaphragmatic breathing or with muscle contractions. Breathing changes intrathoracic pressure and causes an increased uptake of lymph fluid in lymphatic trunks and ducts. Active muscle contractions change pressure in a localized area, enhancing the movement of lymph within lymph vessels. A muscle contraction combined with external forces from a bandage or compression garment can be even more effective in the movement of fluid.<sup>36,70,104,135</sup>

### Comprehensive Regimens and Components

A comprehensive approach to the management of lymphedema is referred to in the literature by a variety of terms, including complex lymphedema therapy, complete or complex decongestive therapy (CDT), or decongestive lymphatic therapy.\* Treatment typically is divided into two phases. Phase I is the intensive treatment phase, and phase II is the maintenance phase. The goal of phase I treatment is reduction, whereas the goal of phase II treatment is long-term management.<sup>19,62,70,135</sup> Therapist-directed care is replaced by patient-directed care as treatment moves from phase I to phase II. Box 26.4 summarizes the components of these programs.

**Manual lymphatic drainage.** MLD involves slow, very light repetitive stroking and circular massage movements done in a specific sequence with the involved extremity.<sup>78,9,23,24,29,67,113,134,135</sup> Proximal congestion in the trunk, groin, buttock, or axilla is cleared first to make room for fluid from the more distal areas. The direction of the

### BOX 26.4 Components of a Decongestive Lymphatic Therapy Program

#### Phase I

- Manual lymphatic drainage (MLD)
- Multiple layer compression bandaging
- Skin and nail care
- Exercise

#### Phase II

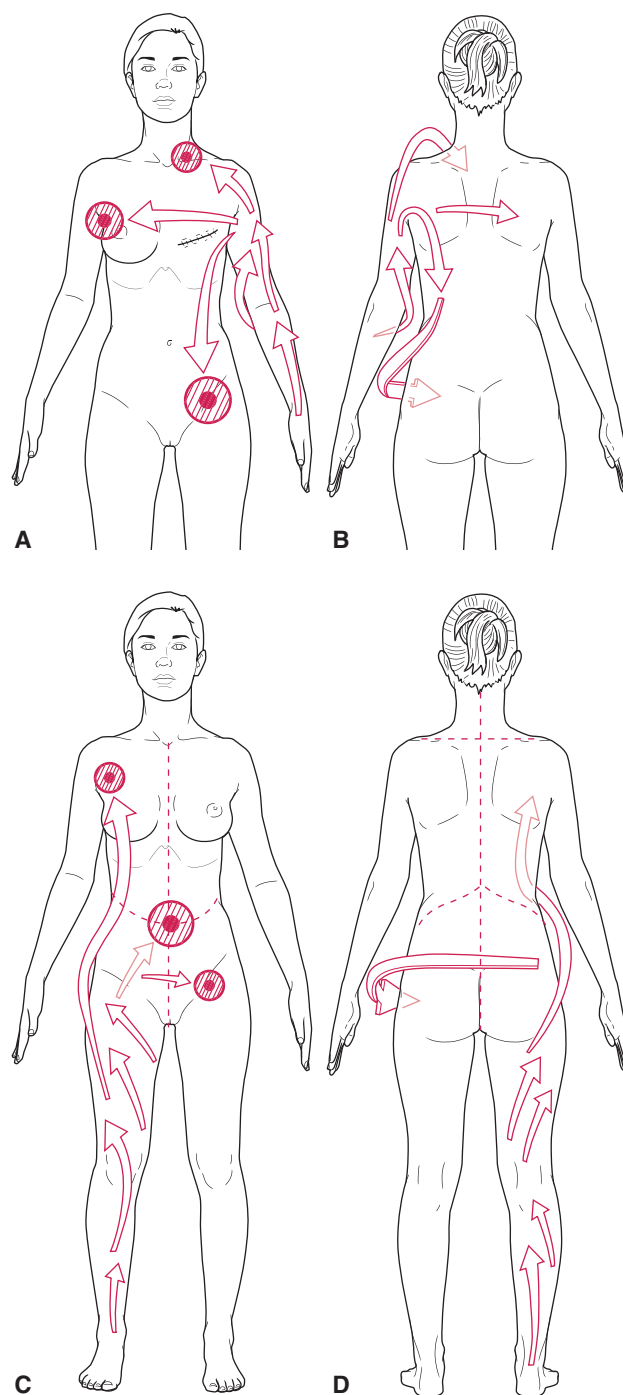

- Self-MLD by the patient
- Compression therapy
  - Compression garment during the day
  - Multiple layer bandaging in the evening/night
- Skin and nail care
- Exercise

massage is toward specific lymph nodes and usually involves distal-to-proximal stroking. Fluid in the involved extremity is then cleared, first in the proximal portion and then in the distal portion of the limb. Because MLD is extremely labor and time intensive, methods of self-massage are taught to a patient as soon as possible in a treatment program. The manual technique involved in lymphatic drainage is positively correlated to the results seen in tissue decongestion.<sup>36,135</sup> The specific techniques of MLD include several principles:<sup>36,135</sup>

- Hand position should match the anatomical shape and size of the area being treated.
- The pressure applied in each stroke should maximize the elasticity available in the superficial tissue. Too much pressure can cause vasodilation.
- Each stroke has a working phase and a resting phase. The purpose of the working phase is to move fluid into the lymphatic system, with the directional stretch facilitating the lymphatic angions.<sup>30,107</sup> The resting phase elicits a pressure change in the tissue and allows the lymph fluid to fill the lymphatic collectors.
- Repetition of the strokes is needed to help reduce the high viscosity of the lymphatic fluid.
- MLD sequences direct lymphatic fluid from an area of congestion, across lymphatic watershed areas to an area of no tissue congestion.

Application of these principles for upper and lower extremity clearance of lymphedema is depicted in Figure 26.4.<sup>135</sup>

**Exercise.** Active ROM, stretching, and low-intensity resistance exercises are integrated with manual drainage techniques.<sup>6,12,19,23,25,26,73,80,84,85,91,135</sup> Exercises are performed while wearing a compressive garment or bandages and in a specific sequence to facilitate lymphatic flow. A low-intensity cardiovascular/pulmonary endurance activity, such as bicycling, often follows ROM and strengthening exercises. Specific exercises and a suggested sequence for the upper and lower

**FIGURE 26.4** Application of manual lymphatic drainage sequences for (A & B) upper extremity and (C & D) lower extremity lymphatic pathways.

extremities, compiled from several sources, are described and illustrated in the last section of this chapter.

**Compression therapy.** The type of compression used depends on the phase of treatment. During phase I of treatment, only low-stretch bandages are used, which provide a low resting pressure on a limb but a high working pressure.<sup>36,135</sup> High-stretch sports bandages, such as Ace™ wraps,

are not recommended for treating lymphedema.<sup>9,12,19,123</sup> Given that a low-stretch bandage has a low resting pressure, the bandage can be worn during the day and at night. During the active reduction phase of treatment, it is recommended that compression be applied in the form of low-stretch bandaging at all times except for bathing.<sup>36,105,135</sup> Under the low-stretch bandage, nonwoven padding is used and can be combined with foam pads to aid in the softening and reduction of fibrotic tissue (Fig. 26.5).

**FIGURE 26.5** Upper extremity multilayer bandaging with padding from the upper arm to the hand.

As a patient moves from phase I to a maintenance phase of treatment, compression is transitioned from low-stretch bandaging at all times to a compression garment during the day. A compression garment has a high resting pressure and low working pressure.<sup>36,135</sup> Therefore, the use of a garment is not recommended during long periods of inactivity (night rest). The garment should be viewed as a method to maintain limb size during the day, giving a patient a more cosmetic appearance and ease of wearing clothing. During phase II, it is still recommended that a patient wear the low-stretch bandages at night.<sup>19,105</sup> In summary, the bandages are used for continued limb reduction, and a garment keeps the size of the extremity stable.

Compression garments are made in specific compression categories or classes (Table 26.1).<sup>19,105,135</sup> Patients can most often be fit with a premade garment, but custom garments are available. For patients with lymphedema of the trunk, genital area, or face, custom garments can be fabricated.

**FOCUS ON EVIDENCE**

Forner-Cordero and coinvestigators<sup>37</sup> conducted a study to identify the factors that best predicted response to CDT. A prospective multicenter, controlled cohort study was undertaken with 171 patients with breast cancer–related lymphedema. Following statistical analysis, compliance with bandaging was one of the most predictive indicators of response to CDT. The length of time from the development of the lymphedema to treatment did not predict response to treatment in this study.

**TABLE 26.1** Garment Compression Classification

Class of Compression	mm Hg	Indications
<b>Class 1</b>	20–30 mm Hg	<ul style="list-style-type: none"> <li>■ Mild lymphedema</li> <li>■ Typically used for UE, not LE</li> <li>■ Patient with fragile skin or the elderly</li> </ul>
<b>Class 2</b>	30–40 mm Hg	<ul style="list-style-type: none"> <li>■ Most commonly used for stage II UE lymphedema</li> <li>■ Minimum compression for LE lymphedema</li> </ul>
<b>Class 3</b>	40–50 mm Hg	<ul style="list-style-type: none"> <li>■ Rarely used for UE lymphedema</li> <li>■ Typically for stage II LE lymphedema</li> <li>■ For patients with LE lymphedema involved in high-intensity, repetitive activities</li> </ul>
<b>Class 4</b>	50–60 mm Hg	<ul style="list-style-type: none"> <li>■ Rarely used</li> <li>■ Only for LE lymphedema</li> <li>■ Only available as custom-made garments</li> </ul>

LE, Lower extremity; UE, upper extremity

However, there was an inverse correlation between severity of lymphedema and response to CDT.

Another form of compression therapy is a pneumatic compression pump.<sup>79,132</sup> The use of compression pumps, however, has been controversial over the years. Studies have shown that a compression pump can be a positive adjuvant therapy to CDT but should not be the sole therapeutic modality in the treatment of lymphedema.<sup>77,82,112</sup> The main criticism of pump compression is the pumping of fluid in a distal to proximal sequence, which is opposite of the principles of MLD. There is also the potential to cause swelling in adjoining areas of the body, mainly the genital area, for a patient with lower extremity edema.<sup>10</sup> When used correctly, a pneumatic compression pump can be a positive therapeutic intervention, especially in severe or refractory cases. More advanced pumps are now available that follow the sequence of MLD more closely, treating the trunk first and then the extremity in a proximal-to-distal sequence. Recommendations for pressure and timing settings to effectively elicit lymph flow with an intermittent pneumatic compression device have been reported in the literature.<sup>132</sup>

**Skin care and hygiene.** Lymphedema predisposes the patient to skin breakdown, infection, and delayed wound healing. Meticulous attention to skin care and protection of the edematous limb are essential elements of self-management of lymphedema.<sup>12,24,82,123</sup>

### Surgical Intervention for Lymphedema

A surgical procedure, such as a lymphovenous bypass or a vascularized lymph node transfer, may be chosen for management of lymphedema depending on the availability of intact lymphatic channels and the extent of fibrosis in the tissue. The purpose of these surgical interventions is to facilitate restoration of the physiological balance in the tissue by eliminating the excess of protein and other cellular components in the extracellular space.<sup>62,110</sup> With a lymphovenous bypass, lymphatic channels are identified along the length of the limb and are anastomosed with a venule of corresponding size.<sup>27,28,62,110</sup> In a lymph node transfer a lymph node from a distant site along with vasculature is transplanted in the affected limb.<sup>62,110</sup> Liposuction is another surgical option that has been shown to be effective in long-term follow-up studies.<sup>14,15,86</sup> Liposuction reduces the overall girth of a limb by removing the proliferation of adipose tissue.<sup>14,15,62</sup>

A growing body of evidence has become available in the literature to support the benefits and efficacy of selected surgical interventions.<sup>7,14,15,27,28</sup> The results of these studies have shown that the majority of patients following surgical intervention report subjective, symptomatic improvement. However, improvements identified by objective testing have been reported in a lesser percentage of patients.<sup>27,28,95</sup> Irrespective of the surgical approach taken, patients must continue with many of the presurgical interventions for lymphedema management, including daily compression therapy.

### Online Resources

A valuable resource for patients and health-care professionals is the National Lymphedema Network ([www.lymphnet.org](http://www.lymphnet.org)). This nonprofit organization provides education and guidance about lymphedema. Other resources include the National Comprehensive Cancer Network ([www.nccn.org](http://www.nccn.org)), the Peninsula Medical, Inc., website ([www.lymphedema.org](http://www.lymphedema.org)), and Lymph Notes ([www.lymphnotes.com](http://www.lymphnotes.com)).

## Breast Cancer–Related Lymphatic Dysfunction

### Background

Breast cancer–related dysfunction of the lymphatic system and subsequent lymphedema of the upper extremity is a somewhat common and potentially serious complication of the treatment for breast cancer. The incidence of lymphedema following surgical intervention for breast cancer varies widely in the literature.\* Much of the variation is related to how lymphedema is diagnosed and defined. Some studies quantify lymphedema in the upper extremity only, whereas other studies define breast cancer–related lymphedema as including the remaining breast or chest wall and trunk. Other factors contributing to the variation in incidence of lymphedema reported are the use of sentinel lymph node biopsy versus axillary dissection. The time of onset of lymphedema also varies widely in the literature, with onset varying from 6 months to 3 years in the majority of patients who develop persistent swelling.<sup>53,55,94,116</sup>

Current treatment for breast cancer involves a multimodality approach. Surgery, chemotherapy or hormonal therapy, and radiation may be employed. The type of surgery performed, the extent of axillary nodes removed, and the use of radiation all affect the incidence of lymphedema in a patient with breast cancer.

Axillary dissection and removal of lymph nodes interrupt and slow the circulation of lymph, which in turn can lead to lymphedema.<sup>6,13,19,34</sup> Radiation therapy can cause fibrosis of tissues in the area of the axilla, which obstructs the lymphatic vessels and contributes to pooling of lymph in the arm and hand.<sup>6,13,19,34</sup> The extent of the axillary dissection and exposure to radiation is associated with the degree of risk for lymphedema to develop. In addition, shoulder motion can become impaired as the result of incisional pain, delayed wound healing, skin ulcerations (associated with radiation therapy), and postoperative weakness of the muscles of the shoulder girdle.<sup>19,82</sup>

A comprehensive approach to postoperative management that emphasizes patient education and includes therapeutic exercise and other direct interventions to reduce the risk of or to treat lymphedema and other impairments or limitations of function are key to successful outcomes.<sup>4,12,19,43,82,98</sup>

\*2,42,54,71,81,94,106,117

As with most cancers, the diagnosis of breast cancer and the ensuing treatments have an enormous emotional impact on patients and their families.<sup>15,90</sup> The advent of breast cancer–related lymphedema not only has an impact on a breast cancer survivor’s physical function, but also is known to have a significantly adverse effect on health-related quality of life, making prevention—and if it develops, aggressive treatment—of lymphedema a high priority for management.<sup>72,94,102</sup>

## Surgical Procedures

Surgical treatment of breast cancer falls into two broad categories—mastectomy and breast-conserving surgery—both of which are coupled with either sentinel lymph node biopsy and/or axillary lymph node dissection. Differences in surgical procedures are related to the extent of removal of breast tissue and surrounding or underlying soft tissues.<sup>1,8,56</sup> A course of radiation therapy routinely follows surgery to decrease the risk of regional recurrence of the disease in patients who undergo breast-conserving surgeries. Chemotherapy also may be initiated preoperatively or postoperatively to reduce the risk of systemic spread of the disease.

### Mastectomy

Mastectomy involves removing the entire breast. In addition, a mastectomy may involve removing the fascia over the chest muscle. With late-stage, invasive disease, a radical mastectomy in which the pectoralis muscles also are excised may be required, leading to significant muscle weakness and impaired shoulder function.

### Breast-Conserving Surgery

Options for resecting the tumor and preserving a portion of the breast include lumpectomy, which involves excision of the mass and a margin of healthy surrounding breast tissue, or segmental mastectomy (also known as quadrectomy), which is excision of the affected quadrant of the breast. Rather than mastectomy, these procedures are being used increasingly in combination with adjuvant therapy for patients with stage I or II tumors.<sup>1,56</sup>

There are now multiple randomized clinical trials that show that the 10- to 20-year survival rate for patients with stage I or II disease who underwent breast-conserving surgery combined with radiation therapy is equivalent to that achieved by patients who underwent mastectomy alone or mastectomy with adjuvant therapy.<sup>1</sup>

Patients who undergo breast-conserving procedures without removal of lymph nodes are still at risk for developing postoperative lymphedema and impaired shoulder mobility because of potential complications from radiation therapy and biopsy of at least one lymph node.<sup>19,82</sup>

### Evaluation of Lymph Node Involvement

In the past, axillary lymph node dissection was a standard part of mastectomy and breast-conserving surgery.<sup>1,56</sup> A minimum of a level I and, most often, a level II axillary dissection was

performed. Currently, the sentinel lymph node biopsy is used to determine disease presence in the axilla, therefore sparing removal of uninvolved lymph nodes when possible.

Sentinel lymph node biopsy is used with patients who present with no clinically evident disease in the axilla.<sup>119</sup> With a radiosensitive substance, the specific lymph nodes that a tumor first drains into are identified and removed.<sup>135</sup> If clear, research has shown that an axillary dissection is not required and risk of disease in further lymph nodes is low.<sup>16</sup> If the sentinel lymph nodes show signs of disease, then axillary lymph nodes are removed. More extensive dissection for metastatic or regional bulky disease removes the nodes under the pectoralis minor muscle or around the clavicle.

### Breast Reconstruction Options

Depending on breast cancer presentation and staging at the time of diagnosis, a woman may have a choice of breast conservation or mastectomy. If a mastectomy is chosen, then reconstruction (immediate versus delayed) may be considered. A patient’s body type, breast size, and tumor size become factors in the determination of which procedures are viable options. Immediate reconstruction is done at the time of the definitive breast cancer surgery so that an additional surgery is not required. However, an immediate reconstruction increases surgical time and length of stay in the hospital. Delayed reconstruction requires an additional surgery at some point following the completion of breast cancer treatment but gives a woman additional time to consider reconstructive options.<sup>68,97</sup>

Implications for physical therapy management during postoperative rehabilitation depend on the reconstructive approach performed (Table 26.2).<sup>115</sup> Alloplastic procedures, using expanders and implants, construct a “breast pocket” under the pectoralis muscle on the chest wall, whereas autologous procedures involve use of a woman’s own tissue to reconstruct the breast. These procedures can include tissue only or muscle as well.<sup>68,97</sup>

### Radiation Therapy

Radiation therapy is rarely used as the sole treatment intervention for breast cancer. Most often radiation is employed following breast-conserving surgery as an adjuvant treatment modality.<sup>71</sup> Radiation delivered to the whole breast is standard following breast-conserving therapy. The parameters of the radiation field include the tissue from the clavicle to 2 cm below the inframammary line and from the midsternum to the mid-axillary line laterally.<sup>90</sup> Radiation typically is delivered over a course of 5 to 6 weeks with effects not felt until 2 to 3 weeks into treatment. In patients who undergo mastectomy, depending on the disease presentation, radiation may be offered. The radiation field usually includes the surgical scar, chest wall, and sometimes the regional lymphatics.

Radiation causes changes in most types of soft tissue and can be categorized as having acute or chronic effects.<sup>71</sup> Acute

**TABLE 26.2** Implications for Rehabilitation Following Breast Reconstruction Surgery

\*Flap integrity and perfusion are of primary importance.

effects of radiation include acute dermatitis or skin burn. Chronic or late effects of radiation involve tissue fibrosis that can restrict ROM and changes to lymphatic vessel function.<sup>120</sup> It is important to note that the chronic effects of radiation can extend for many years following the end of the radiation therapy.<sup>121</sup>

## Impairments and Complications Related to Breast Cancer Treatment

The following impairments and complications may occur in association with treatment of breast cancer. Many of these problems are interrelated and must be considered jointly when a comprehensive postoperative rehabilitation program is developed for the patient.\*

### Postoperative Pain

**Incisional pain.** A transverse incision across the chest wall is made to remove the breast tissue and underlying fascia on the chest musculature. The incision extends into the axilla for lymph node dissection. Postoperatively, the sutured skin over the breast area may feel tight along the incision. Movement of the arm pulls on the incision and is uncomfortable for the patient. Healing of the incision may be delayed as the result of radiation therapy. Delayed wound healing, in turn, prolongs pain in the area of the incision.

\*5,11,13,19,41,43,47,48,59,82,93,127,130,135

**Posterior cervical and shoulder girdle pain.** Pain and muscle spasm may occur in the neck and shoulder region as a result of muscle guarding. The levator scapulae, teres major and minor, and infraspinatus often are tender to palpation and can restrict active shoulder motion. Decreased use of the involved upper extremity after surgery due to pain sets the stage for the patient to develop a chronic frozen shoulder and increases the likelihood of lymphedema in the hand and arm.

### Postoperative Vascular and Pulmonary Complications

Decreased activity and extended time in bed increase venous stasis and the risk of a deep vein thrombosis (DVT). Risk of pulmonary complications, such as pneumonia, also is higher because of the patient's reduced activity level. Incisional pain may make the patient reluctant to cough or breathe deeply, both of which are necessary postoperatively to keep the airways clear of fluid accumulation.

### Lymphedema

As noted previously, patients who undergo any level of lymph node dissection or whose treatment regimen includes radiation therapy remain at risk throughout life for developing ipsilateral upper extremity lymphedema.<sup>6,19,82,135</sup> Lymphedema can occur almost immediately after lymph node dissection, during the course of radiation therapy, or many months or even years after treatment has been completed. It is typically evident in the hand and arm but occasionally develops in the anterior chest wall, remaining breast, or back area.<sup>6,13,19,82,93,135</sup> In turn, lymphedema leads to impaired upper extremity function, poor cosmesis, and emotional distress.<sup>19,41,93,111</sup>

### FOCUS ON EVIDENCE

Fu et al<sup>40</sup> conducted a study involving two groups of breast cancer survivors. One group received breast cancer–related lymphedema education during their treatment for breast cancer. The other group received no lymphedema-specific education. Information was collected from both groups to identify physical symptoms and overall knowledge related to lymphedema following treatment. In both groups, the mean number of physical symptoms reported was three. However, fewer women in the intervention group than in the control group reported physical symptoms such as swelling, heaviness, limited shoulder movement, seroma formation, or breast swelling. As a result of this study, the authors recommended the active engagement of breast cancer survivors in education regarding ways to reduce the risk of lymphedema.

### Chest Wall Adhesions

Restrictive scarring of underlying tissues on the chest wall can develop as the result of surgery, radiation fibrosis, or wound infection. Chest wall adhesions can lead to increased risk of postoperative pulmonary complications, restricted mobility

of the shoulder, postural asymmetry and dysfunction, and discomfort in the neck, shoulder girdle, and upper back.

### Decreased Shoulder Mobility

It is well documented that patients may experience temporary and sometimes long-term loss of shoulder mobility after surgery or radiation therapy for treatment of breast cancer.<sup>6,48,59,72,82,98,109,126,127,130</sup> Factors contributing to impaired shoulder mobility after surgery are listed in Box 26.5.

One of these factors, lymphatic cording, or axillary web syndrome (AWS), is a fairly new term for a condition that is quite common in patients treated for breast cancer. The incidence among breast cancer survivors ranges from 28% to 36%.<sup>118,120</sup> However, the incidence varies in the literature, and onset can be as soon as one week following surgery to years later.<sup>87,120,131</sup> AWS is thought to be caused by the interruption of the lymphatics in the axilla following a sentinel lymph node biopsy or axillary dissection, with resulting thrombosis of lymphatic channels.<sup>54,72</sup> Visually, AWS can be described as a web of skin covering “cords” that are more visible with shoulder abduction (Fig. 26.6).<sup>66,87</sup> These cords can extend

from the axilla distally to the antecubital space and into the forearm. Lymphatic cording can be painful and limit movement of the entire upper extremity.<sup>19,66</sup> Patients often present with complaints of pain that extends down the arm, even into the hand. Cording can also be seen in the lateral trunk.<sup>120</sup> Numbness or tingling may also be reported. Treatment for AWS typically includes gentle stretching and soft tissue release of the lymphatic cord, as well as MLD.<sup>66,120</sup> AWS may resolve if left untreated, but more research is needed to clarify long-term outcomes.<sup>131</sup>

### FOCUS ON EVIDENCE

Verbelen and coinvestigators<sup>118</sup> conducted a systematic review of the literature to identify the shoulder impairments found in patients following sentinel lymph node biopsy. The shoulder and arm impairments identified included loss of mobility and strength, pain, AWS, and sensory disorders. The highest incidence of restricted range of motion occurred at 1 month following surgery, with shoulder abduction and forward flexion being most limited. Shoulder abduction and internal rotation remained restricted in approximately 40% of patients at 2 years.

#### BOX 26.5 Factors Contributing to Impaired Shoulder Mobility After Breast Cancer Surgery

- Incisional pain immediately after surgery or associated with delayed wound healing
- Muscle guarding and tenderness of the shoulder and posterior cervical musculature
- Need for protected shoulder ROM until the surgical drain is removed
- Fibrosis of soft tissues in the axillary region due to adjuvant radiation therapy
- Adherence of scar tissue to the chest wall, causing adhesions
- Temporary or permanent weakness of the muscles of the shoulder girdle
- Rounded shoulders and kyphotic or scoliotic trunk posture associated with age or incisional pain
- A feeling of heaviness of the upper extremity due to lymphedema
- Decreased use of the hand and arm for functional activities
- Axillary web syndrome

FIGURE 26.6 Axillary web syndrome.

### Weakness of the Involved Upper Extremity

**Shoulder weakness.** If the long thoracic nerve is traumatized during axillary dissection and removal of lymph nodes, this results in weakness of the serratus anterior and compromised stability of the scapula, limiting active flexion and abduction of the arm. Faulty shoulder mechanics and use of substitute motions with the upper trapezius and levator scapulae during overhead reaching can cause subacromial impingement and shoulder pain. Shoulder impingement, in turn, can be a precursor to a frozen shoulder. If the pectoralis muscles were disturbed, which occurs with a radical mastectomy for advanced disease, weakness is evident in horizontal adduction.

**Decreased grip strength.** Grip strength is often diminished as the result of lymphedema and secondary stiffness of the fingers.

### Postural Malalignment

The patient may sit or stand with rounded shoulders and kyphosis because of pain, skin tightness, or psychological reasons. An increase in thoracic kyphosis associated with aging is commonly seen in the older patient.<sup>47</sup> This contributes to faulty shoulder mechanics and eventually restricts active use of the involved upper extremity. Asymmetry of the trunk and abnormal scapular alignment may occur as the result of a subtle lateral weight shift, particularly in a large-breasted woman.

### Fatigue and Decreased Endurance

Patients undergoing radiation therapy or chemotherapy often experience debilitating fatigue.<sup>1,44,72</sup> Fatigue has been reported by more than 60% of patients undergoing cancer treatment.<sup>21,88</sup>

Many cancer survivors experience fatigue for months, even years, after treatment has been completed.<sup>83</sup> Anemia may develop as a result of chemotherapy. Nutritional intake and subsequent energy stores may be diminished, particularly if a patient is experiencing nausea for several days after a cycle of chemotherapy.

Fatigue is also associated with depression. As a result, exercise tolerance and endurance during functional activities are markedly reduced. Multiple studies support the initiation of an exercise program as one of the most effective methods to combat fatigue related to cancer treatment.<sup>21,88,89</sup> The findings of a recent systematic review and meta-analysis by Meneses-Echavez<sup>83</sup> demonstrated that supervised aerobic exercise is the most beneficial form of exercise.

### Psychological Considerations

A patient undergoing treatment for breast cancer experiences a wide range of emotional and social issues.<sup>111</sup> The needs and concerns of both the patient and the family must be considered. The patient and family members must cope with the potentially life-threatening nature of the disease and a difficult treatment regimen. It is common for a patient to feel anxiety, agitation, anger, depression, a sense of loss, and significant mood swings during treatment of and recovery from breast cancer.

In addition to the obvious physical disfigurement and altered body image associated with mastectomy, medications such as immunosuppressants and corticosteroids can affect

the emotional state of a patient. Psychological manifestations affect physical well-being and can contribute to general fatigue, the patient's perception of functional disability, and motivation during treatment.

## Guidelines for Management Following Breast Cancer Surgery

Guidelines for postoperative management for the patient who has undergone a mastectomy or breast-conserving surgery and who may currently be receiving adjuvant therapy are outlined in Box 26.6. The guidelines identify therapeutic interventions for common impairments during the early postoperative period and those that could develop at a later time.

**NOTE:** The guidelines outlined in Box 26.6 also can be modified to prevent or manage problems that can develop in the trunk and lower extremities after surgery for abdominal or pelvic cancers and accompanying inguinal lymph node dissection.

### Special Considerations

**Patient education.** The length of an in-hospital stay following surgery for breast cancer is short. Ideally, intervention by the therapist is initiated preoperatively with an emphasis on patient education for reducing the risk of postoperative complications and impairments, including pulmonary complications, thromboemboli, lymphedema, and loss of shoulder mobility. Recommendations for reducing the risk of

#### BOX 26.6 MANAGEMENT GUIDELINES— After Surgery for Breast Cancer

##### Potential Postoperative Structural and Functional Impairments

- Pulmonary and circulatory complications
- Lymphedema
- Restricted mobility of the upper extremity
- Postural malalignment
- Weakness and decreased functional use of the upper extremity
- Fatigue and decreased endurance for functional activities
- Emotional and social adjustments

##### Plan of Care

1. Prepare the patient for postoperative self-management
2. Prevent postoperative pulmonary complications and thromboemboli

##### Interventions

1. Interdisciplinary patient education involving all aspects of potential impairments and functional limitations  
Self-management activities and preparation for participation in a home program as indicated per surgical protocol
2. Pre- or postoperative instruction in deep breathing, emphasizing maximal inspirations and effective coughing  
Active ankle exercises (calf-pumping exercises)

**Intervention**

3. Minimize postoperative swelling	<p>3. Elevation of the involved upper extremity on pillows (about 30°) while the patient is in bed or sitting in a chair            Squeeze a ball on the operative side to produce a pumping action in the muscles            Early ROM exercises</p> <p><b>PRECAUTION:</b> Avoid static, dependent positioning of the arm</p>
4. Identify and treat early signs of lymphedema should it develop	<p>4. Manual lymphatic drainage massage            Daily regimen of exercises to include flexibility and strengthening exercises            Compression therapy (low-stretch compression bandaging and/or compression garments)            Adherence to lymphedema risk-reducing behaviors (see Box 26.3)</p>
5. Prevent postural deformities	<p>5. Posture-awareness training; encourage the patient to assume an erect posture when sitting or standing to minimize a rounded shoulder posture            Posture exercises with an emphasis on scapular retraction exercises</p>
6. Prevent muscle tension and guarding in cervical musculature	<p>6. Active ROM of the cervical spine to promote relaxation            Shoulder shrugging and shoulder circle exercises            Gentle massage to cervical musculature</p>
7. Prevent restricted mobility of the upper extremity	<p>7. Shoulder motion performed within protected ROM, usually no more than 90° of elevation of the arm until after removal of drains            No repetitive motion until drains removed</p>
8. Regain strength and functional use of the involved extremity	<p>8. Initiate resistance exercise following full postoperative healing. Consider exercise parameters if patient is at risk for lymphedema or has lingering weakness in the involved extremity</p>
9. Improve exercise tolerance and sense of well-being; reduce fatigue	<p>9. Graded, low-intensity aerobic exercise such as walking or cycling</p>
10. Provide information about resources for patient and family support and ongoing patient education	<p>10. Resources: American Cancer Society for family support and ongoing patient education (<a href="http://www.cancer.org">www.cancer.org</a>); National Breast Cancer Coalition (<a href="http://www.nobreastcancer.org">www.nobreastcancer.org</a>); National Lymphedema Network (<a href="http://www.lymphnet.org">www.lymphnet.org</a>)</p>

**PRECAUTIONS:** Observe the incision and sutures carefully during exercises. Avoid any undue tension on the incision or blanching of the scar during shoulder ROM. Avoid exercises with the involved arm in a dependent position. Progress graded exercise program slowly, particularly if the patient is receiving adjuvant therapy. Consider other adjuvant therapies when designing an exercise program.

lymphedema or for self-management if it develops is reviewed with the patient (see Box 26.3). Following surgery, once the drains are removed, an exercise program can then be individualized based on a patient's surgical procedure and anticipated adjuvant treatments.

**Exercise.** The postoperative exercise program focuses on three main areas: improving shoulder function, regaining an overall level of fitness, and reducing the risk of or managing lymphedema. Early, but protected, assisted or active ROM of the shoulder is the key to restoring shoulder mobility. Postoperative risks that contribute to restricted shoulder mobility were summarized previously (see Box 26.5).<sup>1,19,56,82,85</sup> These risks are highest during the early postoperative period until drains have been removed and the incision has healed.

### CLINICAL TIP

Radiation therapy to the axillary and breast areas can delay wound healing beyond the typical 3- to 4-week period.<sup>1,56</sup> Even after initial healing of the incision, the scar has a tendency to contract and can become adherent to underlying tissues, which, in turn, can restrict shoulder motion. Because radiation changes can occur months following treatment, educating the patient to continue with ROM and flexibility exercises should be encouraged. Deep-breathing exercises should also be performed regularly if the chest wall was included in the radiation field.<sup>121</sup>

Although strengthening exercises and aerobic conditioning are important for upper extremity function and total body fitness, considerations should be taken in an exercise program. Programming considerations may include the type of chemotherapy given and the specific side effects of the drugs. For example, some chemotherapy can cause peripheral neuropathy, proximal muscle weakness, and differing fatigue patterns.<sup>61,88</sup> Exercises must be progressed gradually, excessive fatigue must be avoided, and energy conservation must be emphasized. Exercise precautions for a patient undergoing treatment are noted in Box 26.7.<sup>6,19,72,85,88,98</sup>

Early intervention for reducing the risk of lymphedema and upper extremity mobility impairments is often advocated by therapists and suggested in descriptive articles in the literature. However, patients often are not referred for postoperative rehabilitation until after impairments and activity limitations have developed. This may be due to concerns raised in the literature<sup>34</sup> that early postoperative ROM could delay wound healing or that exercises, if performed too vigorously, could initiate or exacerbate lymphedema. In addition, few studies have rigorously investigated the efficacy of specific interventions or rehabilitation protocols.<sup>82,126</sup> A recent review of the literature on exercise and cancer-related lymphedema revealed, however, that exercise neither worsened pre-existing lymphedema nor was associated with a significant increase in the occurrence of lymphedema.<sup>6</sup>

### BOX 26.7 Exercise Precautions During Treatment of Breast Cancer

- Exercise only at a moderate level and never to the point that the affected arm aches, throbs, or feels heavy during or after exercise, even if there is no evidence of lymphedema.
- Adjust the timing of exercise during cycles of radiation therapy or chemotherapy. With some chemotherapy medications, a patient can develop cardiac arrhythmia or cardiomyopathy.<sup>61</sup>
- Avoid exercising 1 to 2 hrs before blood is drawn.
- Gradually return to a regular pattern of exercise and recreational activities based on the fitness level prior to diagnosis and specific side effects of treatment.
- Be aware of blood counts, including white blood cell count and hemoglobin and platelet counts when designing exercise programs.

From the information available in the literature, the following recommendations for exercise are made:<sup>\*</sup>

- Integrate ROM, flexibility, and strengthening exercises into a patient's comprehensive plan of care.
- Implement posture-awareness training and exercise early in a postoperative program to prevent postural malalignment and muscle imbalance, especially following mastectomy.
- Include moderate-intensity aerobic conditioning exercises to improve fitness and quality of life and to reduce chemotherapy-related fatigue.
- Progress all forms of exercise gradually, and teach the patients individualized exercise parameters based on specific surgical interventions and adjuvant therapies.

### Community and Online Resources

Reach to Recovery is a one-to-one patient education program sponsored by the American Cancer Society ([www.cancer.org](http://www.cancer.org)). Representatives of this program, most of whom are breast cancer survivors, provide emotional support to the patient and family, as well as current information on breast prostheses and reconstructive surgery. The National Lymphedema Network ([www.lymphnet.org](http://www.lymphnet.org)) and the National Comprehensive Cancer Network ([www.nccn.org](http://www.nccn.org)) are other valuable sources of information for patients at risk for or who have developed lymphedema.

## Exercises for the Management of Lymphedema

### Background and Rationale

As noted previously in this chapter, exercise is just one aspect of a decongestive lymphatic therapy program. The rationale for including exercise in the comprehensive treatment of

<sup>\*</sup>5,11,12,13, 17,19,41,48,60,76,80,84,85,91,112,126,127,134,135

patients with upper or lower extremity lymphedema is to move and drain lymph fluid to reduce the edema and to improve the functional use of the involved limb or limbs. The principles and rationale upon which exercises for lymphatic drainage are based are summarized in Box 26.8.<sup>6,84,91,135</sup>

The exercises employed in lymph drainage regimens cover a wide spectrum of therapeutic exercise interventions, specifically deep breathing, flexibility, strengthening, and cardiovascular conditioning exercises, combined with a sequence of lymphatic drainage exercises. Exercise regimens have been described in an extensive number of publications.\*

No particular combination or sequence of exercises has been shown to be superior to another. Although an older critical review of the literature<sup>75</sup> indicated that the effectiveness of exercise regimens for lymph drainage was based primarily on clinical observations and opinions of experienced practitioners or case reports, there is now an emerging body of evidence documenting the efficacy of specific components of these programs.<sup>6,60,80,82,112</sup>

## Components of Exercise Regimens for Management of Lymphedema

### Deep Breathing Exercises

Deep breathing is interwoven throughout exercise regimens for the management of lymphedema. It has been suggested that the use of abdominal-diaphragmatic breathing assists in the movement of lymphatic fluid as the diaphragm descends during a deep inspiration and the abdominals contract during a controlled, maximum expiration.<sup>19</sup> Changes in intra-abdominal and intrathoracic pressures create a gentle, continual pumping action that moves fluids in the

central lymphatic vessels, which run superiorly in the chest cavity and drain into the venous system in the neck (see Fig. 26.1).

### Flexibility Exercises

Gentle, self-stretching exercises are used to minimize soft tissue and joint hypomobility, particularly in proximal areas of the body that may contribute to static postures and lymph congestion.

### Strengthening and Muscular Endurance Exercises

Both isometric and dynamic exercises using self-resistance, elastic resistance, and weights or weight machines are appropriate if done against light resistance (initially 1 to 2 lb) and progressing resistance and repetitions gradually.<sup>91</sup> Regardless of whether lymphedema has developed, it is important to monitor the circumferential size and the skin texture of the involved limb closely to determine whether an appropriate intensity of exercise has been established. Emphasis is placed on improving endurance and strength of central and peripheral muscle groups that enhance an erect posture and minimize fatigue in muscles that contribute to the efficiency of the lymphatic pump mechanism.

### Cardiovascular Conditioning Exercises

Activities such as upper extremity ergometry, swimming, cycling, and walking increase circulation and stimulate lymphatic flow.<sup>19,91</sup> Thirty minutes of aerobic endurance exercises complement lymph drainage exercises. Conditioning exercises are done at low intensity (at 40% to 50% of the target heart rate) when lymphedema is present and at higher intensities (as high as an 80% level) when the lymphedema has been reduced and exercise is otherwise safe.<sup>19,84</sup>

\*8,9,19,23-26,58,60,73,75,76,84,85,91,98,102,112,134,135

#### BOX 26.8 Exercises for Lymphatic Drainage: Principles and Rationale

- Contraction of muscles pumps fluids by direct compression of the collecting lymphatic vessels.
- Exercise reduces soft tissue and joint hypomobility that can contribute to static positioning and lead to lymphostasis.
- Exercise strengthens and prevents atrophy of muscles of the limbs, which improves the efficiency of the lymphatic pump.
- Exercise increases heart rate and arterial pulsations, which in turn contribute to lymph flow.
- Exercise should be sequenced to clear the central lymphatic reservoirs before the peripheral areas.
- Wearing a compression sleeve or compression bandaging during exercises enhances lymph flow and protein resorption more efficiently than exercising without bandages.

#### FOCUS ON EVIDENCE

In a randomized, controlled study by Schmitz and associates,<sup>104</sup> weight lifting was studied in a group of 141 breast cancer survivors with stable upper extremity lymphedema over a 1-year period. The exercise intervention consisted of progressive weight lifting twice a week and the use of a compression sleeve during exercise. The authors of the investigation hypothesized that controlled resistance training could improve the functional ability of the affected arm to withstand the insults of daily living. Women in the study ranged from 1 to 15 years following diagnosis.

The intervention program included cardiovascular as well as resistance exercise in a controlled and supervised setting. Exercises were advanced gradually. Results of the study demonstrated that a program of weight lifting did not adversely affect lymphedema in the study participants. Additionally, the results showed that when compared with the control group, women in the intervention (weight-lifting)

group reported fewer complaints about their affected arm and hand and had increased overall muscle strength and fewer lymphedema exacerbations following completion of the study.

### Lymphatic Drainage Exercises

Lymphatic drainage exercises, often referred to as pumping exercises, move fluids through lymphatic channels. Active, repetitive ROM exercises are performed throughout each session. The exercises follow a specific sequence to move lymph away from congested areas.<sup>19,23,25,26,135</sup> It is similar to the sequence of massage applied during manual lymph drainage.<sup>67,91,113</sup> In general, the exercises first focus on proximal areas of the body to clear central collecting vessels and then involve distal muscle groups to begin to move peripheral edema in a centripetal direction to the central lymph vessels. The affected upper or lower extremity or extremities are held in an elevated position during many of the exercises. Static, dependent postures are avoided. Self-massage also is interspersed throughout the exercise sequence to further enhance drainage. These exercises also maintain mobility of the involved limbs.

### Guidelines for Lymphatic Drainage Exercises

The patient should follow these guidelines when performing a sequence of lymphatic drainage exercises. These guidelines apply to management of upper or lower extremity lymphedema and reflect the combined opinions of several authors and experts in the field.<sup>19,23-25,84,135</sup>

#### Preparation for Lymphatic Drainage Exercises

- Set aside approximately 20 to 30 minutes for each exercise session.
- Perform exercises twice daily every day.
- Have needed equipment at hand, such as a foam roll, wedge, or exercise wand.

#### During Lymphatic Drainage Exercises

- Wear compression bandages or a customized compression garment if the patient has lymphedema.
- Precede lymphatic drainage exercises with diaphragmatic breathing.
- Follow a specified order of exercises.
- Perform active, repetitive movements slowly, about 1 to 2 seconds per repetition.
- Elevate the involved limb above the heart during distal pumping exercises.
- Combine deep-breathing exercises with active movements of the head, neck, trunk, and limbs.
- Initially, perform a low number of repetitions. Increase repetitions gradually to avoid excessive fatigue.
- Do not exercise to the point at which the edematous limb aches.

- Incorporate self-massage into the exercise sequence to further enhance lymph drainage.
- Maintain good posture during exercises.
- When strengthening exercises are added to the lymph drainage sequence, use light resistance and avoid excessive muscle fatigue.

### Follow-Up to Lymphatic Drainage Exercises

- Set aside time several times per week for low-intensity aerobic exercise activities, such as walking or bicycling for 30 minutes.
- Carefully check for signs of redness or increased swelling or reports of aching or throbbing in the edematous limb, any of which could indicate that the level of exercise was excessive.

### Selected Exercises for Lymphatic Drainage: Upper and Lower Extremity Sequences

The selection and sequences of exercises described in this section and summarized in Box 26.9 are designed to assist in the drainage of upper or lower extremity lymphedema. Many of the individual exercises suggested in lymphedema protocols, such as ROM of the cervical spine and some of the shoulder girdle or upper extremity exercises, are not exclusively used for lymph drainage. They also are used to improve mobility and strength. Several of the exercises highlighted in this section already have been described in previous chapters in this text. Only those exercises or variations of exercises that are somewhat unique or not previously addressed are described or illustrated in this section.

#### Sequence of Exercises

- Diaphragmatic breathing is performed prior to lymphatic drainage exercises.
- Exercises for lymphatic drainage should follow a particular sequence to assist lymph flow. The central and proximal lymphatic vessels, such as the abdominal, inguinal, and cervical nodes (see Fig. 26.1), are cleared first with trunk, pelvic, hip, and cervical exercises. Then, for the most part, exercises proceed distally from shoulders to fingers or from hips to toes. If lymph nodes have been surgically removed (e.g., with a unilateral axillary node dissection for breast cancer or a bilateral inguinal node dissection for cancers of the abdominal or pelvic organs), lymph must be channeled to the remaining nodes in the body.

**NOTE:** Because no single sequence of exercises has been shown to be more effective than another, the upper and lower extremity sequences of exercises outlined in this section do not reflect the exercises included in any one specific protocol. Rather, the exercise sequences are based on the recommendations of numerous authors.<sup>19,23-25,60,80,82,84,112,135</sup> Sequences of exercises for upper or lower extremity lymphedema are summarized in the remaining portion of this chapter. Therapists are encouraged to

## BOX 26.9 Sequence of Selected Exercises for Management of Upper or Lower Extremity Lymphedema

### Exercises Common to Upper and Lower Extremity Regimens

**NOTE:** Start an upper or lower extremity regimen with these exercises.

- Deep breathing exercises
- Posterior pelvic tilts and partial curl-ups
- Cervical ROM
- Bilateral scapular movements

### Upper Extremity Exercises

- Active circumduction with the involved arm elevated while lying supine
- Bilateral active movements of the arms while lying supine or on a foam roll
- Bilateral hand press while lying supine or sitting
- Shoulder stretches (with wand, doorway, or towel) while standing
- Active elbow, forearm, wrist, and finger exercises of the involved arm
- Bilateral horizontal abduction and adduction of the shoulders
- Overhead wall press while standing
- Finger exercises
- Partial curl-ups
- Rest with involved upper extremity elevated

### Lower Extremity Exercises

- Alternate knee to chest exercises
- Bilateral knees to chest
- Gluteal setting and posterior pelvic tilts
- Single knee to chest with the involved lower extremity
- External rotation of the hips while lying supine with both legs elevated and resting on a wedge or wall
- Active knee flexion of the involved lower extremity while lying supine
- Active plantarflexion and dorsiflexion and circumduction of the ankles while lying supine with lower extremities elevated
- Active hip and knee flexion with legs externally rotated and elevated against a wall
- Active cycling and scissoring movements with legs elevated
- Bilateral knee to chest exercises, followed by partial curl-ups
- Rest with lower extremities elevated

modify or add other exercises to the sequences in this chapter as they see fit to meet the individual needs of their patients.

### Exercises Common to Upper and Lower Extremity Sequences

These initial exercises should be included in programs for unilateral or bilateral upper or lower extremity lymphedema. They are designed to help the patient relax and then to clear the central channels and nodes.

- **Diaphragmatic breathing**
  - Have the patient assume a comfortable supine position.
  - Place hands lightly on the abdomen.
  - Inhale deeply through the nose, feeling the abdomen rise against the hands; exhale by blowing air out of the mouth, as if blowing through a straw.
  - Perform diaphragmatic breathing periodically throughout the entire sequence and throughout the day. Avoid breath-holding and the Valsalva maneuver.
- **Posterior pelvic tilts and partial curl-ups.** Perform these exercises in the supine position with hips and knees flexed.
- **Unilateral knee-to-chest movements.** These exercises are designed to target the inguinal nodes and are important even for upper extremity lymphedema.
  - In the supine position, flex one hip and knee and grasp the lower leg. Pull the knee to the chest. Gently press or bounce the thigh against the abdomen and chest about 15 times.

- Repeat the procedure with the opposite lower extremity.
- If lymphedema is present in only one lower extremity, initiate the knee-to-chest exercises with the uninvolved lower extremity.
- **Cervical ROM.** Perform each motion for a count of five for five repetitions.
  - Rotation
  - Lateral flexion
- **Scapular exercises.** Perform each exercise for a count of five for five repetitions.
  - Active elevation and depression (shoulder shrugs)
  - Active shoulder rolls
  - Active scapular retraction and protraction; with arms at sides and elbows flexed, bilaterally retract the scapulae, pointing elbows posteriorly and medially, and then protract the scapulae

### CLINICAL TIP

Be sure to shrug the shoulders as high as possible and then actively pull down the shoulders (depress the scapulae) as far as possible.

### Exercises Specifically for Upper Extremity Lymphedema Clearance

The following sequence of exercises is performed after the general, total body exercises just described. The exercises,

which are performed in a proximal-to-distal sequence, are done specifically for upper extremity lymph clearance.

### CLINICAL TIP

Periodically during the exercise sequence, have the patient perform self-massage to the axillary node area of the *uninvolved* side proceeding from the axilla to the chest.

- **Active circumduction of the arm (Fig. 26.7).** While lying supine, flex the involved arm to 90° (reach toward the ceiling) and perform active circular movements of the arm about 6 to 12 in. in diameter. Do this clockwise and counterclockwise, five repetitions in each direction.

FIGURE 26.7 Active circumduction of the edematous extremity.

**PRECAUTION:** Avoid pendular motions or circumduction of the edematous upper extremity with the arm in a dependent position.

- **Exercises on a foam roll (Fig. 26.8).** While lying supine on a firm foam roll (approximately 6 in. in diameter), perform

FIGURE 26.8 Active shoulder exercises while lying on a firm, foam roll.

horizontal abduction and adduction, as well as flexion and extension of the shoulder. These movements target congested axillary nodes and are done unilaterally. For home exercises, if special equipment such as an Ethyfoam® roller is not available, have the patient perform these exercises on a foam pool “noodle.” Although the diameter is smaller, a towel or folded sheet can be wrapped around the foam “noodle” to increase the diameter of the roll.

- **Bilateral hand press.** With arms elevated to shoulder level or higher and with the elbows flexed, place the palms of the hands together in front of the chest or head. Press the palms together (for an isometric contraction of the pectoralis major muscles) while breathing in for a count of five. Relax, and then repeat as many as five times.
- **Wand exercise, doorway or corner stretch, and towel stretch.** Incorporate several exercises to increase shoulder mobility and to decrease congestion and assist lymph flow in the upper extremity. Hold the position of stretch for several seconds with each repetition. These exercises are described and illustrated in Chapter 17.
- **Unilateral arm exercises with the arm elevated.** The following exercises are done with the patient seated and the arm supported at shoulder level on a tabletop or countertop or with the patient supine and the arm supported on a wedge or elevated overhead.
  - Shoulder rotation with the elbow extended. Turn the palm up, then down, by rotating the shoulder, not simply pronating and supinating the forearm.
  - Elbow flexion and extension
  - Circumduction of the wrist
  - Hand opening and closing
- **Bilateral horizontal abduction and horizontal adduction.** While standing or sitting, place both hands behind the head. Horizontally adduct and abduct the shoulders by bringing the elbows together and then pointing them laterally.
- **Overhead wall press.** Face a wall; place one or both palms on the wall with the hands above shoulder level. Gently press the palms into the wall for several seconds without moving the body. Relax, and repeat approximately five times.
- **Wrist and finger exercises.** If swelling is present in the wrist and hand, repetitive active finger movements are indicated with the arm elevated.
  - After performing the overhead wall press as just described, keep the heel of the hand on the wall and alternately move all of the fingers away from and back to the wall (Fig. 26.9).
  - In the same position as just described, alternately press individual fingers into the wall, as if playing a piano, while keeping the heel of the hand in contact with the wall.
  - Place the palms of both hands together with the hands overhead or at least above shoulder level. One finger at a time, press matching fingers together and then pull them away from each other.

**FIGURE 26.9** Overhead wall press.

- **Partial curl-ups.** To complete the exercise sequence, perform additional curl-ups (about five repetitions) with hands sliding on the thighs.
- **Rest.** Rest in a supine position with the involved arm elevated on pillows for about 30 minutes after completing the exercise sequence.

### Exercises Specifically for Lower Extremity Lymphedema Clearance

**NOTE:** After completing the general lower body, neck, and shoulder exercises previously described, have the patient perform self-massage first to the axillary lymph nodes on the involved side of the body. Then massage the lower abdominal area superiorly to the waist and then laterally and superiorly to the axillary area of the involved side. This sequence is repeated periodically throughout the lower extremity exercise sequence.

- **Unilateral knee-to-chest movements.** In the supine position, repeat this exercise for another 15 repetitions. If lymphedema is present in only one lower extremity, perform repeated knee-to-chest movements with the uninvolved leg first and then the involved leg.
- **Bilateral knees to chest.** In the supine position, flex both hips and knees, grasp both thighs, and gently pull them to the abdomen and chest. Repeat 10 to 15 times.
- **Gluteal setting and posterior pelvic tilts.** Repeat five times, holding each contraction for several seconds and then slowly releasing.
- **External rotation of the hips (Fig. 26.10).** Lie in the supine position with the legs elevated and resting against a wall or on a wedge. Externally rotate the hips, pressing the buttocks together and holding the outwardly rotated position. Repeat several times.
- **Knee flexion to clear the popliteal area.** While lying in the supine position and keeping the uninvolved lower extremity extended, flex the involved hip and knee enough to clear

**FIGURE 26.10** Repeated outward rotation of the hips with legs elevated and resting on a wall.

the foot from the mat table. Actively flex the knee as far as possible by quickly moving the heel to the buttocks. Repeat approximately 15 times.

- **Active ankle movements.** With both legs elevated and propped against a wall, or with just the involved leg propped against a door frame and the uninvolved leg resting on the floor, actively plantarflex the ankle and curl the toes; then dorsiflex the ankle and extend the toes as far as possible for multiple repetitions. Lastly, actively circumduct the foot clockwise and counterclockwise for several repetitions.
- **Wall slides in external rotation (Fig. 26.11).** With the feet propped up against the wall, legs externally rotated, and heels touching, slide both feet down the wall as far as possible and then back up the wall for several repetitions.

**FIGURE 26.11** Sliding feet up and down a wall with hips externally rotated.

- **Leg movements in the air** (Fig. 26.12). With both hips flexed and the back flat on the floor and both feet pointed to the ceiling, alternately move the legs, simulating cycling, walking, and scissoring motions.

**FIGURE 26.12** Repetitive walking movements.

- **Hip adduction across the midline** (Fig. 26.13). Lie in the supine position with the uninvolved leg extended. Flex the hip and knee of the involved leg. Grasp the lateral aspect of the knee with the contralateral hand; pull the involved knee repeatedly across the midline in a rocking motion.

**FIGURE 26.13** Hip adduction across the midline to clear inguinal nodes.

**NOTE:** If lymphedema is bilateral, repeat this exercise with the other lower extremity.

- **Bilateral knee to chest.** Repeat bilateral gentle, bouncing movements of the legs previously described.
- **Partial curl-ups.** To complete the exercise sequence, perform additional partial curl-ups, about five repetitions.
- **Rest.** With feet elevated and legs propped up against the wall, rest in this position for several minutes after completing exercises. Then rest the legs partially elevated on a wedge, and remain in this position for another 30 minutes.

## Independent Learning Activities

### Critical Thinking and Discussion

1. You have been asked to participate in a patient education program at your community's cancer society for patients who have undergone treatment for breast cancer. Your responsibility in this program is to help breast cancer survivors reduce the risk of physical impairments and functional limitations associated with their surgery and any related adjuvant therapies. Outline the components of such a program, and explain the rationale for the activities you have chosen to include.
2. A patient has developed lymphedema as a result of a right mastectomy 5 years ago. She presents to physical therapy with finger and hand swelling extending proximally to the upper arm. Elevation has not been effective. The tissue is pitting in the hand but hard to palpation in the forearm. Stage this lymphedema and outline a proposed treatment plan describing the pathways that would be used for MLD.
3. Describe the anatomy of the lymphatic system. Explain the terms *transport capacity* and *lymphatic load*.
4. Outline the components of CDT and the relationship between each component. Describe a home management program that corresponds to CDT.

### Laboratory Practice

Perform the sequence of exercises and suggested repetitions for the exercise plan you have designed for Case 1, Case 2, and Case 3.

### Case Studies

#### Case 1

Ms. L underwent surgery for metastatic pelvic cancer and lymphadenectomy (lymph node dissection) 3 months ago. She also received a series of radiation therapy treatments as part of her comprehensive oncological management. About 2 weeks ago, she began to notice bilateral swelling in her legs, most notably in her feet and ankles.

She has been referred by her oncologist to the outpatient facility where you work to “evaluate and treat” her for her lymphedema. Describe the examination procedures you would use in your evaluation, and then develop a plan of care, including a program of exercise, to help her manage and reduce her lymphedema and prevent potential complications related to the lymphedema.

**Case 2**

Mrs. B is a 50-year-old female who recently underwent a lumpectomy and axillary lymph node dissection. She is referred to physical therapy following the removal of her surgical drain. She will be starting chemotherapy shortly, followed by a course of radiation therapy. She reports that prior to her diagnosis and surgery, she was an active individual who enjoyed a variety of recreational activities, including swimming, doubles tennis, and camping, and would like to return to those activities as soon as possible. Design a postoperative exercise program taking into consideration the upcoming chemotherapy and radiation therapy.

**Case 3**

Ms. H is a 33-year-old female recently diagnosed with stage II breast cancer on her dominant side. Her physician has recommended a mastectomy based on the location and size of the tumor. Ms. H would prefer to conserve her breast but is advised that a lumpectomy would leave her with a less than optimal cosmetic outcome. She is now considering the following options: latissimus dorsi flap, TRAM flap, DIEP flap, or tissue expander with eventual permanent implant. Design a postoperative rehabilitation program for each surgical reconstruction procedure.

- radial and ulnar deviation of
- manual resistance exercise, 212
- manual stretching, 117
- muscles of, 660t
- self-assisted range of motion, 74, 75f
- strengthening exercises, 707, 707f
- range of motion techniques for, 68, 68f, 69, 69f
- self-assisted, 74, 75f
- rheumatoid arthritis of, 338f, 664–665, 664f, 668
- sprain of, 686
- surgery for disorders of, 667–668
- arthrodesis, 668
- carpal tunnel syndrome, 408
- total wrist arthroplasty, 668–671
- tenosynovitis/tendinitis in, 685–686
- traumatic injuries of, 686–701
- Wrist extension
- manual resistance exercise for, 212
- manual stretching technique for, 116, 117f
- muscles of, 660t
- range of motion techniques for, 68
- strengthening exercises for, 650, 650f, 706, 707f
- stretching techniques for, 116, 117f, 705, 706f
- Wrist flexion
- manual resistance exercise for, 212, 212f
- manual stretching technique for, 116
- muscles of, 660t
- range of motion techniques for, 68, 68f
- strengthening exercises for, 650, 706, 707f
- stretching techniques for, 116, 705
- Wrist muscles, 660–661t, 660–663, 661f, 662f
- extensors, 626
- in elbow overuse syndromes, 643
- self-stretching of, 647, 647f
- strengthening of, 650, 650f
- flexors, 626, 661f
- in elbow overuse syndromes, 643
- self-stretching of, 647
- length-tension relationships for, 661
- relationship to elbow, 626
- strengthening exercises for, 706–708, 707f–708f
- Wrist roller, 650, 650f

## Y

- Y ligament of Bigelow (iliofemoral), 715, 715f, 716
- Y-Balance Test (YBT), 275t, 276, 287
- Young's modulus, 90

## Z

- Zigzag deformity of thumb, 665
- Zigzag forward hops/jumps, 935, 935f
- Zygapophyseal joints. *See* Facet joints
