

# Therapeutic Exercise

**FOUNDATIONS AND TECHNIQUES**

Seventh Edition

# PERFECT WHEREVER YOU ARE...

## in class, in clinical, and in practice!

## Ther Ex Notes

Clinical Pocket Guide, 2nd Edition

Carolyn Kisner, PT, MS | Lynn Allen Colby, PT, MS

- Convenient organization by body region
- Concise exercise guidelines for selected orthopedic pathologies and operative procedures
- Exercise interventions for mobility, muscle performance, stability and balance
- Over 300 photos of stretching, joint mobilization, plyometrics, and more

KNEE

Intermediate: Moderate Protection Phase (3-6 Wk)

- Progress ambulation w/o assistive device; continue w/protective bracing
- Increase mobility (supine wall-slides, patellar mobs, stationary cycling)
- Improve knee muscle performance for functional control
  - Multiple-angle isometrics (quads, HS); SLR & hip add
  - Electrical stimulation to quads if extensor lag present
  - OKC resistance & CKC exercises; use protective bracing when needed
- **Precautions:** Avoid ranges that stress the injured ligament:
  - ACL: Stress occurs w/
    - OKC terminal knee ext (40°-90°) w/ret
    - CKC squatting between 60°-90° knee flex
  - PCL: Stress occurs w/OKC knee flex (HS)
  - MCL: Stress occurs w/OKC hip add
  - LCL: Stress occurs w/OKC hip abd
- Stabilization & balance training
- Cardiopulmonary endurance (bike, pool, s walk/jog)

Advanced: Return to Function (6-8 Wk and Beyond)

- Advance OKC PRE (see precautions above)
- Advance CKC exer (jumping, hopping, direct to plyometrics)
- Advance stabilization & balance training
- Agility drills ("figure eight," cutting)
- Progress cardiopulmonary endurance (runni
- Sport- /work-specific drills

187

**Purpose:** Develop isom strength & stability of WB LE  
**Technique:** Elastic resistance to NWB LE  
 • Perform w/knee of stance leg positioned in varying degrees of flex

**Purpose:** Strengthen knee flexors.  
**Technique:** Scooting on wheeled stool  
 • Place heel on floor & pull body wt forward

**Purpose:** Strengthen & control quads in terminal knee ext  
**Technique:** Elastic resistance  
 • Begin w/knee in 30°-45° flex  
 • Extend knee against elastic resistance  
 • Maintain knee ext for several seconds; then slowly release & allow knee to flex

Continued

KNEE

*“Very clear and quick to assist in bring[ing] clarity to my notes. One of the DPT’s in my clinic bought one after seeing mine.”*

—Lou Russo

*“Great. I am a physical therapist and this guide is wonderful to keep at work for reference.”*

—Jenny Goodlett

As new scientific information becomes available through basic and clinical research, recommended treatments and drug therapies undergo changes. The author(s) and publisher have done everything possible to make this book accurate, up to date, and in accord with accepted standards at the time of publication. The author(s), editors, and publisher are not responsible for errors or omissions or for consequences from application of the book, and make no warranty, expressed or implied, in regard to the contents of the book. Any practice described in this book should be applied by the reader in accordance with professional standards of care used in regard to the unique circumstances that may apply in each situation. The reader is advised always to check product information (package inserts) for changes and new information regarding dose and contraindications before administering any drug. Caution is especially urged when using new or infrequently ordered drugs.

*To our parents—who were supportive throughout our lives.*

*To our students—who have taught us so much.*

*To our colleagues—who have been helpful and stimulating in our professional growth.*

—LC, CK, and JB

# Preface to the Seventh Edition

When Lynn Colby and I first began writing a book on therapeutic exercise over 30 years ago, it was simply an idea to fill a basic need in the education of physical therapists. Our first effort was a soft-cover product in outline form that was primarily marketed as a laboratory manual. The evolution of each succeeding edition came about from our creative insights and collaborative efforts to bring to the student and professional community the most up-to-date resource possible. Lynn has decided that this is the last edition with which she will be involved—I will miss her exceptional abilities, her collegiality, and the partnership that has grown over the years. I am at a loss to know how to thank her for her many years of love and dedication to this project and the friendship that has developed through our partnership. I simply say, thank you Lynn. Enjoy your well-deserved retirement.

For this edition we brought on a new co-author, John Borstad, PT, PhD. He was a contributor in our 6th edition and has been involved in other publications and research. You will see his name on many of the chapters in this edition as he has stepped into the roles of updating, revising, and editing. His biographical information follows in the About the Authors section. It is exciting to have him on board, and I look forward to our ongoing collaborative efforts.

The authors and contributors of this book have continually sought to incorporate current trends and research to support the foundational concepts of therapeutic exercise on

which the student can learn and the practitioner can grow in their expertise of treating patients. In addition to the extensive and thorough revisions of content, the Focus on Evidence and Clinical Tips features, as well as links to video demonstrations of key interventions, are again highlighted in this edition. Whenever applicable, *Clinical Practice Guidelines (CPGs)* are included within the Focus on Evidence sections.

We have added a new chapter on Exercise in the Older Adult (Chapter 24). With this being such a critical area of practice in physical therapy, we anticipate that the content of the chapter will provide a foundation of information and suggested interventions that all practitioners will find useful when working with older individuals. There has also been important updating of information on use of the ICF language (International Classification of Functioning Disability and Health) in Chapter 1; an expansion of information on prevention, health, and wellness in Chapter 2; and incorporation of managing male incontinence in Chapter 25. With the expanding use of the Internet we decided to move some of our tables, boxes, and glossary online. When these resources are available, the reader will be referred to the F.A. Davis website associated with this edition for easy access to this feature.

As with previous editions, it is our hope that this updated text will provide a resource for learning and professional growth for the students and health-care practitioners who utilize therapeutic exercise.

# Acknowledgments

We wish to acknowledge and express our sincere gratitude to the educators and clinicians who contributed their knowledge, insights, and professional perspectives to the revision of this edition.

A special thank you to Vicky Humphrey for editing the ancillary features for faculty that are associated with this edition and for her contributions to the pocket version *Ther Ex Notes, ed. 2*.

A special thank you goes to Marsha Hall, Project Manager, Progressive Publishing Services, who spearheaded the copyediting and production process. And once again, a special thank you to the F. A. Davis staff, particularly to our Senior Acquisitions Editor, Melissa Duffield, and to our Senior Developmental Editor, Jennifer Pine, both of who helped bring the 7th edition to fruition.

# About the Authors

## **Carolyn Kisner, PT, MS**

Carolyn was on the faculty at The Ohio State University for 27 years and was awarded Emeritus status after taking early retirement. During her tenure at OSU she received the Excellence in Teaching award from the School of Allied Medical Professions and was recognized as Outstanding Faculty by the Sphinx and Mortarboard Honor Societies. She organized and managed the honors and re-

search program for the Physical Therapy Division, managed the Advanced Orthopedic track in the master's program, and advised numerous graduate students. Carolyn then taught at the College of Mount St. Joseph in Cincinnati for 7 years. During her tenure there she chaired the curriculum committee, which coordinated revision of the master's program and developed the entry-level Doctor of Physical Therapy program. She was awarded the Sister Adele Clifford Excellence in Teaching at the Mount and at the spring convocation in 2010 was awarded with the Lifetime Achievement in Physical Therapy.

Carolyn co-authored the textbook *Therapeutic Exercise: Foundations and Techniques* with Lynn Colby, PT, MS, first published in 1985. She and Lynn have always attempted to maintain current with the trends in physical therapy, which is reflected in each of the revisions of this book; they have also co-authored the pocket-sized flip book titled *Ther Ex Notes: Clinical Pocket Guide*. Her primary teaching experience includes medical kinesiology, orthopedic evaluation and intervention, therapeutic exercise, and manual therapy. She has presented numerous workshops on peripheral joint mobilization, spinal stabilization, kinesiology, gait, and functional exercise both nationally and internationally, including multiple visits to the Philippines, Brazil, Canada, and Mexico. Active clinical involvement throughout her career has primarily been in outpatient orthopedics and home health.

## **Lynn Allen Colby, PT, MS**

Lynn Allen Colby is Assistant Professor Emeritus, The Ohio State University (OSU). She received her BS in physical therapy and MS in Allied Medicine from OSU, Columbus, Ohio. She is co-author of the textbook, *Therapeutic Exercise: Foundations and Techniques*, now in its 7th edition, and *Ther Ex Notes: Clinical Pocket Guide*.

Recently retired, she taught in the physical therapy program in the School of Allied Medical Professions at OSU for 35 years. As a faculty member, she also advised physical therapists enrolled in the postprofessional graduate program in Allied Medicine. Her primary teaching responsibilities in the physical therapy curriculum included therapeutic exercise interventions for musculoskeletal and neurological conditions and pediatric physical therapy. Experience in the clinical setting has included acute care in orthopedics, extended care in skilled nursing facilities, and inpatient and outpatient care in various pediatric settings.

During her long career in physical therapy, she was a recipient of the Excellence in Teaching Award from the School of Allied Medical Professions at OSU and was named the Ohio Physical Therapist of the Year in 2001 by the Ohio Physical Therapy Association. Most recently, she was honored by the OSU Alumni Association with the Ralph Davenport Mershon Award for Service and Leadership.

**John Borstad, PT, PhD**

John is professor and chair at the College of St. Scholastica in Duluth, Minnesota. After 7 years as a clinician, he began the academic phase of his career in 1999 at the University of Minnesota, earning a PhD in Rehabilitation Science in 2003. He spent the next 13 years on the faculty of the Physical Therapy Division in the School of Health and Rehabilitation Sciences at The Ohio State University. While at

Ohio State, he was funded by the NIH, the Komen Foundation, and NHTSA to study shoulder biomechanics and to advise and train several MS and PhD students. John has

presented his research at many national and international forums, including in Scotland, Japan, and Brazil. He was a co-author on the study that received the Rose Research Award for Excellence in Orthopaedic Physical Therapy Research in 2005 and received the School of Health and Rehabilitation Sciences Faculty Research Award in 2007. He moved back to his home state of Minnesota in 2016 to begin serving in academic leadership at St. Scholastica.

John has taught biomechanics, musculoskeletal science and application, evidence-based practice, and advanced therapeutic progressions during his academic career. In addition to being a contributor to the 6th edition of *Therapeutic Exercise: Foundations and Techniques*, he has co-authored textbook chapters related to the shoulder for Levangie and Norkin's *Joint Structure and Function: A Comprehensive Analysis* and for *Grieve's Musculoskeletal Physiotherapy*.

## Independent Learning Activities 37

Almost everyone, regardless of age, values the ability to function as independently as possible during activities of everyday life. Health-care consumers (patients and clients) typically seek out or are referred for physical therapy services because of physical impairments associated with disorders of the movement system caused by injury, disease, or health-related conditions that restrict their ability to participate in any number of activities that are necessary or important to them. Physical therapy services may also be sought by individuals who have no impairments or functional deficits but who wish to improve their overall level of fitness and quality of life or reduce the risk of injury or disease. An individually designed therapeutic exercise program is almost always a fundamental component of the physical therapy services provided. This stands to reason because the ultimate goal of a therapeutic exercise program is the achievement of an optimal level of symptom-free movement during basic to complex physical activities.

To develop and implement effective exercise interventions, a therapist must understand how the many forms of exercise affect tissues of the body and body systems and how those exercise-induced effects have an impact on key aspects of physical function as they relate to the human movement system. A therapist must also integrate and apply knowledge of anatomy, physiology, kinesiology, pathology, and the behavioral sciences across the continuum of patient/client management from the initial examination to discharge planning. To

develop therapeutic exercise programs that culminate in positive and meaningful functional outcomes for patients and clients, a therapist must understand the relationships among physical functioning, health, and disability and apply these conceptual relationships to patient/client management to facilitate the provision of effective and efficient health-care services. Lastly, a therapist, as a patient/client educator, must know and apply principles of motor learning and motor skill acquisition to exercise instruction and functional training.

Therefore, the purpose of this chapter is to present an overview of the scope of therapeutic exercise interventions used in physical therapy practice. This chapter also discusses several models of health, functioning, and disability as well as patient/client management as they relate to therapeutic exercise and explores strategies for teaching and progressing exercises and functional motor skills based on principles of motor learning.

## Therapeutic Exercise: Impact on Physical Function

Of the many procedures used by physical therapists in the continuum of care of patients and clients, therapeutic exercise takes its place as one of the key elements that lies at the center

of programs designed to improve or restore an individual's function or to prevent dysfunction.<sup>4</sup>

## Definition of Therapeutic Exercise

*Therapeutic exercise*<sup>4,5</sup> is the systematic, planned performance of physical movements, postures, or activities intended to provide a patient/client with the means to:

- Remediate or prevent impairments of body functions and structures.
- Improve, restore, or enhance activities and participation.
- Prevent or reduce health-related risk factors.
- Optimize overall health, fitness, or sense of well-being.

The beneficial effects of therapeutic exercise for individuals with a wide variety of health conditions and related physical impairments are documented extensively in the scientific literature<sup>182</sup> and are addressed in each of the chapters of this textbook.

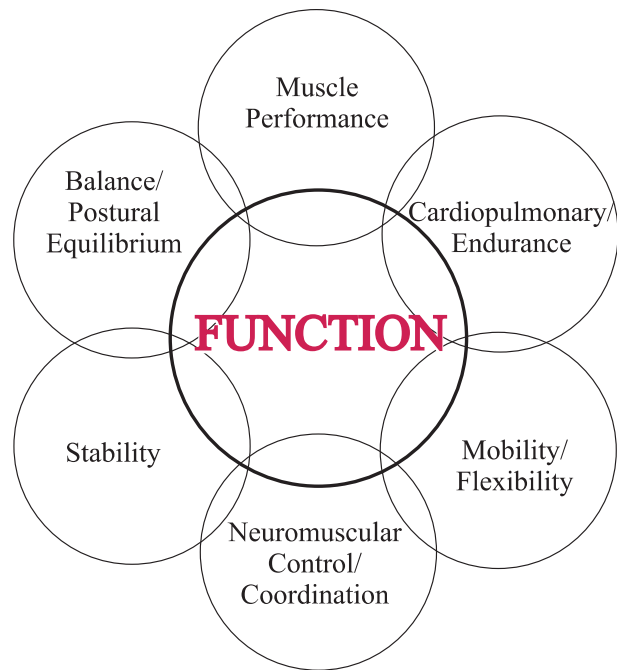

Therapeutic exercise programs designed by physical therapists are *individualized* to the unique needs of each patient or client. A *patient* is an individual with impairments and functional deficits diagnosed by a physical therapist and is receiving physical therapy care to improve function and prevent disability.<sup>4</sup> A *client* is an individual without diagnosed movement dysfunction who engages in physical therapy services to promote health and wellness and to prevent dysfunction.<sup>4</sup> Because the focus of this textbook is on the management of individuals with body function and structure impairments, activity limitations, and participation restrictions, the authors have chosen to use the term “patient,” rather than “client” or “patient/client,” throughout this text. We believe that all individuals receiving physical therapy services must be active participants rather than passive recipients in the rehabilitation process to learn how to self-manage their health needs.

## Components of Physical Function Related to Human Movement: Definition of Key Terms

The ability to function independently at home, in the workplace, within the community, or during leisure and recreational activities is contingent upon physical as well as psychological and social function. The multidimensional aspects of physical function encompass the diverse yet interrelated areas of movement performance that are depicted in Figure 1.1. These elements of function are characterized by the following definitions.

**Balance.** The ability to align body segments against gravity to maintain or move the body (center of mass) within the available base of support without falling; the ability to move the body in equilibrium with gravity via interaction of the sensory and motor systems.<sup>4,94,107,125,166,169,170</sup>

**Cardiopulmonary endurance.** The ability to perform moderate-intensity, repetitive, total body movements (walking,

**FIGURE 1.1** Interrelated components of physical function.

jogging, cycling, swimming, etc.) over an extended period of time.<sup>2,115</sup> A synonymous term is cardiopulmonary fitness.

**Coordination.** The correct timing and sequencing of muscle firing combined with the appropriate intensity of muscular contraction leading to the effective initiation, guiding, and grading of movement. Coordination is the basis of smooth, accurate, efficient movement and occurs at a conscious or automatic level.<sup>139,142,165</sup>

**Flexibility.** The ability to move freely, without restriction; used interchangeably with mobility.

**Mobility.** The ability of structures or segments of the body to move or be moved in order to allow the occurrence of range of motion (ROM) for functional activities (functional ROM).<sup>4,177</sup> Passive mobility is dependent on soft tissue (contractile and noncontractile) extensibility; in addition, active mobility requires neuromuscular activation.

**Muscle performance.** The capacity of muscle to produce tension and do physical work. Muscle performance encompasses strength, power, and muscular endurance.<sup>4</sup>

**Neuromuscular control.** Interaction of the sensory and motor systems that enables synergists, agonists, and antagonists, as well as stabilizers and neutralizers, to anticipate or respond to proprioceptive and kinesthetic information and, subsequently, to work in correct sequence to create coordinated movement.<sup>102</sup>

**Postural control, postural stability, and equilibrium.** Used interchangeably with static or dynamic balance.<sup>73,166,169</sup>

**Stability.** The ability of the neuromuscular system through synergistic muscle actions to hold a proximal or distal body

segment in a stationary position or to control a stable base during superimposed movement.<sup>73,169,177</sup> Joint stability is the maintenance of proper alignment of bony partners of a joint by means of passive and dynamic components.<sup>122</sup>

The human movement system is the foundation for physical therapy and the focus for physical function.<sup>160</sup> The systems of the body that interact to control each of these elements of physical function react, adapt, and develop in response to forces and physical stresses (stress = force / area) placed upon tissues that make up the component parts of movement.<sup>115,121,160</sup> Gravity, for example, is a constant force that affects the musculoskeletal, neuromuscular, and circulatory systems. Additional forces, incurred during routine physical activities, help the body maintain a functional level of strength, cardiopulmonary fitness, and mobility. Imposed forces and physical stresses that are excessive can cause acute injuries, such as sprains and fractures, or chronic conditions, such as repetitive stress disorders.<sup>121</sup> The absence of typical forces on the body also can cause degeneration, degradation, or deformity. For example, the absence of normal weight bearing associated with prolonged bed rest or immobilization weakens muscle and bone.<sup>2,3,17,121</sup> Prolonged inactivity also leads to decreased efficiency of the circulatory and pulmonary systems.<sup>2</sup>

Impairment of any one or more of the body systems and subsequent impairment of any aspect of the human movement system, separately or jointly, can limit or restrict an individual's ability to carry out or participate in daily activities. Therapeutic exercise interventions involve the application of carefully graded physical stresses and forces that are imposed on the human movement system, specific tissues, or individual structures in a controlled, progressive, safely executed manner to enhance movement and improve the human experience.<sup>5,160</sup>

**NOTE:** In a recent article, Sahrman<sup>160</sup> summarized the culmination of several decades of research by physical therapy leaders to more clearly define the role of physical therapy in health care. It has been proposed that physical therapy identify as a profession with a specific body system rather than with a type of intervention in order to gain professional recognition for content expertise. These proponents have defined the human movement system as a physiological system that represents the scope of practice and expertise of physical therapy. In this context, the human movement system is described as a separate physiological system comprised of interacting organs and systems including the nervous and musculoskeletal systems that produce movement and the pulmonary, cardiovascular, endocrine and integumentary systems that support movement.

## Types of Therapeutic Exercise Interventions

Therapeutic exercise embodies a wide variety of activities, movements, and techniques. The individualized therapeutic exercise program is based on a therapist's determination of the underlying risk or cause of impairments in body function or structure, activity limitations, or participation restrictions as identified in the patient examination.<sup>5</sup> The types of therapeutic

exercise interventions presented in this textbook are listed in Box 1.1.

**NOTE:** Although joint mobilization and manipulation procedures often are categorized as manual therapy techniques, not therapeutic exercise,<sup>4</sup> the authors of this textbook have chosen to include joint manipulative procedures under the broad definition of therapeutic exercise to address the full scope of soft tissue stretching techniques.

## Exercise Safety

Regardless of the type of therapeutic exercise intervention, safety is a fundamental consideration whether the exercises are performed independently or under a therapist's direct supervision. Patient safety, of course, is paramount; nonetheless, the safety of the therapist also must be considered, particularly when the therapist is directly involved in the application of an exercise procedure or a manual technique.

Many factors can influence a patient's safety during exercise. Prior to engaging in exercise, a patient's health history and current health status must be explored. A patient unaccustomed to physical exertion may be at risk for the occurrence of an adverse effect from exercise associated with a known or an undiagnosed health condition. Medications can adversely affect a patient's balance and coordination during exercise or cardiopulmonary response to exercise. Therefore, risk factors must be identified and weighed carefully before an exercise program is initiated. Medical clearance from a patient's physician may be indicated before beginning an exercise program.

The environment in which exercises are performed also affects patient safety. Adequate space and a proper support surface for exercise are necessary prerequisites for patient safety. If exercise equipment is used in the clinical setting or at home, to ensure patient safety the equipment must be well maintained and in good working condition, must fit the patient, and must be applied and used properly.

Specific to each exercise in a program, the accuracy with which a patient performs an exercise affects safety, including proper posture or alignment of the body, execution of the correct movement patterns, and performance of each exercise

### BOX 1.1 Therapeutic Exercise Interventions

- Aerobic conditioning and reconditioning
- Muscle performance exercises: strength, power, and endurance training
- Stretching techniques including muscle-lengthening procedures and joint mobilization/manipulation techniques
- Neuromuscular control, inhibition, and facilitation techniques and posture awareness training
- Postural control, body mechanics, and stabilization exercises
- Balance exercises and agility training
- Relaxation exercises
- Breathing exercises and ventilatory muscle training
- Task-specific functional training

with the appropriate intensity, speed, and duration. A patient must be informed of the signs of fatigue, the relationship of fatigue to the risk of injury, and the importance of rest for recovery during and after an exercise routine. When a patient is being directly supervised in a clinical or home setting while learning an exercise program, the therapist can control these variables. However, when a patient is carrying out an exercise program independently at home or at a community fitness facility, patient safety is enhanced and the risk of injury or re-injury is minimized by effective exercise instruction and patient education. Suggestions for effective exercise instruction and patient education are discussed in a later section of this chapter.

As mentioned, therapist safety also is a consideration to avoid work-related injury. For example, when a therapist is using manual resistance during an exercise designed to improve a patient's strength or is applying a stretch force manually to improve a patient's ROM, the therapist must incorporate principles of proper body mechanics and joint protection into these manual techniques to minimize his or her own risk of injury.

Throughout each of the chapters of this textbook, precautions, contraindications, and safety considerations are addressed for the management of specific health conditions, impairments, activity limitations, and participation restrictions and for the use and progression of specific therapeutic exercise interventions.

## Classification of Health Status, Functioning, and Disability—Evolution of Models and Related Terminology

### Background and Rationale for Classification Systems

Knowledge of the complex relationships among health status, functioning, and disability provides a foundation for the delivery of effective health-care services.<sup>87,153,174</sup> Without a common conceptual understanding and vocabulary, the ability to communicate and share information across disciplines and internationally is compromised for research, clinical practice, academia, policy making, and legislation.<sup>153,176,199</sup>

*Disablement* refers to the impact and functional consequence of acute or chronic conditions, such as disease, injury, and congenital or developmental abnormalities, that compromise basic human performance and an individual's ability to meet necessary, customary, expected, and desired societal functions and roles.<sup>85,123,193</sup> Disability is more than a consequence of a medical condition; rather, it is part of the human condition that is experienced by everyone either temporarily or permanently.<sup>76,199</sup> The disabling process depends on countless factors, such as access to quality care, severity and duration of the condition, motivation and attitude of the patient, and support from family and society. Depending on individual

variables and social support, the disabling course is altered and levels of functioning vary among patients with the same medical diagnosis.<sup>85,123,176,193</sup> Defining a person's ability to function in the presence or absence of a health condition is a complex task that is better understood if practitioners, researchers, educators, policy makers, and legislators are using the same vocabulary and classification system.

## Models of Functioning and Disability—Past and Present

### Early Models

Several models that describe disability have been proposed worldwide over the past several decades. Two early theories were the Nagi model<sup>123,124</sup> and the International Classification of Impairments, Disabilities, and Handicaps (ICIDH) model for the World Health Organization (WHO).<sup>67,75</sup> The National Center for Medical Rehabilitation Research (NCMRR) created a third model that introduced individual risk factors for disability based on both physical and social risks.<sup>126</sup>

During the 1990s, physical therapists began to explore the potential use of disablement models and suggested that disablement schema and related terminology provided an appropriate framework for clinical decision-making in practice and research.<sup>64,84,162</sup> In addition, practitioners and researchers suggested that adoption of disablement-related language could be a mechanism to standardize terminology for documentation and communication in the clinical and research settings.<sup>65</sup> The American Physical Therapy Association (APTA) subsequently incorporated an extension of the Nagi disablement model and related terminology in its consensus document, the *Guide to Physical Therapist Practice*<sup>4</sup> (often called the *Guide*) in both its first edition in 1997 and second edition in 2001. Within the profession, this created a unifying force for documentation, communication, clinical practice, and research by designating a disablement framework for organizing and prioritizing clinical decisions made during the continuum of physical therapy care.

The conceptual frameworks of the Nagi, ICIDH, and NCMRR models, although applied widely in clinical practice and research, have been criticized internationally for their perceived focus on pathology.<sup>41</sup> These early models all describe a *unidirectional* path toward disability caused directly by the consequences of disease based on a medical-biological description without consideration of environmental or social influences.<sup>41,176</sup> In response to these criticisms, the WHO undertook a broad revision of its ICIDH model, and in 2001 the International Classification of Functioning, Disability, and Health (ICF) was introduced and characterized as a biopsychosocial model where environmental factors and personal factors are integrated into the concept of functioning and disability (Fig. 1.2).<sup>76,77,173,174,175</sup>

While the ICF is used to classify functioning and disability associated with health conditions, the WHO has a companion classification system to classify health conditions (diseases, disorders, and injuries) called the International Classification of Disease (ICD). Together, the use of these two classification systems provides a broader and more

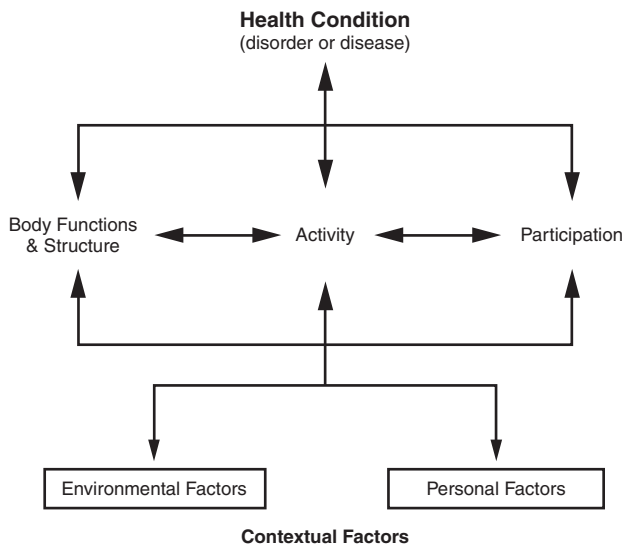

FIGURE 1.2 The ICF Framework.

meaningful picture of the health of both individuals and populations worldwide.<sup>77</sup>

### The ICF—An Overview of the Model

Unlike previous models, the ICF does not focus on disability or on disease, but is intended to classify and code different health and health-related states experienced by everyone. The ICF takes a neutral approach to the human experience as it relates to components of health and functioning, experienced by all people, not just people with disabilities.<sup>76,77,199</sup> The ICF

also includes both environmental and personal factors that influence how people with or without disability live and participate in society.<sup>41,77,199</sup>

As shown in Table 1.1, the ICF model organizes information about health into two basic parts. The first, labeled *Part 1: Functioning and Disability*, is subdivided into two components: (1) Body Functions and Structures and (2) Activities and Participation. The two *umbrella* terms, functioning and disability, are based on the classification of body functions and structures combined with activities and participation. *Functioning* is characterized by positive interactions that are defined by the integrity of body functions and structures and the ability to perform activities and participate in life situations. In contrast, *disability* is characterized by the negative interactions of health situations defined as impairments in body functions and structures, activity limitations, and participation restrictions.<sup>76,77</sup>

The second, labeled *Part 2: Contextual Factors*, also shown in Table 1.1, is subdivided into two components: (1) Environmental Factors and (2) Personal Factors. Contextual factors represent the complete background of an individual’s life and living situation.<sup>77</sup> Environmental factors make up the physical, social, and attitudinal circumstances in which the individual lives either with or without a health problem.<sup>77</sup> These factors are external to the individual but have either facilitating or hindering influences on the individual’s performance at the levels of body functions and structures, execution of activities, and participation in society. For this reason, Part 1 of the model is not classified separately from Part 2 as they are hierarchal in their coding to represent the biopsychosocial paradigm of a person’s health condition.<sup>1,77,144</sup>

TABLE 1.1 An Overview of the International Classification of Functioning, Disability and Health (ICF)\*

	Part 1: Functioning and Disability		Part 2: Contextual Factors	
Components	Body Functions and Structures	Activities and Participation	Environmental Factors	Personal Factors
Domains	Body functions Body structures	Life areas (tasks, actions)	External influences on functioning and disability	Internal influences on functioning and disability
Constructs	Changes in body functions (physiological) Changes in body structures (anatomical)	Capacity: Executing tasks in a standard environment Performance: Executing tasks in the current environment	Facilitating or hindering impact of features of the physical, social, and attitudinal world	Impact of attitudes of the person
Functioning				
Positive aspect	Functional and structural integrity	Activities Participation	Facilitators	Not applicable
Disability				
Negative aspect	Functional and/or structural Impairment	Activity limitation Participation restriction	Barriers Hindrances	Not applicable

\*From *International Classification of Functioning, Disability and Health: ICF*. Geneva: World Health Organization, 2008, p 13, with permission.

Definitions of key terms are summarized in Box 1.2.<sup>76,77,184</sup> Numerous examples of these components are identified later in this chapter.

**NOTE:** The ICF classification and coding methodology is also unique from other models in its unit of measure. The *individual* is not placed in a classification, but rather the coding describes the *situation* of each person within an array of health and health-related domains. The coding used in ICF is complex and multifactorial, with inclusion of health, functioning, and environmental elements combined to describe the ability of an individual to perform activities and participate in society.<sup>1,41,77,88,174,175</sup>

## Components of the ICF and Applications in Physical Therapy

### Background

Traditionally, the physical therapy profession has been defined by a body of knowledge and clinical applications that are directed toward the elimination or remediation of disability.<sup>150</sup> However, as the physical therapy profession has evolved, the scope of practice has moved beyond solely the management and remediation of disability and now includes promoting the well-being of healthy individuals and preventing or reducing risk factors that may lead to disability while considering the external environmental and internal personal factors that influence each person's response to their health condition.<sup>6</sup>

#### BOX 1.2 Definition of Key Terms in the ICF

- **Impairments in body function:** Problems associated with the physiology of the body systems (including psychological functions).
- **Impairments in body structure:** Problems with the anatomical features of the body.
- **Activity limitations:** Difficulties an individual may have in executing actions, tasks, and activities.
- **Participation restrictions:** Problems an individual may experience with involvement in life situations, including difficulties participating in self-care; responsibilities in the home, workplace, or the community; and recreational, leisure and social activities.
- **Contextual factors:** The entire background of an individual's life and living situation composed of:
  - **Environmental factors:** Factors associated with the physical, social, and attitudinal environment in which people conduct their lives; factors may facilitate functioning (facilitators) or hinder functioning and contribute to disability (barriers).
  - **Personal factors:** Features of the individual that are not part of the health condition or health state; includes age, gender, race, lifestyle habits, coping skills, character, affect, cultural and social background, education, etc.

In 2008, the APTA officially endorsed the biopsychosocial framework, vocabulary, and classification system of the ICF. This began a continuing initiative over the past decade to integrate this framework and vocabulary into research, clinical documentation, education, policy making, and legislation.<sup>5,77,141</sup> To facilitate use of the ICF in clinical practice, several articles have been published to provide suggestions for integrating the ICF into specific components of physical therapy practice, ethics, and patient management.<sup>1,48,49,144,153</sup> In 2013, the third edition of the *Guide* was published and is available only in an electronic version in order to facilitate timely updates to reflect the rapid changes in physical therapy practice, including the integration of ICF as the adopted framework for defining the realm of functioning and disability.<sup>5</sup>

For example, use of ICF language for documentation in the clinical setting is being encouraged.<sup>16,141</sup> The most noteworthy application of the ICF can be found in a series of clinical practice guidelines developed and published by the specialty sections of the APTA. These guidelines use the ICF as the basis for describing and classifying care provided by physical therapists.<sup>58,95</sup> Information from the guidelines addressing the efficacy of therapeutic exercise interventions for health conditions and associated impairments commonly seen in orthopedic physical therapy practice is discussed in the regional chapters of this textbook.

### Health Conditions

Health conditions, based on the terminology of the ICF framework, are acute or chronic diseases, disorders, or injuries or circumstances such as aging, pregnancy, or stress that have an impact on a person's level of function (see Fig. 1.2).<sup>76,77</sup> Health conditions are the basis of a medical diagnosis and are coded using the WHO's companion classification system, the International Classification of Disease (ICD).<sup>77</sup>

Physical therapists in all areas of practice treat patients with a multitude of health conditions. Knowledge of health conditions is important background information, but it does not tell the therapist how to assess impairments in body function or structure or how to assess when activities are limited or participation is restricted as a result of the health condition. Despite an accurate medical diagnosis and a therapist's thorough knowledge of specific health conditions, the experienced therapist knows that two patients with the same medical diagnosis, such as rheumatoid arthritis, and the same extent of joint destruction (confirmed radiologically) may have very different severities of impairment, activity limitation, and participation restriction. Consequently, they may have very different degrees of disability. This emphasizes the need for physical therapists to always assess the impact of a particular health condition on movement and function when designing meaningful management strategies to improve functional abilities.

### Body Functions and Body Structures

As noted previously, the first component of classification in Part 1 of the ICF is body functions and structures (see Table 1.1). Body functions are the physiological functions of the body,

whereas body structures describe the anatomical parts of the body. These domains of classification occur at the cellular, tissue, or body system level.

### Types of Impairments

Impairments are defined by the loss of integrity of the physiological, anatomical, and/or psychological functions and structures of the body and are a partial reflection of a person's health status.

Some *impairments of body structure* are readily apparent during a physical therapy examination through visual inspection. Such impairments include joint swelling, scarring, presence of an open wound, lymphedema or amputation of a limb, or through palpation, such as adhesions, muscle spasm, and joint crepitus. Other structural impairments must be identified by a variety of imaging techniques, such as radiographic imaging to identify joint space narrowing associated with arthritis or magnetic resonance imaging (MRI) to identify a torn muscle or ligament.

*Impairments of body function* such as pain, reduced sensation, decreased ROM, deficits in muscle performance (strength, power, and endurance), impaired balance or coordination, abnormal reflexes, and reduced ventilation are those most commonly identified by physical therapists and managed with therapeutic exercise interventions. Some representative examples are noted in Box 1.3.

#### BOX 1.3 Common Body Function Impairments Managed With Therapeutic Exercise

##### Musculoskeletal

- Pain
- Muscle weakness/reduced torque production
- Decreased muscular endurance
- Limited range of motion due to:
  - Restriction of the joint capsule
  - Restriction of periarticular connective tissue
  - Decreased muscle length
  - Joint hypermobility
- Faulty posture
- Muscle length/strength imbalances

##### Neuromuscular

- Pain
- Impaired balance, postural stability, or control
- Incoordination, faulty timing
- Delayed motor development
- Abnormal tone (hypotonia, hypertonia, and dystonia)
- Ineffective/inefficient functional movement strategies

##### Cardiovascular/Pulmonary

- Decreased aerobic capacity (cardiopulmonary endurance)
- Impaired circulation (lymphatic, venous, and arterial)
- Pain with sustained physical activity (intermittent claudication)

##### Integumentary

- Skin hypomobility (e.g., immobile or adherent scarring)

Physical therapists typically provide care and services to patients with impairments associated with the musculoskeletal, neuromuscular, cardiovascular/pulmonary, and integumentary body systems when movement is compromised. In a biopsychosocial model, like the ICF, impairments are identified and documented as a first step to investigating the impact that a health condition has on activities and participation within the specific environment of the patient.

**Primary and secondary impairments.** Impairments may arise directly from the health condition (*direct/primary impairments*) or may be the result of preexisting impairments (*indirect/secondary impairments*). A patient, for example, who has been referred to physical therapy with a medical diagnosis of impingement syndrome or tendonitis of the rotator cuff (pathological condition), may exhibit primary impairments of body function, such as pain, limited ROM of the shoulder, and weakness of specific shoulder girdle and glenohumeral musculature during the physical therapy examination (Fig. 1.3 A and B). The patient may have developed

A

B

**FIGURE 1.3 (A)** Impingement syndrome of the shoulder and associated tendonitis of the rotator cuff (health condition/pathology) leading to **(B)** limited range of shoulder elevation (impairment of body function) are identified during the examination.

the shoulder pathology from a preexisting postural impairment (secondary impairment), which led to altered use of the upper extremity and impingement from faulty mechanics.

**Composite impairments.** When an impairment is the result of multiple underlying causes and arises from a combination of primary or secondary impairments, the term *composite impairment* is sometimes used. For example, a patient who sustained a severe inversion sprain of the ankle resulting in a tear of the talofibular ligament and whose ankle was immobilized for several weeks is likely to exhibit a balance impairment of the involved lower extremity after the immobilizer is removed. This composite impairment could be the result of chronic ligamentous laxity (body structure impairment) and impaired ankle proprioception from the injury or muscle weakness (body function impairments) due to immobilization and disuse.

Regardless of the types of physical impairment exhibited by a patient, a therapist must keep in mind that impairments manifest differently from one patient to another. An important key to effective patient management is to identify *functionally relevant impairments*, in other words, impairments that directly contribute to current or future activity limitations and participation restrictions in a patient's daily life. Impairments that can predispose a patient to secondary health conditions or impairments also must be identified.

Equally crucial for the effective management of a patient's condition is the need to analyze and determine, or at least infer and certainly not ignore, the *underlying causes* of the identified physical impairments of body function or body structure, particularly those related to impaired movement.<sup>158,159,160</sup> For example, are biomechanical abnormalities of soft tissues the source of restricted ROM? If so, which soft tissues are restricted, and why are they restricted? This information assists the therapist in the selection of appropriate, effective therapeutic interventions that target the *underlying causes* of the impairments, the impairments themselves, and the associated activity limitations and participation restrictions.

Although most physical therapy interventions, including therapeutic exercise, are designed to correct or reduce physical impairments of body function, such as decreased ROM or strength, poor balance, or limited cardiopulmonary endurance, the focus of treatment ultimately must be to improve performance of activities and participation in life events. From a patient's perspective, *successful outcomes* of treatment are determined by restoration of activities and participation levels.<sup>144</sup> A therapist cannot simply assume that intervening at the impairment level (e.g., with strengthening or stretching exercises) and subsequently reducing physical impairments (by increasing strength and ROM) generalize to improvement in a patient's level of activity and participation in work and social roles. Mechanisms for integrating task-specific training within the therapeutic exercise intervention are explored in a model of effective patient management presented in a later section of this chapter.

## Activities and Participation

The second component of Part 1 of the ICF is Activities and Participation (see Table 1.1). *Activity* is defined as the execution of a task or action by an individual, whereas *participation* is the involvement of the individual in a life situation. The ICF structure of classification for this component is based on one single list of activities and life areas.<sup>77</sup> The therapist is encouraged to differentiate the components on a case by case basis depending on the patient's life situation. There has been extensive research to determine if these two components of functioning are distinct or interrelated.<sup>1,26,89,144</sup> Because of the varied environmental and personal influences (contextual factors), there is not a clear distinction between an individual's ability to perform a task and participation. Additional empirical research is recommended to provide a clearer operationalization of the two components to enhance data comparison between disciplines and countries.<sup>77</sup>

### Activity Limitation and Participation Restriction

In the language of the ICF, *activity limitations* occur when a person has difficulty executing or is unable to perform tasks or actions of daily life (see Box 1.2).<sup>41,76,77,173,174,175,184</sup> For example, as shown in Figure 1.4, restricted ROM (impairment of body function) of the shoulder as the result of adhesive capsulitis (health condition) can limit a person's ability to reach overhead (activity limitation) while performing personal grooming or household tasks.

**FIGURE 1.4** Limited ability to reach overhead (activity limitation) as the result of impaired shoulder mobility may lead to loss of independence in self-care and difficulty performing household tasks independently (participation restriction).

Many studies have linked body function impairments with activity limitations, particularly in older adults. Links have been identified between limited ROM of the shoulder and difficulty reaching behind the head or back while bathing and

dressing,<sup>185</sup> between decreased isometric strength of lower extremity musculature and difficulty stooping and kneeling,<sup>71</sup> as well as a link between decreased lower extremity peak power and reduced walking speed and difficulty moving from sitting to standing.<sup>140</sup> However, it should also be noted that a single or even several mild impairments of body function or structure do not consistently result in activity limitations for all individuals. For example, results of a 2-year observational study of patients with symptomatic hip or knee osteoarthritis (OA) demonstrated that increased joint space narrowing (a body structure impairment that is considered an indicator of progression of the disease) confirmed radiologically was not associated with an increase in activity limitations as measured on a self-report assessment of physical functioning.<sup>24</sup> Furthermore, evidence from other studies suggests that the severity and complexity of impairments must reach a critical level, which is different for each person, before degradation of functioning begins to occur.<sup>134,143</sup> These examples reinforce the ICF construct that environmental and personal factors interact with all aspects of functioning and disability. Thus, each individual experiences a unique response to a health condition.

**Activity limitation.** Activities and participation require the performance of sensorimotor tasks—that is, total body actions that typically are *components or elements* of functional activities. Activity limitations involve technical and physiological problems that are task-specific and related to performance. Box 1.4 identifies a number of activity limitations that can arise from physical impairments in body function or structure, involve *whole-body movements or actions*, and are necessary component motions of simple to complex daily living tasks. Defining limitations in this way highlights the importance of identifying abnormal or absent component motions of motor skills through task analysis during the physical therapy examination and later integrating task-specific functional motions into a therapeutic exercise program.

When a person is unable or has only limited ability to perform any of the whole-body component motions identified in Box 1.4, activities may be limited and participation may be restricted. The following is an example of the interplay of activities and participation in everyday life. To perform a basic home maintenance task such as painting a room, a person must be able to grasp and hold a paintbrush or roller, climb a ladder, reach overhead, kneel, or stoop down to the floor. If any one of these component movements is limited, it may not be possible to perform the overall task of painting the room. If the individual views home maintenance as a personal or social role, the inability to perform the task of painting may result in participation restriction.

An essential element of a physical therapy examination and evaluation is the analysis of motor tasks to identify the component motions that are difficult for a patient to perform.

### BOX 1.4 Common Tasks Related to Activity Limitations

#### Difficulties with or limitation of:

- Reaching and grasping
- Lifting, lowering, and carrying
- Pushing and pulling
- Bending and stooping
- Turning and twisting
- Throwing and catching
- Rolling
- Sitting or standing tolerance
- Squatting (crouching) and kneeling
- Standing up and sitting down (from and to a chair, the floor)
- Getting in and out of bed
- Moving around (crawling, walking, and running) in various environments
- Ascending and descending stairs
- Hopping and jumping
- Kicking or swinging an object

This analysis helps the therapist determine why a patient is unable to perform specific daily living tasks. This information, coupled with identification and measurement of the impairments that are associated with the altered or absent component movement patterns, in turn, is used for treatment planning and selection of interventions to restore the ability to complete activities or to participate in personal, social, work, or life situations.

**Participation restrictions.** As identified in the ICF model (see Table 1.1), participation restrictions are defined as problems a person may experience in his or her involvement in life situations as measured against social standards (see Box 1.2).<sup>76,77,173,174,175,184</sup> More specifically, participation restriction is about not being able to take part in social practices in situations of significance or meaningfulness in the context of a person's attitudes and environment (contextual factors).<sup>26,144</sup>

Social expectations or roles that involve interactions with others and participation in activities are an important part of the individual. These roles are specific to age, gender, sex, and cultural background. Categories of activities or roles that, if limited, may contribute to participation restrictions are summarized in Box 1.5.

### Contextual Factors

In the ICF, Part 2 consists of *contextual factors*, once again divided into two components: (1) *environmental factors* and (2) *personal factors*. These classifications represent the external and internal domains that influence functioning and disability, taking into consideration the complete

### BOX 1.5 Areas of Functioning Associated With Participation Restrictions

- Self-care
- Mobility in the community
- Occupational tasks
- School-related tasks
- Home management (indoor and outdoor)
- Caring for dependents
- Recreational and leisure activities
- Socializing with friends/family
- Community responsibilities and service

background of an individual's life and living situation (see Table 1.1).

Environmental factors are outside of the individual, but every feature of the physical, social, and attitudinal world has either a facilitating or hindering impact on functioning and disability.<sup>77</sup>

Because disability is such a complex concept, the extent to which each aspect of functioning affects one's perceived level of disability is not clearly understood. An assumption is made that when impairments and activity limitations are so severe or of such long duration that they cannot be overcome to a degree acceptable to an individual, a family, or society, the perception of "being disabled" occurs.<sup>143</sup> The perception of disability is highly dependent on a person's or society's expectations of how or by whom certain roles or tasks *should* be performed.

Personal factors are unique to the individual and may include characteristics such as race, gender, family background, coping styles, education, fitness, and psychological assets.<sup>77</sup>

**NOTE:** Because personal factors are features of the individual, they are not part of the health condition, and they are not classified or coded in the ICF (see Table 1.1). However, they must be considered in any provision of care because they will influence the outcome of the intervention.<sup>77</sup>

### The Role of Prevention

Understanding the relationships among a health condition, impairments, activity limitations, participation restrictions, and the impact of environmental and personal factors on functioning is fundamental to the prevention or reduction of disability.<sup>25,61,85</sup> Disability is not caused by any one level of impairment or activity limitation or participation restriction; rather, the process is bidirectional and complex.

Take, for example, a relatively inactive person with longstanding osteoarthritis of the knees. The inability to get up from the floor or from a low seat (activity limitation) because of limited flexion of the knees and power deficits of the hip

and knee extensors (impairments in body function) could indeed lead to restricted participation in life's activities and disability in several areas of everyday functioning. Disability could be expressed by problems in self-care (inability to get in and out of a tub or stand up from a standard height toilet seat), home management (inability to perform selected housekeeping, gardening, or yard maintenance tasks), or community mobility (inability to get into or out of a car or van independently).

The perception of disability possibly could be minimized if the patient's functional ROM and strength can be improved with an exercise program and the increased ROM and strength are incorporated into progressively more challenging functional activities or if the physical environment can be altered sufficiently with the use of adaptive equipment and assistive devices.

Adjusting expected roles or tasks within the family might also have a positive impact on the prevention or reduction of disability. Factors within the individual also can have an impact on the prevention, reduction, or progression of disability. Those factors include level of motivation or willingness to make lifestyle changes and accommodations as well as the ability to understand and cope with an adjusted lifestyle.<sup>193</sup> This example highlights that inherent in any discussion of disability is the assumption that it can be prevented or remediated.<sup>25</sup>

**Categories of prevention.** Prevention falls into three categories.<sup>4</sup>

- *Primary prevention:* Activities such as health promotion designed to prevent disease in an at-risk population.
- *Secondary prevention:* Early diagnosis and reduction of the severity or duration of existing disease and sequelae.
- *Tertiary prevention:* Use of rehabilitation to reduce the degree or limit the progression of existing disability and improve multiple aspects of function in persons with chronic, irreversible health conditions.

Therapeutic exercise, the most frequently implemented physical therapy intervention, has value at all three levels of prevention. Health and wellness have moved to the forefront of health care, and physical therapists are becoming involved in wellness screens, community health fairs, and annual check-ups as a form of primary prevention. The use of resistance exercises and aerobic conditioning exercises in weight-bearing postures is often advocated for the primary and secondary prevention of age-related osteoporosis.<sup>40,70</sup> In addition, therapists who work with patients with chronic musculoskeletal or neuromuscular diseases or disorders routinely are involved with tertiary prevention of disability.

### Risk Factors

Modifying risk factors through an intervention, such as therapeutic exercise, is an important tool for preventing or reducing the impact of health conditions and subsequent impairments, activity limitations, and participation restrictions associated with disability. Risk factors are influences

or characteristics that predispose a person to impaired functioning and potential disability. As such, they exist *prior to* the onset of a health condition and associated impairments, limitations, or restrictions.<sup>25,85,193</sup> Some factors that increase the risk of disabling conditions are biological characteristics, lifestyle behaviors, psychological characteristics, and the impact of the physical and social environments. Examples of each of these types of risk factor are summarized in Box 1.6.

Some of the risk factors, in particular lifestyle characteristics and behaviors and their impact on the potential for disease or injury, have become reasonably well known because of public service announcements and distribution of educational materials in conjunction with health promotion campaigns, such as *Healthy People 2010*<sup>188</sup> and *Healthy People 2020*.<sup>189</sup> Information on the adverse influences of health-related risk factors, such as a sedentary lifestyle, obesity, and smoking, has been widely disseminated by these public health initiatives. Although the benefits of a healthy lifestyle, which includes regular exercise and physical activity, are well founded and widely documented,<sup>2,188,189</sup> initial outcomes of a previous national campaign, *Healthy People 2000*,<sup>191</sup> suggest that an increased awareness of risk factors has not translated effectively into dramatic changes in

lifestyle behaviors to reduce the risk of disease or injury.<sup>50</sup> This demonstrates that increased knowledge does not necessarily change behavior.

When a health condition exists, the reduction of risk factors by means of *buffers* (interventions aimed at reducing the progression of a pathological condition, impairments, limitations, restrictions, and potential disability) is appropriate.<sup>85</sup> This focus of intervention is categorized as secondary or tertiary prevention. Initiating a regular exercise program, increasing the level of physical activity on a daily basis, or altering the physical environment by removing architectural barriers or using assistive devices for a range of daily activities are examples of buffers that can reduce the risk of disability. (Refer to Chapter 2 of this textbook for additional information on prevention, reduction of health-related risk factors, and wellness.)

### Summary

An understanding of the concepts of functioning and disability; of the relationships among the components of functioning, disability, and health; and of the various models and classification systems that have been developed over the past several decades provides a conceptual framework for practice and research. This knowledge also establishes a foundation for sound clinical decision-making and effective communication and sets the stage for delivery of effective, efficient, meaningful physical therapy care and services for patients.

#### BOX 1.6 Risk Factors for Disability

##### Biological Factors

- Age, sex, and race
- Height/weight relationship
- Congenital abnormalities or disorders (e.g., skeletal deformities, neuromuscular disorders, cardiopulmonary diseases, or anomalies)
- Family history of disease; genetic predisposition

##### Behavioral/Psychological/Lifestyle Factors

- Sedentary lifestyle
- Cultural biases
- Use of tobacco, alcohol, and/or other drugs
- Poor nutrition
- Low level of motivation
- Inadequate coping skills
- Difficulty dealing with change or stress
- Negative affect

##### Physical Environment Characteristics

- Architectural barriers in the home, community, and workplace
- Ergonomic characteristics of the home, work, or school environments

##### Socioeconomic Factors

- Low economic status
- Low level of education
- Inadequate access to health care
- Limited family or social support

## Principles of Comprehensive Patient Management

An understanding of the concepts of functioning and disability, coupled with knowledge of the process of making informed clinical decisions based on evidence from the scientific literature, provides the foundation for comprehensive management of patients seeking and receiving physical therapy services. Provision of quality patient care involves the ability to make sound clinical judgments; solve problems that are important to a patient; and apply knowledge of the relationships among a patient's health condition(s), impairments, limitations in daily activities, and participation restrictions throughout each phase of management.

The primary purpose of this section of the chapter is to describe a model of patient management used in physical therapy practice. Inasmuch as clinical reasoning and evidence-based decision-making are embedded in each phase of patient management, a brief overview of the concepts and processes associated with clinical decision-making and evidence-based practice is presented before exploring a systematic process of patient management in physical therapy. Relevant examples of the clinical decisions a therapist must make are highlighted within the context of the patient management model.

## Clinical Decision-Making

*Clinical decision-making* refers to a dynamic, complex process of reasoning and analytical (critical) thinking that involves making judgments and determinations in the context of patient care.<sup>93</sup> One of the many areas of clinical decision-making in which a therapist is involved is the selection, implementation, and modification of therapeutic exercise interventions based on the unique needs of each patient or client. To make effective decisions, merging clarification and understanding with critical and creative thinking is necessary.<sup>101</sup> A number of requisite attributes are necessary for making informed, responsible, efficient, and effective clinical decisions.<sup>46,101,113,167</sup> Those requirements are listed in Box 1.7.

There is a substantial body of knowledge in the literature that describes various strategies and models of clinical decision-making in the context of patient management by physical therapists.<sup>43,46,65,79,80,92,93,148,151,152</sup> One such model, the Hypothesis-Oriented Algorithm for Clinicians II (HOAC II), describes a series of steps involved in making informed clinical decisions.<sup>152</sup> The use of clinical decision-making in the diagnostic process also has generated extensive discussion in the literature.<sup>19,22,42,46,59,62,83,84,149,158,183,187,201</sup>

To assist in the decision-making process and ultimately improve patient care, tools known as *clinical prediction rules* (CPRs), first developed in medicine, also have been developed for use by physical therapists.<sup>32,52</sup> Some CPRs contain predictive factors that help a clinician establish specific diagnoses or

improve the accuracy of prognoses, whereas others identify subgroupings of patients within large, heterogeneous groups who are most likely to benefit from a particular approach to treatment or specific therapeutic interventions. To date, some prediction tools in physical therapy have been developed to assist in the diagnosis of health conditions, including osteoarthritis in patients with hip pain<sup>178</sup> and deep vein thrombosis in patients with leg pain.<sup>147</sup> However, a greater number of CPRs in physical therapy have been established to predict likely responses of patients to treatment. As examples, CPRs have been developed to identify a subgrouping of patients with patellofemoral pain syndrome who are most likely to respond positively to lumbopelvic manipulation,<sup>78</sup> patients with low back pain most likely to respond to stabilization exercises,<sup>72</sup> and those with neck pain for whom thoracic spine manipulation is most likely to be effective.<sup>35</sup>

It is important to note, however, that little research, thus far, has focused on validation of published CPRs<sup>15</sup> or their impact on the effectiveness of patient care from specific therapeutic interventions. The results of two systematic reviews of the literature underscore these points. One review<sup>15</sup> concluded that there is considerable variation in the quality of studies used to validate CPRs developed for interventions used by physical therapists. The results of the other review of CPRs for musculoskeletal conditions<sup>172</sup> demonstrated that currently there is only limited evidence to support the use of these rules to predict the effectiveness of specific interventions or to optimize treatment. Additional information from studies directed toward clinical decision-making is integrated into the remainder of this section on patient management or is addressed in later chapters.

### BOX 1.7 Requirements for Skilled Clinical Decision-Making During Patient Management

- Knowledge of pertinent information about the problem(s) based on the ability to collect relevant data by means of effective examination strategies
- Cognitive and psychomotor skills to obtain necessary knowledge of an unfamiliar problem
- Use of an efficient information-gathering and information-processing style
- Prior clinical experience with the same or similar problems
- Ability to recall relevant information
- Ability to integrate new and prior knowledge
- Ability to obtain, analyze, and apply high-quality evidence from the literature
- Ability to critically organize, categorize, prioritize, and synthesize information
- Ability to recognize clinical patterns
- Ability to form working hypotheses about presenting problems and how they might be solved
- Understanding of the patient's values and goals
- Ability to determine options and make strategic plans
- Application of reflective thinking and self-monitoring strategies to make necessary adjustments

## Coordination, Communication, and Documentation

Health care continues to move in the direction of physical therapists being primary practitioners through whom consumers gain access to services without physician referral. As the coordinator of physical therapy care and services, the therapist has the responsibility to communicate verbally and through written documentation with all individuals involved in the care of a patient. The adoption of direct access has been scrutinized in regard to the ability of physical therapists to make sound clinical decisions and the potential for therapists to miss critical signs and symptoms (*red flags*) and neglect to refer patients when appropriate.<sup>91</sup> However, the literature shows several circumstances where therapists have shown evaluative and diagnostic skills resulting in appropriate decisions to involve other providers in the coordination of care of the patient.<sup>23,68,91</sup>

The following are descriptions of circumstances where it is appropriate for the physical therapist to communicate and coordinate care of the patient with another provider.<sup>5</sup>

- *Comanagement*: Sharing responsibility.
- *Consultation*: Providing or seeking professional expertise/judgement.

- *Supervision*: Delegation of some portion of treatment while remaining responsible for the care provided.
- *Referral*: Includes both referring to another provider and receiving referrals from another provider.

Even during the intervention or discharge phase of patient management, a therapist might make the clinical decision that referral to another practitioner is appropriate and complementary to the physical therapy services. This requires coordination and communication with other health-care practitioners. For example, a therapist might refer a patient who is generally deconditioned from a sedentary lifestyle and who is also obese to a nutritionist for dietary counseling to complement the physical therapy program designed to improve the patient's aerobic capacity (cardiopulmonary endurance) and general level of fitness.

Coordination, communication, and documentation are required of the physical therapist throughout the entire episode of patient management. This role encompasses many patient-related administrative tasks and professional responsibilities, such as writing reports (evaluations, plans of care, and discharge summaries); designing home exercise programs; contacting third-party payers, other health-care practitioners, or community-based resources; and participating in team conferences.

## Evidence-Based Practice

Physical therapists who wish to provide high-quality patient care must make informed clinical decisions based on sound clinical reasoning and knowledge of the practice of physical therapy. An understanding and application of the principles of evidence-based practice provide a foundation to guide a clinician through the decision-making process during the course of patient care.

In recent years, evidence-based practice has been highlighted in the strategic plans of the APTA by establishing guidelines, setting goals for therapists to be engaged in applying and integrating research findings into everyday practice, and encouraging use of validated clinical practice guidelines.<sup>8</sup>

### Definition and Description of the Process

*Evidence-based practice* is “the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of an individual patient.”<sup>156</sup> Evidence-based practice also involves combining knowledge of evidence from well-designed research studies with the expertise of the clinician and the values, goals, and circumstances of the patient.<sup>157</sup>

The process of evidence-based practice involves the following steps:<sup>37,157</sup>

1. Identify a patient problem and convert it into a specific question.
2. Search the literature and collect clinically relevant, scientific studies that contain evidence related to the question.
3. Critically analyze the pertinent evidence found during the literature search and make reflective judgments about the quality of the research and the applicability of the information to the identified patient problem.
4. Integrate the appraisal of the evidence with clinical expertise and experience and the patient's unique circumstances and values to make decisions.
5. Incorporate the findings and decisions into patient management.
6. Assess the outcomes of interventions and ask another question if necessary.

This process enables a practitioner to select and interpret the findings from the evaluation tools used during the examination of the patient and to implement effective treatment procedures that are rooted in sound theory and scientific evidence (rather than anecdotal evidence, opinion, or clinical tradition) to facilitate the best possible outcomes for a patient.

### FOCUS ON EVIDENCE

In a survey of physical therapists, all of whom were members of APTA, 488 respondents answered questions about their beliefs, attitudes, knowledge, and behavior about evidence-based practice.<sup>90</sup> Results of the survey indicated that the therapists believed that the use of evidence in practice was necessary and that the quality of care for their patients was better when evidence was used to support clinical decisions. However, most thought that carrying out the steps involved in evidence-based practice was time consuming and seemed incompatible with the demands placed on therapists in a busy clinical setting.

It is impractical to suggest that a clinician must search the literature for evidence to support each and every clinical decision that must be made. Despite time constraints in the clinical setting, when determining strategies to solve complex patient problems or when interacting with third-party payers to justify treatment, the “thinking therapist” has a professional responsibility to seek out evidence that supports the selection and use of specific evaluation and treatment procedures.<sup>12</sup>

### Accessing Evidence

One method for staying abreast of evidence from the current literature is to read one's professional journals on a regular basis. It is also important to seek out relevant evidence from high-quality studies (randomized controlled trials, systematic reviews of the literature, etc.) from journals of other professions.<sup>38</sup> Journal articles that contain systematic reviews of the literature or summaries of multiple systematic reviews are an efficient means to access evidence because they provide a concise compilation and critical appraisal of a number of scientific studies on a topic of interest.

Evidence-based *clinical practice guidelines* for management of specific physical conditions or groupings of impairments also have been developed; they address the relative effectiveness of specific treatment strategies and procedures. These guidelines provide recommendations for management based on systematic reviews of current literature.<sup>139,161</sup> Initially, clinical practice guidelines that address four broadly defined musculoskeletal conditions commonly managed by physical therapists—specifically knee pain,<sup>135</sup> low back pain,<sup>136</sup> neck pain,<sup>137</sup> and shoulder pain<sup>138</sup>—were developed by the Philadelphia Panel, a panel of experts from physical therapy and medicine.

As mentioned previously in this chapter, a series of clinical practice guidelines has been created and published by several sections of the APTA. These guidelines provide evidence-based recommendations for physical therapy management (diagnosis, prognosis, selection of therapeutic interventions, and use of outcome measures) of a number of impairment/function-based groupings that are based on the ICF.<sup>58</sup> Some examples include clinical practice guidelines for management of neck pain,<sup>33</sup> knee pain and mobility impairments,<sup>104</sup> knee stability impairments,<sup>105</sup> hip pain and mobility deficits associated with osteoarthritis,<sup>34</sup> heel pain associated with plantar fasciitis,<sup>117</sup> and deficits associated with Achilles tendonitis.<sup>29</sup> All of the published clinical practice guidelines can be found at PTNow.org—a resource of the APTA.<sup>7</sup> More specific information from recently published guidelines is integrated into the regional chapters of this textbook.

If articles that contain systematic reviews of the literature on a specific topic have not been published, a therapist may find it necessary and valuable to perform an individual literature search to identify evidence applicable to a clinical question or patient problem. Journals exclusively devoted to evidence-based practice are another means to assist the practitioner who wants to identify well-designed research studies from a variety of professional publications without doing an individual search. These journals provide abstracts of research studies that have been critically analyzed and systematically reviewed.

Online bibliographic databases also facilitate access to evidence. Many databases provide systematic reviews of the literature relevant to a variety of health professions by compiling and critiquing several research studies on a specific patient problem or therapeutic intervention.<sup>12,37,119</sup> One example is the Cochrane Database of Systematic Reviews, which reports peer-reviewed summaries of randomized controlled trials and the evidence for and against the use of various interventions for patient care, including therapeutic exercise. Although a recent study<sup>118</sup> identified CENTRAL (Cochrane Central Registry of Controlled Trials), PEDro (Physiotherapy Evidence Database), PubMed, and EMBASE (Excerpta Medica Database) as the four most comprehensive databases indexing reports of randomized clinical trials of physical therapy interventions, only PEDro exclusively reports trials, reviews, and practice guidelines pertinent to physical therapy.<sup>109</sup> Easily accessed online databases such as these streamline the search process and provide a wealth of information from the literature in a concise format.

To further assist therapists in retrieving and applying evidence in physical therapist practice from the Cochrane online library, the *Physical Therapy* journal publishes a recurring feature called Linking Evidence and Practice (LEAP). This feature summarizes a Cochrane review and other scientific evidence on a single topic relevant to physical therapy patient care. In addition, LEAP presents case scenarios to illustrate how the results of the review of evidence can be applied to the decision-making process during patient management.

In support of evidence-based practice, relevant research studies are highlighted or referenced throughout each of the chapters of this text in relationship to the therapeutic exercise interventions, manual therapy techniques, and management guidelines presented and discussed. However, there is also an absence of research findings to support the use of some of the interventions presented. For such procedures, a therapist must rely on clinical expertise and judgment as well as each patient's response to treatment to determine the impact of these interventions on patient outcomes. Interventions without evidence to support efficacy should be used discriminately, and attempts to support and identify new research in those areas is a professional expectation. Examples of how to incorporate the ongoing process of clinical decision-making and application of evidence into each phase of patient management are presented in the following discussion of a model for patient management.

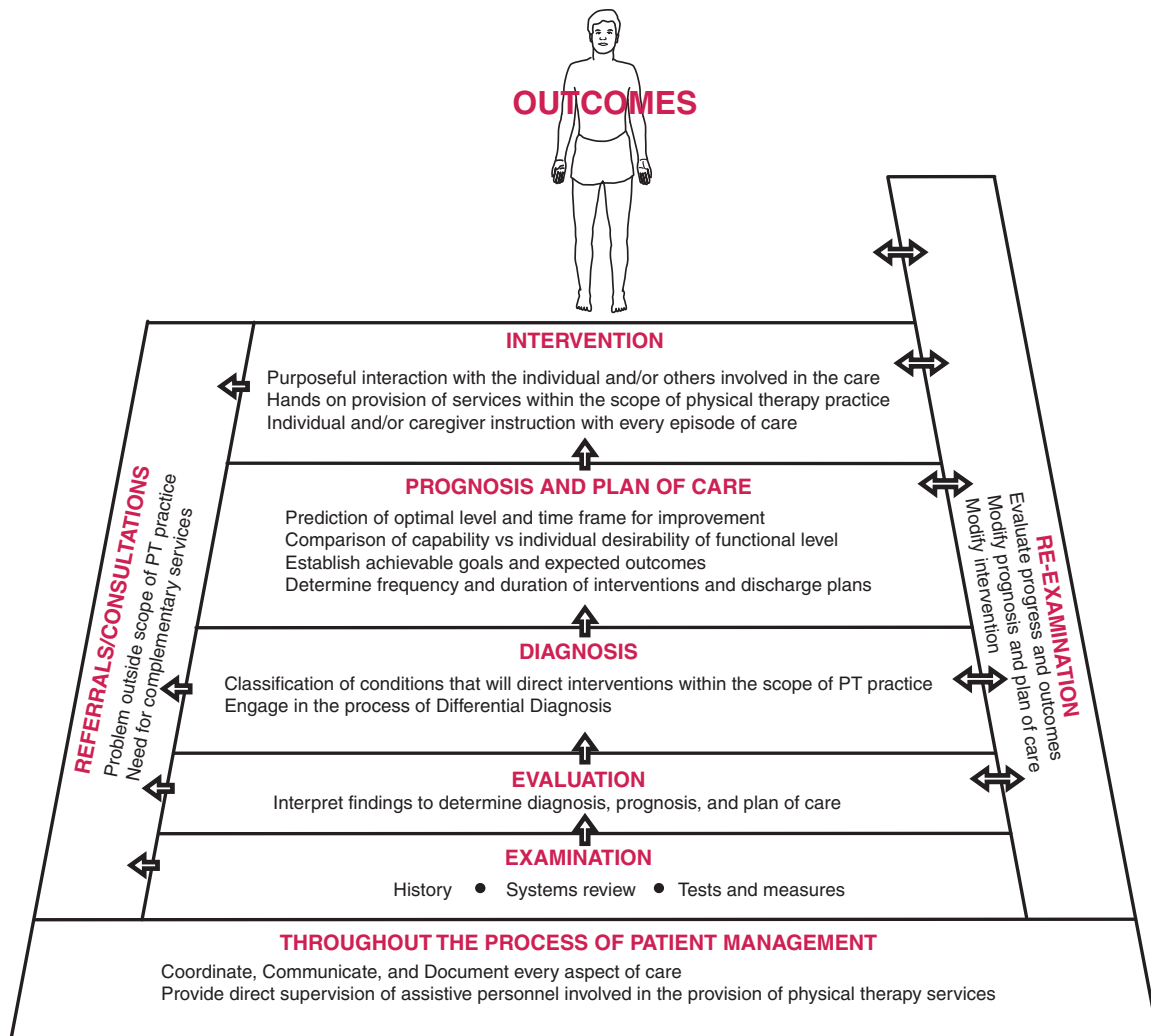

## A Patient Management Model

The physical therapy profession has developed a comprehensive approach to patient management designed to guide a practitioner through a systematic series of steps and decisions for the purpose of helping a patient achieve the highest level of functioning possible.<sup>6</sup> This model is published online in the *Guide to Physical Therapist Practice* and is illustrated in Figure 1.5.

As described in the *Guide to Physical Therapist Practice*, the process of patient management has the following elements:<sup>5,6,19,54</sup>

1. A comprehensive *examination* including successive re-examination as indicated.
2. *Evaluation* of data collected.
3. Determination of a *diagnosis* based on impairments of body structure and function, activity limitations, and participation restrictions that result in movement dysfunction and/or are amenable to physical therapy intervention.
4. Establishment of a *prognosis* and plan of care based on patient-oriented goals.
5. Implementation of appropriate *intervention*.
6. Analysis and communication of *outcomes* resulting from interventions.

The ability to make timely decisions and appropriate judgments and to develop or adjust an ongoing series of working hypotheses makes transition from one phase of patient management to the next occur in an effective, efficient manner.

**FIGURE 1.5** A comprehensive model of the patient management process.

## Examination

The first component of the patient management model is a comprehensive examination of the patient. Examination is the systematic process by which a therapist obtains information about a patient's problem(s) and his or her reasons for seeking physical therapy services. During this initial data collection, the therapist acquires information from a variety of sources. The examination process involves both comprehensive screening and specific diagnostic testing. It is the means by which the therapist gathers sufficient information about the patient's existing or potential problems to ultimately formulate a diagnosis and determine whether these problems can be appropriately treated by physical therapy interventions. If treatment of the identified problems does not fall within the scope of physical therapy practice, referral to another health-care practitioner or resource is warranted. The examination is also the means by which baseline measurements of current impairments of body functions and structures, activity limitations, and participation restrictions are established as a reference point from

which the results of therapeutic interventions can be measured and documented.

There are three distinct elements of a comprehensive examination:<sup>5</sup>

- The patient's health history
- A relevant systems review
- Specific tests and measures

Throughout the examination process, a therapist seeks answers to an array of questions and concurrently makes a series of clinical decisions that shape and guide the examination process. Examples of some questions to be asked and decisions to be made are noted in Box 1.8.

### Health History

The health history is the mechanism by which a therapist obtains an *overview* of current and past information (both subjective and objective) about a patient's present condition(s), general health status (health risk factors and coexisting health problems), and why the patient has sought physical therapy

### BOX 1.8 Key Questions to Consider During the Initial Examination

- What are the most complete and readily available sources for obtaining the patient's history?
- Is there a need to obtain additional information about the patient's presenting health condition or a medical diagnosis if one is available?
- Based on initial working hypotheses, which of the patient's signs and symptoms warrant additional testing by physical therapy or by referral to another health-care practitioner?
- Do the patient's problems seem to fall within or outside the scope of physical therapy practice?
- What types of specific tests and measures should be selected to gather data about the patient's impairments, activity/functional limitations, or extent of participation and resulting disability?
- Based on scientific evidence, which diagnostic tests have a high level of accuracy to identify impairments, functional deficits, or disability?
- What are the most important tests to do first? Which could be postponed until a later visit with the patient?

services. It has been shown in a multicenter study that patients seen in outpatient physical therapy practices have extensive health histories, including use of medications for a variety of medical conditions (e.g., hypertension, pulmonary disorders, and depression) and surgical histories (e.g., orthopedic, abdominal, and gynecological surgeries).<sup>18</sup>

The types of data that can be generated from a patient's health history are summarized in Box 1.9.<sup>4,19,20,97</sup> The therapist determines which aspects of the patient's history are more relevant than others and what data need to be obtained from various sources.

Sources of information about the patient's history include:

- Self-report health history questionnaires filled out prior to or during the initial visit.
- Interviews with the patient, family, or other significant individuals involved in patient care.
- Review of the medical record.
- Reports from the referral source, consultants, or other health-care team members.

The extent of information about a patient's health history that is necessary or available may be extensive or limited and

### BOX 1.9 Information Generated from the Initial History

#### Demographic Data

- Age, sex, race, and ethnicity
- Primary language
- Education

#### Social History

- Family and caregiver resources
- Cultural background
- Social interactions/support systems

#### Occupation/Leisure

- Current and previous employment
- Job/school-related activities
- Recreational and community activities/tasks

#### Growth and Development

- Developmental history
- Hand and foot dominance

#### Living Environment

- Current living environment
- Expected destination after discharge
- Community accessibility

#### General Health Status and Lifestyle Habits and Behaviors: Past/Present (Based on Self or Family Report)

- Perception of health/disability
- Lifestyle health risks (smoking and/or substance abuse)
- Diet, exercise, and sleep habits

#### Medical/Surgical/Psychological History

- Previous inpatient or outpatient services

#### Medications

- Over-the-counter and prescription meds
- Frequency and dosage of meds

#### Family History: Current and Past

- Health risk factors
- Family illnesses

#### Cognitive/Social/Emotional Status

- Orientation and memory
- Communication
- Social/emotional interactions

#### Current Conditions/Chief Complaints or Concerns

- Conditions/reasons physical therapy services sought
- Patient's perceived level of daily functioning and disability
- Patient's needs and goals
- History, onset (date and course), mechanism of injury, and pattern and behavior of symptoms
- Family or caregiver needs, goals, and perception of patient's problems
- Current or past therapeutic interventions
- Previous outcome of chief complaint(s)

#### Functional Status and Activity Level

- Current/prior functional status: basic ADL and IADL related to self-care and home
- Current/prior functional status in work, school, and community-related IADL

#### Other Laboratory and Diagnostic Tests

#### Review of Systems: Any history of health conditions

may or may not be readily accessible prior to the first contact with the patient. Compare, for example, the information available to the therapist working in an acute care facility who has ready access to a patient's medical record versus the home health therapist who may have only a patient's medical diagnosis or brief surgical history. Regardless of the extent of written reports or medical/surgical history available, reviewing this information prior to the initial contact with the patient helps a therapist prioritize the questions asked and areas explored during the interview with the patient.

A general, verbal *review of systems* is conducted during the history-gathering phase to collect information about all major body systems relative to the patient's overall health condition.<sup>5</sup> The review of systems includes questions about past medical history, review of previous medical reports or lab work available, and other signs or symptoms experienced by the individual (see Table 1.2). This information is used to determine whether there

are underlying conditions mimicking or masking musculoskeletal or neuromuscular symptoms or other signs indicative of complications that suggest the need for referral. This is especially important with the prevalence of patients being seen directly by the physical therapist through direct access.<sup>5</sup>

The interview is crucial for determining a patient's chief concerns and functional status—past, current, and desired. It also helps a therapist see a patient's problems from the patient's own perspective, specifically with regard to the perception of limitations in daily activities or participation restrictions in meaningful social or work roles. A patient almost always describes a current problem in terms of limited abilities or perceived quality of life, not the presenting impairment(s). For example, a patient might report, "My elbow really hurts when I pick up something heavy" or "I'm having trouble playing tennis (or bowling or unloading groceries from the car)." During the interview, questions that relate to symptoms (in this case, elbow pain) should identify

**TABLE 1.2** Areas of Screening During the Patient Management Process

<b>All Major Body Systems</b>	<b>Review of Systems: component of the Health History to determine need for referral for additional medical evaluation</b>
<b>Cardiovascular/pulmonary</b>	Shortness of breath, pressure or pain in the chest, pulsating pain, history of heart or lung disease
<b>Endocrine</b>	History of thyroid or other hormonal conditions, medications
<b>Eyes, Ears, Nose, and Throat</b>	History of surgery or use of adaptive equipment
<b>Gastrointestinal</b>	Heartburn, reflux, diarrhea, constipation, vomiting, severe abdominal pain, swallowing problems
<b>Genitourinary/reproductive</b>	Bowel or bladder function, burning with urination, sexual function, unusual menstrual cycles, pregnancy
<b>Hematological or lymphatic</b>	Results of recent bloodwork or treatment, bleeding or lymphedema
<b>Integumentary</b>	History of skin cancer, dermatological conditions (eczema, psoriasis, etc.), lumps or growths
<b>Neurological/musculoskeletal</b>	History of CNS or peripheral nerve symptoms, muscular cramping, spasms, atrophy, weakness
<b>Overall physical and emotional well-being</b>	Persistent fatigue, malaise, fever, chills, sweats, unexplained weight change, depression, mood swings, suicidal thoughts
<b>Human Movement System</b>	<b>Systems Review: component of the hands-on Examination specific to systems affecting movement</b>
<b>Cardiovascular/pulmonary</b>	Heart rate and rhythm, respiratory rate, blood pressure, and edema
<b>Integumentary</b>	Skin temperature, color, texture, integrity, scar formation, wound or incision healing
<b>Musculoskeletal</b>	Symmetry, gross ROM and strength, height and weight
<b>Neuromuscular</b>	General assessment of gross coordinated movement (e.g., balance, gait, locomotion, transfers, transitions) and motor function (motor control, motor learning)
<b>Communication ability, affect, cognition, language, learning style</b>	Ability to make needs known, consciousness, orientation (person, place, time), expected emotional/behavioral responses, learning preferences (e.g., learning barriers, educational needs)

location, intensity, description, and factors that provoke (aggravate) or alleviate symptoms in a 24-hour period.

Collecting health history data through a self-report questionnaire has been shown to be an accurate source of information from patients seen in an outpatient orthopedic physical therapy practice.<sup>22</sup> In addition, depending on a patient's condition and individual situation, the perceptions of family members, significant others, caregivers, or employers are often as important to the overall picture as the patient's own assessment of the current problems.

While taking a health history, it is useful to group the interview questions into categories to keep the information organized. Gathering and evaluating data simultaneously makes it easier to recognize and identify *patterns or clusters of signs and symptoms* and even to begin to formulate one or more initial “working” hypotheses about the patient's problem(s), which later will be supported or rejected as part of the diagnostic process. Making these judgments helps organize and structure the examination.<sup>151,152,183</sup> Experienced therapists tend to form working hypotheses quite early in the examination process, even while reviewing a patient's chart before the initial contact with the patient.<sup>79,80,92,114,194</sup> This enables a therapist to determine and prioritize which definitive tests and measures should be selected for the later portion of the examination.<sup>80</sup>

### Systems Review

A brief but relevant screening of the body systems, known as a *systems review*,<sup>4,5</sup> is performed as a part of the hands on examination process after organizing and prioritizing data obtained from the health history. This baseline screening of the components of the movement system helps to determine which areas of tests and measures will be needed to determine specific diagnoses that impact function and the perception of disability. The systems typically screened by physical therapists are the cardiovascular and pulmonary, integumentary, musculoskeletal, and neuromuscular systems and a general overview of a patient's cognition, communication, and learning preferences (see Table 1.2).

Findings from the systems review, coupled with information about a patient's chief complaints and past history secured from the patient's health history, enable a therapist to begin to make decisions about the possible causes of a patient's impairments and functional deficits and to distinguish between problems that can and cannot be managed effectively by physical therapy interventions.<sup>19</sup> If a therapist determines that a patient has a condition or problem that falls outside the scope of physical therapy practice, then referral to or coordination with another health-care practitioner is appropriate.<sup>4,19,21,59</sup>

### FOCUS ON EVIDENCE

In a case report,<sup>68</sup> a patient was referred to physical therapy 5 weeks after shoulder surgery. During the initial examination the physical therapist identified inconsistent signs and symptoms that were indicative of a possible infection or medical complication including bilateral diffuse multi-joint

arthralgia, generalized fatigue, and other atypical signs. The therapist made the clinical decision to refer the patient back to the primary care physician where a secondary infection was confirmed. The result of this communication and coordination of care and services by the physical therapist was a positive outcome—the patient was able to fully participate in a rehabilitation program after the addition of antibiotic therapy to her medical care.

### Specific Tests and Measures

Once it has been decided that a patient's problems/conditions are most likely amenable to physical therapy intervention, the next determination a therapist must make during the examination process is to decide which aspects of physical function require further investigation through the use of specific tests and measures.

Specific (definitive/diagnostic) tests and measures used by physical therapists provide in-depth information about body function and structure impairments, activity limitations, and participation restrictions.<sup>4,53,57,97</sup> The specificity of these tests enables a therapist to support or refute the working hypotheses formulated while taking the patient's health history and performing the systems review. These tests also give the therapist a clearer picture of a patient's current condition(s) and may reveal information about the patient not previously identified during the history and systems review. If treatment is initiated, the results of these specific tests and measures establish *objective baselines* from which changes in a patient's abilities as the result of interventions are measured.

Given the array of specific tests available to a therapist, the guidelines summarized in Box 1.10 should be considered when determining which definitive tests and measures need to be selected and administered.<sup>4,53,54,146</sup>

There are more than 20 general categories of specific tests and measures commonly performed by physical therapists.<sup>4,180</sup> Typically, testing involves multiple body systems to identify the scope of a patient's functioning or disability by targeting specific impairments, activity limitations, and participation restrictions. When examining a patient with chronic knee pain, for example, in addition to performing a thorough musculoskeletal examination, it also would be appropriate to administer tests that identify the impact of the patient's knee pain on the neuromuscular system (by assessing balance and proprioception) and the cardiopulmonary system (by assessing aerobic capacity).

Because many of the health-related conditions as the result of injury or disease discussed in this textbook involve the neuromusculoskeletal system, some examples of specific tests and measures that identify *musculoskeletal and neuromuscular impairments* are noted here. They include but are not limited to:

- Assessment of pain
- Goniometry and flexibility testing
- Joint mobility, stability, and integrity tests (including ligamentous testing)
- Tests of muscle performance (manual muscle testing and dynamometry)

### BOX 1.10 Guidelines for Selection of Specific Tests and Measures

- Consider why particular tests are performed and how the interpretation of their results may influence the formulation of a diagnosis.
- Select tests and measures that provide accurate information and are valid and reliable and whose efficacy is supported by evidence generated from sound scientific studies.
- Administer tests that target multiple levels of functioning and disability: impairments, activity/functional limitations, and the patient's perceived level of participation restrictions.
- Prioritize tests and measures selected to gather in-depth information about key problems identified during the history and systems review.
- Decide whether to administer generic tests or tests that are specific to a particular region of the body.
- Choose tests that provide data specific enough to support or reject working hypotheses formulated during the history and systems review and to determine a diagnosis, prognosis, and plan of care when the data are evaluated.
- Select tests and measures that will help determine the types of intervention that most likely are appropriate and effective.
- To complete the examination in a timely manner, avoid collecting more information than is necessary to make informed decisions during the evaluation, diagnosis, and treatment planning phases of management.

- Posture analysis
- Assessment of balance, proprioception, and neuromuscular control
- Gait analysis
- Assessment of assistive, adaptive, or orthotic devices

Choice of specific tests and measures should be based on clinical decision-making used by the therapist to confirm or reject hypothesis about why the patient is experiencing less than optimal function and to provide data to support the diagnosis, prognosis, and plan of care.

Although specific testing of impairments is crucial, these tests do not tell the therapist how the impairments are affecting the patient's functional capabilities. Therefore, every examination should also include use of instruments that specifically measure extent of activity limitations and participation restrictions. These tools, often referred to as *functional outcome measures*, are designed to reflect the interaction of a patient's health condition and impairments in body function and structure with functional abilities and health-related quality of life.<sup>11</sup>

The Middle Class Tax Relief Act of 2012 mandated that functional outcomes be reported on the billing claims for Medicare and Medicaid patients receiving therapy services. As a result of this act, in 2013 requirements to report functional limitations and outcomes were established by the Centers for Medicare and Medicaid Services (CMS) for all

outpatient therapy billing claims through the physician fee schedule final rule (77 Federal Regulation 68958). Functional Limitation Reporting, also referred to as "G-Code Reporting," uses a coding system based on the ICF classification of functioning, disability, and health to quantify the type and severity of functional limitation(s) identified through the use of tests and measures at the onset and throughout the "episode of care." The scope and specifics of this legislation and application of G-code reporting are beyond the scope of this textbook. Box 1.11 lists references and websites for those interested in learning more about this topic.

The format of functional testing procedures and instruments varies. The clinical decision-making skill of the therapist is paramount to the effective selection of the ideal test(s) to use to objectively describe the functional limits or abilities of patients based on the carefully synthesized results of examination and re-examination information. Some tests gather information by *self-report* (by the patient or family member);<sup>96</sup> others require *observation and rating of the patient's performance* by a therapist as various functional tasks are carried out.<sup>11</sup> Some instruments measure a patient's ease or difficulty of performing specific physical tasks. Other instruments incorporate temporal (time-based) or spatial (distance-based) criteria, such as measurement of walking speed or distance, in the format.<sup>10</sup> Test scores also can be based on the level of assistance needed (with assistive devices or by another person) to complete a variety of functional tasks.

Indices of disability measure a patient's perception of his or her degree of participation restriction. These self-report instruments usually focus on BADL and IADL, such as the ability or inability to care for one's own needs (physical, social, and emotional) or the level of participation in the community

### BOX 1.11 Resources for Information on Functional Outcome Reporting (G-Codes)

- MLN Matters® Special Edition (SE) 1307: Outpatient Therapy Functional Reporting Requirements: <http://www.cms.gov/outreach-and-education/medicare-learning-network-mln/mlnmattersarticles/downloads/se1307.pdf>
- CMS Manual System Transmittal 165: Implementing the Claims-Based Data Collection Requirement for Outpatient Therapy Services — Section 3005(g) of the Middle Class Tax Relief and Jobs Creation Act (MCTRCA) of 2012: <https://www.cms.gov/Regulations-and-Guidance/Guidance/Transmittals/Downloads/R165BP.pdf>
- CMS-1500 (02/12) Claim Form Example: Functional Limitation Reporting G-codes and Severity/Complexity Modifiers: [https://medicare.fcso.com/Education\\_resources/0299021.pdf](https://medicare.fcso.com/Education_resources/0299021.pdf)
- APTA Resources for Functional Limitation Reporting under Medicare: <http://www.apta.org/Payment/Medicare/CodingBilling/FunctionalLimitation/>

that is currently possible, desired, expected, or required. Information gathered with these instruments may indicate that the patient requires consultation and possible intervention by other health-care professionals to deal with some of the social or psychological aspects of disability.

Functional Limitation Reporting and G-code assignment do not require or limit specific tests to be used to define the functional limitation, its severity, or complexity when determining the G-code. It is the responsibility of the therapist to identify valid, objective tests to provide reliable results throughout the course of treatment from initial evaluation to discharge. Familiarity with evidence-based practice guidelines and use of resources for applying evidence as described earlier in this section will assist both the novice and veteran therapist to successfully accomplish this professional responsibility.

**NOTE:** It is well beyond the scope or purpose of this text to identify and describe the many tests and instruments that identify and measure impairments, activity limitations, and participation restrictions. The reader is referred to several resources in the literature that provide this information.<sup>2,7,10,11,30,108</sup>

## Evaluation

Evaluation is a process characterized by the interpretation of collected data. The process involves analysis and integration of information to establish the diagnosis, prognosis, and plan of care using a series of sound clinical decisions.<sup>4,5</sup> Although evaluation is depicted as a distinct entity or phase of the patient management model (see Fig. 1.5), some degree of evaluation goes on at every phase of patient management, from examination through outcome. By pulling together and sorting out subjective and objective data from the examination, a therapist should be able to determine the following:

- A patient's general health status and its impact on current and potential function.
- The acuity or chronicity and severity of the current condition(s).
- The extent of structural and functional impairments of body systems and impact on functional abilities.
- Which impairments are related to which activity limitations.
- A patient's current, overall level of physical functioning (limitations *and* abilities) compared with the functional abilities needed, expected, or desired by the patient.
- The impact of physical dysfunction on social/emotional function.
- The impact of the physical environment on a patient's function.
- A patient's social support systems and their impact on current, desired, and potential function.

The decisions made during the evaluation process may also suggest that additional testing by the therapist or another practitioner is necessary before the therapist can determine a patient's diagnosis and prognosis for positive outcomes from physical therapy interventions. For example, a patient whose chief complaints are related to episodic shoulder pain but who also indicates during the health history that bouts of depression

sometimes make it difficult to work or socialize should be referred for a psychological consultation and possible treatment.<sup>19</sup> Results of the psychological evaluation could be quite relevant to the success of the physical therapy intervention.

Addressing the questions posed in Box 1.12 during the evaluation of data derived from the examination enables a therapist to make pertinent clinical decisions that lead to the determination of a diagnosis and prognosis and the selection of potential intervention strategies for the plan of care.

During the evaluation, it is particularly useful to ascertain if and to what extent relationships exist among measurements of impairments, activity limitations, participation restrictions, and the patient's perceived level of disability. These relationships often are not straightforward as indicated in the following investigations.

## FOCUS ON EVIDENCE

In a study of patients with cervical spine disorders,<sup>70</sup> investigators reported a strong correlation between measurements of impairments (pain, ROM, and cervical muscle strength) and functional limitations (functional axial rotation and lifting capacity) but a relatively weak statistical relationship between measurements of functional limitations and the patient's perceived level of disability, as determined by three self-report measures. In another study<sup>185</sup> that compared shoulder ROM with the ability of patients to perform basic self-care activities, a strong correlation was noted between the

### BOX 1.12 Key Questions to Consider During the Evaluation and Diagnostic Processes

- What is the extent, degree, or severity of structural and functional impairments, activity/functional limitations, or participation restrictions/disability?
- What is the stability or progression of dysfunction?
- To what extent are any identified personal and environmental barriers to functioning modifiable?
- Is the current health condition(s) acute or chronic?
- What actions/events change (relieve or worsen) the patient's signs and symptoms?
- How do preexisting health conditions (comorbidities) affect the current condition?
- How does the information from the patient's medical/surgical history and tests and measures done by other health-care practitioners relate to the findings of the physical therapy examination?
- Have identifiable clusters of findings (i.e., patterns) emerged relevant to the patient's dysfunction?
- Is there an understandable relationship between the patient's extent of impairments and the degree of activity/functional limitation or participation restriction/disability?
- What are the causal factors that seem to be contributing to the patient's impairments, activity/functional limitations, or participation restriction/disability?

degree of difficulty of performing these tasks and the extent of shoulder motion limitation.

Although the results of these studies to some extent are related to the choice of measurement tools, these findings highlight the complexity of evaluating disability and suggest that identifying the strength or weakness of the links among the levels of functioning and disability may help a therapist predict more accurately a patient's prognosis. Evaluating these relationships and answering the other questions noted in Box 1.12 lay the foundation for determining a diagnosis and prognosis and developing an effective plan of care.

## Diagnosis

The term *diagnosis* can be used in two ways—it refers to either a process or a category (label) within a classification system.<sup>62,5</sup> Both usages of the word are relevant to physical therapy practice. Physical therapists use a systematic process, sometimes referred to as differential diagnosis, to identify an appropriate diagnostic category amenable to physical therapy intervention.<sup>5</sup> The diagnosis is an essential and required element of patient management whose primary purpose is to guide the physical therapy prognosis, plan of care, and interventions.<sup>4,53,97,129,158,183,202</sup>

### Diagnostic Process

The diagnostic process is a complex *sequence* of actions and decisions that includes (1) the collection of data (examination); (2) the analysis and interpretation of all relevant data collected, leading to the generation of working hypotheses (evaluation); and (3) organization of data, recognition of clustering of data (a pattern of findings), formation of a diagnostic hypothesis, and subsequent classification of data into categories.<sup>4,43,59,149,159,183,202</sup>

Through the diagnostic process a physical therapist identifies impairments of body structure and function that affect the human movement system, whereas a physician identifies disease.<sup>59,84,97,129,149,187</sup> For the physical therapist, the diagnostic process is a mechanism by which discrepancies and consistencies between a patient's current level of performance and desired level of function and his or her capacity to achieve that level of function are identified.<sup>4</sup>

### Diagnostic Category

A diagnostic category (clinical classification) identifies and describes patterns or clusters of findings from the examination and conclusions from the evaluation. The purpose of this label is to guide the therapist in the development of a prognosis, plan of care, and interventions.<sup>5</sup>

A diagnostic category used in physical therapy should describe the impact of a health condition or disease on function of the human movement system at the level of the whole person.<sup>4</sup> This category, defined by the therapist, indicates the primary dysfunctions to be addressed in the selection of interventions and development of the plan of care.

The physical therapy profession has not officially adopted a specific classification system for diagnosis, although the ICF

is recommended. The following are guidelines listed in the *Guide* for choosing a classification scheme that is relevant for the therapist to make a diagnosis:<sup>5</sup>

- The classification system must be within the legal boundaries placed on the profession and within societal approval.
- The health professional must use acceptable tests and measures to confirm the diagnostic decision.
- The diagnostic label must describe a condition or problem that is within the scope of intervention legally allowed by the clinician making the diagnosis.

As the profession of physical therapy has advanced to a doctoral level and the position as a primary care provider has evolved, the role of diagnostician has become the focus of both research and practice.<sup>5,36,120,129,160</sup> The exclusive use of ICD diagnostic categories does not always identify a problem within the scope of physical therapy intervention because this classification focuses primarily on the diagnosis of pathology. A diagnostic classification system developed by physical therapists is needed for delineating the knowledge base and scope of practice of physical therapy.<sup>4,42,62,84,149,158,201</sup> Because the diagnosis is intended to guide the treatment plan, a universally accepted diagnostic classification scheme would foster clarity of communication in practice and clinical research.<sup>36,53,84,120</sup>

Suffice it to say that it is well beyond the scope of this text to discuss the history and the future of the development of a classification system for accurately labeling diagnoses amenable to physical therapy intervention.

**NOTE:** The impairment/function-based diagnoses in the clinical practice guidelines developed by multiple practice sections of the APTA are based on the classification and coding system described in the ICF combined, as appropriate, with the ICD as recommended by the WHO. The diagnostic classifications in the approved clinical practice guidelines are linked to recommendations for physical therapy interventions based on “best evidence” from the scientific literature.<sup>29,33,34,104,105,117</sup> However, research shows that there continues to be a gap in the use of diagnostic classification systems and the selection of interventions that are directly related to the diagnostic label used by clinicians in practice.<sup>120</sup>

## Prognosis and Plan of Care

After the initial examination has been completed, data have been evaluated, and a diagnosis has been established, a *prognosis* (see Fig. 1.5), including a plan of care, must be determined before initiating any interventions. A prognosis is a prediction of a patient's optimal level of function expected as the result of a plan for treatment during an episode of care and the anticipated length of time needed to reach specified functional outcomes.<sup>4,97,141</sup> Some factors that influence a patient's prognosis and functional outcomes are noted in Box 1.13.

Determining an accurate prognosis is, indeed, challenging even for experienced therapists. The more complex a patient's problems, the more difficult it is to project the patient's optimal level of function, particularly at the onset of treatment.

### BOX 1.13 Factors That Influence a Patient's Prognosis/Expected Outcomes

- Complexity, severity, acuity, or chronicity and expected course of the patient's health condition(s) (pathology), impairments, and activity/functional limitations
- Patient's general health status and presence of comorbidities (e.g., hypertension, diabetes, and obesity) and risk factors
- The patient's previous level of functioning or disability
- The patient's living environment
- Patient's and/or family's goals
- Patient's motivation and adherence and responses to previous interventions
- Safety issues and concerns
- Extent of support (physical, emotional, and social)
- Health literacy of the patient

For example, if an otherwise healthy and fit 70-year-old patient who was just discharged from the hospital after a total knee arthroplasty is referred for home-based physical therapy services, it is relatively easy to predict the time frame that will be needed to prepare the patient to return to independence in the home and community. In contrast, it may be possible to predict only incremental levels of functional improvement at various stages of rehabilitation for a patient who has sustained multiple fractures and soft tissue injuries as the result of an automobile accident.

In these two examples of establishing prognoses for patients with musculoskeletal conditions, as with most other patient problems, the accuracy of the prognosis is affected in part by the therapist's clinical decision-making ability based on the following<sup>4</sup>:

- Familiarity with the patient's current health condition(s) and the surgical intervention(s) and previous history of diseases or disorders.
- Knowledge of the process and time frames of tissue healing.
- Experience managing patients with similar surgical procedures, pathological conditions, impairments, and functional deficits.
- Knowledge of the efficacy of tests and measures performed, accuracy of the findings, and effectiveness of the physical therapy interventions.

#### Plan of Care

The *plan of care*, an integral component of the prognosis, is established in coordination with the patient and, if indicated, others involved in the care of the patient. It should include the following components:<sup>4</sup>

- Patient goals that are functionally driven and time limited.
- Expected functional outcomes that are meaningful, utilitarian, sustainable, and measurable.
- Extent of improvement predicted and length of time necessary to reach that level.

- Specific interventions.
- Proposed frequency and duration of interventions.
- Specific discharge plans.

#### Setting Goals and Outcomes in the Plan of Care

Developing a plan of care involves *collaboration* and *negotiation* between the patient (and, when appropriate, the family) and the therapist.<sup>4,84,97</sup> The *anticipated goals* and *expected outcomes* documented in the plan of care must be patient centered—that is, the goals and outcomes must be meaningful to the patient.<sup>141</sup> These goals and outcomes also must be measurable and linked to each other. Goals describe the intended impact on functioning established with specific time limits.<sup>4</sup> Outcomes are the actual results of the episode of care measured with the specific tests and measures that were used to establish a baseline at the initial examination, and repeated periodically during the episode of care. Results are based on reduction of impairments, activity limitations, and participation restrictions coupled with achieving the optimal level possible of function, general health, and patient satisfaction.<sup>4</sup>

Establishing and prioritizing meaningful, functionally relevant goals and determining expected outcomes requires engaging the patient and/or family in the decision-making process from a therapist's first contact with a patient. Knowing what a patient wants to be able to accomplish as the result of treatment and ascertaining which accomplishments are the most important to the patient helps a therapist develop and prioritize intervention strategies that target the patient's functional limitations and associated impairments. This, in turn, increases the likelihood of successful outcomes from treatment.<sup>132,141,142</sup> Some key questions a therapist often asks a patient or the patient's extended support system that are critical for establishing anticipated goals and expected outcomes in the plan of care are listed in Box 1.14.<sup>9,97,132,142</sup>

An integral aspect of effective goal and outcome setting is explaining to a patient how the health condition and identified impairments are associated with the patient's activity limitations and participation restrictions and why specific interventions will be used. Discussing an expected time frame for achieving the negotiated goals and outcomes puts the treatment plan and the patient's expectation for progress in a realistic context. This type of information helps a patient and family members set goals that are not just meaningful, but also realistic and attainable. Setting up *short-term* and *long-term goals*, particularly for patients with severe or complex problems, is also a way to help a patient recognize incremental improvement and progress during treatment.

The plan of care also indicates the optimal level of improvement that will be reflected by the functional outcomes as well as how those outcomes will be measured. An outline of the specific interventions, their frequency and duration of use, and how the interventions are directly related to attaining the stated goals and outcomes also must appear in the plan. Finally, the plan of care concludes with the criteria for discharge. These criteria are addressed following a discussion of elements of intervention in the patient management process.

### BOX 1.14 Key Questions to Establish and Prioritize Patient-Centered Goals and Outcomes in the Plan of Care

- What activities are most important to you at home, school, work, in the community, or during your leisure time?
- What activities do you currently need help with that you would like to be able to do independently?
- Of the activities you are finding difficult to do or cannot do at all at this time, and which ones would you like to be able to do better or do again?
- Of the problems you are having, which ones do you want to try to eliminate or minimize first?
- In what areas do you think you have the biggest problems during the activities you would like to do on your own?
- What are your goals for coming to physical therapy?
- What would you like to be able to accomplish through therapy?
- What would make you feel that you were making progress in achieving your goals?
- How soon do you want to reach your goals?

**NOTE:** Periodic re-examination of a patient and re-evaluation of a patient's response to treatment may necessitate modification of the initial prognosis and plan of care (see Fig. 1.5).

### Intervention

Intervention, a component of patient management, is the purposeful interaction of the therapist with the patient and with other family members, caregivers, or providers as appropriate.<sup>4,5</sup> The therapist selects, prescribes, and implements interventions based on the examination, evaluation, diagnosis, prognosis, and goals established for the patient. Interventions are updated, progressed, or discontinued based on patient response, achievement of goals, or results of outcomes (see Fig. 1.5).

The *Guide* describes nine categories of intervention appropriate for use by physical therapists in the care of patients.<sup>5</sup> These categories are listed in Box 1.15. Clinical reasoning, decision-making, clinical practice guidelines, clinical prediction rules, and the use of evidence-based practice are tools that therapists use during the patient management process to assist in the selection of specific, individualized interventions.<sup>37,38,91,95,120</sup>

If interventions are to be considered effective, they must result in the reduction or elimination of body function or structure impairments, activity limitations, and/or participation restrictions and, whenever possible, reduce the risk of future dysfunction. Moreover, the efficacy of each intervention should be supported by sound evidence, preferably based on prospective, randomized, controlled research studies.

Although the intended outcome of therapeutic exercise programs has always been to enhance a patient's functional capabilities or prevent loss of function, until the past few decades the focus of exercise programs in physical therapy was on the resolution of impairments. Success was measured

### BOX 1.15 Categories of Intervention Used by Physical Therapists

- Patient or Client Instruction (universally used with all patients)
- Airway Clearance Techniques
- Assistive Technology: Prescription, Application, and as appropriate, Fabrication or Modification
- Biophysical Agents
- Functional Training in Self-Care and in Domestic, Education, Work, Community, Social, and Civic Life
- Integumentary Repair and Protection Techniques
- Manual Therapy Techniques
- Motor Function Training
- Therapeutic Exercise

primarily by the reduction of the identified impairments or improvements in various aspects of physical performance, such as strength, mobility, or balance as depicted in Figure 1.6.

**FIGURE 1.6** Manual resistance exercise, a procedural intervention, is a form of therapeutic exercise used during the early stage of rehabilitation if muscle strength or endurance is impaired.

In the past, it was assumed that if impairments were resolved, improvements in functional abilities would subsequently follow. Physical therapists now recognize that this assumption is not valid. To improve activity performance and participation in expected roles and to improve a patient's health-related quality of life, not only should therapeutic exercise interventions be implemented that correct functionally limiting impairments, but whenever possible, exercises should be task specific—that is, they should be performed using movement patterns that closely match a patient's intended or desired functional activities. In Figure 1.7, strengthening exercises are demonstrated using a task-specific lifting pattern.

**FIGURE 1.7** Task-specific strengthening exercises are carried out by lifting and lowering a weighted crate in preparation for functional tasks at home or work.

The importance of designing and implementing exercises that closely replicate the desired functional outcomes is demonstrated by the following study:

### **FOCUS ON EVIDENCE**

Task-specific functional training was investigated in a study of the effects of a resistance exercise program on the stair-climbing ability of ambulatory older women.<sup>39</sup> Rather than having the subjects perform resisted hip and knee extension exercises in nonweight-bearing positions, they trained by ascending and descending stairs while wearing a weighted backpack. This activity not only improved muscle performance (strength and endurance), but also directly enhanced the subjects' efficiency in stair climbing during daily activities.

Another way to use therapeutic exercise interventions effectively to improve functional ability is to integrate safe but progressively more challenging functional activities that utilize incremental improvements in strength, endurance, and mobility into a patient's daily routine as early as possible in the treatment program. With this functionally oriented approach to exercise, the activities in the treatment program are specific to and directly support the expected functional outcomes. Selection and use of exercise procedures that target more than one goal or outcome are also appropriate and efficient ways to maximize improvements in a patient's function in the shortest time possible.

Effective use of any intervention must include determining the appropriate *intensity*, *frequency*, and *duration* of each intervention and periodic re-examination of a patient's responses

to the interventions. While implementing therapeutic exercise interventions, a patient's response to exercise is continually monitored to decide when and to what extent to increase the difficulty of the exercise program or when to discontinue specific exercises. Each of the chapters of this textbook provides detailed information on factors that influence selection, application, and progression of therapeutic exercise interventions.

### **Patient or Client Instruction**

Although patient instruction is one of the nine intervention categories, it is the only one that is specified to be used for every patient throughout the entire episode of care<sup>5</sup> (see Box 1.15). Because this intervention is universal for all patients, it is covered in more detail in this section. According to the revised third edition of the *Guide*, patient education is emphasized in the following way: *Patient or client instruction* is a type of intervention that physical therapists use with every individual they see. Education should include not only the patient, but also family members, caregivers, and other health professionals involved in the care of the patient.<sup>5</sup> There is no question that physical therapists perceive themselves as patient educators, facilitators of change, and motivators.<sup>31,55,82,106,127</sup> Patient education spans all three domains of learning: cognitive, affective, and psychomotor domains. Education ideally begins during a patient's initial contact with a therapist and involves the therapist *explaining* information, *asking* pertinent questions, and *listening* to the patient or a family member.

*Patient-related instruction* is the means by which a therapist helps a patient *learn* how to reduce his or her impairments and how to participate fully in the plan of care to achieve goals.<sup>31</sup> Patient-related instruction first may focus on providing a patient with background information, such as the interrelationship of the primary health condition and the associated impairments and limitations in activity or explaining the purpose of specific interventions in the plan of care. Instruction, such as physical therapist-directed exercise counseling,<sup>181</sup> may be implemented as an alternative to direct supervision of an exercise program and typically focuses on specific aspects of a treatment program, such as teaching a patient, family member, or caregiver a series of exercises to be carried out in a home program. Education may also help to prepare an individual for transition to a different role or setting or to understand risk factors for developing a problem and the need for health, wellness, or fitness programs. Therapists should also review health and wellness materials and clarify directions for safe use of equipment to be used at home.

A therapist must use multiple methods to convey information to a patient or family member, such as one-to-one, therapist-directed instruction; videotaped instruction; or written materials. Each has been shown to have a place in patient education as highlighted by the following studies.

### **FOCUS ON EVIDENCE**

It has been shown that patients, who were taught exercises by a therapist, performed their exercises more accurately in a home program than patients whose sole source of information

about their exercises was from reading a brochure.<sup>51</sup> In another study, the effectiveness of three modes of instruction in an exercise program were evaluated. The subjects who received in-person instruction by a therapist or two variations of videotaped instruction performed their exercise program more accurately than subjects who received only written instructions.<sup>145</sup>

However, written materials, particularly those with illustrations, can be taken home by a patient and used to reinforce verbal instructions from a therapist or videotaped instructions.

To be an effective patient educator, a therapist must possess an understanding of the process of learning, which most often is directed toward learning or modifying motor skills. As a patient educator, a therapist also must be able to recognize a patient's learning style, implement effective teaching strategies, and motivate a patient to *want* to learn new skills, adhere to an exercise program, or change health-related behaviors.

## Outcomes

Simply stated, outcomes are results. Collection and analysis of outcome data related to health-care services are necessities, not options.<sup>66</sup> Measurement of outcomes is a means by which quality, efficacy, and cost-effectiveness of services can be assessed. Patient-related outcomes are monitored throughout an episode of physical therapy care—that is, intermittently during treatment and at the conclusion of treatment.<sup>132</sup> Evaluation of information generated from periodic re-examination and re-evaluation of a patient's response to treatment enables a therapist to ascertain if the anticipated goals and expected outcomes in the plan of care are being met and if the interventions that have been implemented are producing the intended results. It may well be that the goals and expected outcomes must be adjusted based on the extent of change or lack of change in a patient's function as determined by the level of the interim outcomes. This information also helps the therapist decide if, when, and to what extent to modify the goals, expected outcomes, and interventions in the patient's plan of care (see Fig. 1.5).

There are several broad areas of outcomes commonly assessed by physical therapists during the continuum of patient care. They are listed in Box 1.16.

### Functional Outcomes

The key to the justification of physical therapy services in today's cost-conscious health-care environment is the identification and documentation of successful patient-centered, functional outcomes that can be attributed to interventions.<sup>4,10,30,63,179</sup> As discussed previously (in the Tests and Measures section), functional limitation reporting became mandatory in 2013 for all outpatient therapy being billed to Medicare. G-code reporting is the methodology for providing a nonpayment code to track functional improvements for a patient over the course of the billing period.

Functional outcomes must be *meaningful*, *practical*, and *sustainable*.<sup>179</sup> Outcomes that have an impact on a patient's ability to function at work, in the home, or in the community

### BOX 1.16 Areas of Outcomes Assessed by Physical Therapists

- Level of a patient's physical functioning, including impairments, activity/functional limitations, participation restrictions, and perceived disability
- Extent of prevention or reduced risk of occurrence or recurrence of future dysfunction related to health conditions, associated impairments, activity/functional limitations, participation restrictions, or perceived disability
- Patient's general health status or level of well-being and fitness
- Degree of patient satisfaction
- Level of safety and patient/family understanding
- Adherence/compliance with home exercises or instructions

in ways that have been identified as important by the patient, family, significant others, caregivers, or employers are considered *meaningful*. If the formulation of anticipated goals and expected outcome has been a collaborative effort between the patient and the therapist, the outcomes will be meaningful to the patient. The *practical* aspect of functional outcomes implies that improvements in function have been achieved in an efficient and cost-effective manner. Improvements in function that are maintained over time after discharge from treatment (to the extent possible given the nature of the health condition) are considered *sustainable*.

### Measuring Outcomes

The expected outcomes identified in a physical therapy plan of care must be *measurable*. More specifically, changes in a patient's status over time must be *quantifiable*. As noted in the previous discussion of the examination component of the patient management model, many of the specific tests and measures used by physical therapists traditionally have focused on measurement of impairments (i.e., ROM, muscle performance, joint mobility/stability, and balance). The reduction of impairments may reflect the impact of interventions on the pathological condition but may or may not translate into improvements in a patient's health-related quality of life, such as safety and functional abilities. Hence, there is the need for measurement not only of impairments, but also of a patient's levels of physical functioning and perceived participation ability to accurately assess patient-related outcomes that include but are not limited to the effectiveness of physical therapy interventions, such as therapeutic exercise.

**Impact of interventions on patient-related, functional outcomes.** In response to the need to produce evidence that supports the effectiveness of physical therapy interventions for reducing movement dysfunction, a self-report instrument called OPTIMAL (Outpatient Physical Therapy Improvement in Movement Assessment Log) has been developed for measuring the impact of physical therapy interventions on function and has been tested for validity and reliability.<sup>63</sup> The instrument

measures a patient's difficulty with or confidence in performing a series of 22 actions, most of which are related to functional mobility, including moving from lying to sitting and sitting to standing, kneeling, walking, running, climbing stairs, reaching, and lifting. In addition, to assist the therapist with setting goals for the plan of care, the patient is asked to identify three activities that he or she would like to be able to do without difficulty.

OPTIMAL also is considered to be a valid test for assisting in the assignment of G-codes for Functional Limitation Reporting. As such, in 2012 the APTA mapped each of the test activities in OPTIMAL to the Activity and Participation categories for G-code reporting to assist the clinician to use this tool more effectively. A number of studies that have investigated the benefits of exercise programs for individuals with impaired functional abilities<sup>86,98,155</sup> reflect the trend in research to include an assessment of changes in a patient's health-related quality of life as the result of interventions. Assessment of outcomes related to the reduction of risks of future injury or further impairment, prevention of further functional limitations or disability, adherence to a home program, or the use of knowledge that promotes optimal health and fitness may also help determine the effectiveness of the services provided. To substantiate that the use of physical therapy services for prevention is cost-effective, physical therapists are finding that it is important to collect follow-up data that demonstrate a reduced need for future physical therapy services as the result of interventions directed toward prevention and health promotion activities.

**Patient satisfaction.** Another area of outcomes assessment that has become increasingly important in physical therapy practice is that of *patient satisfaction*. An assessment of patient satisfaction during or at the conclusion of treatment can be used as an indicator of quality of care. Patient satisfaction surveys often seek to determine the impact of treatment based on the patient's own assessment of his or her status at the conclusion of treatment compared with that at the onset of treatment.<sup>154</sup> Instruments, such as the Physical Therapy Outpatient Satisfaction Survey (PTOPS)<sup>154</sup> or the MedRisk Instrument for Measuring Patient Satisfaction with physical therapy (MRPS),<sup>13,14</sup> also measure a patient's perception of many other areas of care. An important quality of patient satisfaction questionnaires is their ability to discriminate among the factors that influence satisfaction. Identification of factors that adversely influence satisfaction may enable the clinician to take steps to modify these factors to deliver an optimal level of services to patients.<sup>14</sup>

Factors that may influence the extent of patient satisfaction are noted in Box 1.17.<sup>13,14,27,154</sup>

### FOCUS ON EVIDENCE

A recent systematic review of the literature addressed the degree of patient satisfaction with musculoskeletal physical therapy care and identified the factors that were associated with high patient satisfaction in outpatient settings across North America

#### BOX 1.17 Examples of Determinants of Patient Satisfaction\*

- Interpersonal attributes of the therapist (communication skills, professionalism, helpfulness, and empathy) and the impact on the patient-therapist relationship
- Perception of a therapist's clinical skills
- Extent of functional improvement during the episode of care
- Extent of participation in goal setting in the plan of care
- The acuity of the patient's condition (higher satisfaction in acute conditions)
- Convenience of access to services
- Administrative issues, such as continuity of care, flexible hours for scheduling, waiting time at each visit, duration of treatments, and cost of care

\*Determinants are not rank ordered.

and Northern Europe.<sup>74</sup> The review included articles if they were a survey, clinical trial, qualitative study, or patient interview. Only 15 of several thousand articles met the inclusion criteria. A meta-analysis of pooled data from the included studies revealed that on a scale of 1 to 5 (5 being the highest level of satisfaction), the degree of patient satisfaction was 4.41 (95% confidence interval = 4.41–4.46), indicating that patients are highly satisfied with physical therapy care directed toward musculoskeletal conditions. One finding of interest in the studies reviewed is the quality of the patient-therapist relationship consistently ranked higher as an indicator of patient satisfaction than the extent of improvement in the patient's physical functioning as a result of the episode of care.

### Discharge Planning

Planning for discharge begins early in the rehabilitation process. As previously noted, criteria for discharge are identified in a patient's plan of care. Ongoing assessment of outcomes is the mechanism by which a therapist determines when discharge from care is warranted. A patient is discharged from physical therapy services when the anticipated goals and expected outcomes have been attained.<sup>4</sup> The discharge plan often includes some type of home program, appropriate follow-up, possible referral to community resources, or re-initiation of physical therapy services (an additional episode of care) if the patient's needs change over time and if additional services are approved.

Discontinuation of services is differentiated from discharge.<sup>4</sup> *Discontinuation* refers to the ending of services prior to the achievement of anticipated goals and expected outcomes. Several factors may necessitate discontinuation of services, which may include a decision by a patient to stop services, a change in a patient's medical status such that progress is no longer possible, or the need for further services cannot be justified to the payer.

In conclusion, the patient management model discussed in this section establishes a comprehensive, systematic approach to the provision of effective and efficient physical therapy care and services to patients and clients. The model is a mechanism to demonstrate the interrelationships among the phases of the continuum of patient care set in a conceptual framework of functioning and disability; it is aimed at improving a patient's function and health-related quality of life. The management model also places an emphasis on reducing risk factors for disease, injury, impairments, or disability and promoting health and well-being in patients and clients seeking and receiving physical therapy services.

## Strategies for Effective Exercise and Task-Specific Instruction

As discussed in the previous section of this chapter, patient-related instruction is an essential element of the intervention phase of patient management. As a patient educator, a therapist spends a substantial amount of time teaching patients, their families, or other caregivers how to perform exercises correctly and safely. An understanding of health literacy level and learning style, assessed during the examination screening, combined with the skill of the therapist to communicate in plain language with the patient or caregiver is critical to effective exercise instruction. Effective strategies founded on principles of motor learning that are designed to help patients initially learn an exercise program under therapist supervision and then carry it out on an independent basis over a necessary period of time contribute to successful outcomes for the patient.

### Health Literacy

*Health literacy* is the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions.<sup>190</sup> This definition was formulated by the National Library of Medicine and has been consistently incorporated into national initiatives to improve health-care access, quality, and outcomes and to teach healthy lifestyles.<sup>189,190</sup> Physical therapists have a professional and ethical responsibility to understand health literacy and to develop the teaching and communication skills required to provide quality patient instruction and education that fits the learning needs and literacy levels unique to each patient.<sup>5,47,145</sup> Communicating in plain language, including the use of easily understood handouts, brochures, videos, pictures, and feedback, closes the gap between what the professional knows and what the patient understands.<sup>47,145,190</sup> Teaching is an essential function in the practice of physical therapy; providing intervention without incorporating elements of health promotion and education can result in less than optimal outcomes for patients.

## Preparation for Exercise Instruction

When preparing to teach a patient a series of exercises, a therapist should have a plan that will facilitate learning prior to and during exercise interventions. A positive relationship between the therapist and the patient is a fundamental aspect for creating a motivating environment that fosters learning. A collaborative relationship should be established when the goals for the plan of care are negotiated. This, of course, occurs before exercise instruction begins. Effective exercise instruction is also based on knowing a patient's learning style—that is, if he or she prefers to learn by watching, reading about, or doing an activity. This may not be known early in treatment, so several methods of instruction may be necessary.

Identifying a patient's attitudes toward exercise helps a therapist determine how receptive a patient is likely to be about learning and adhering to an exercise program. Answers to the following questions may help a therapist formulate a strategy for enhancing a patient's motivation to exercise:

- Does the patient believe exercise will lessen symptoms or improve function?
- Is the patient concerned that exercising will be uncomfortable?
- Is the patient accustomed to engaging in regular exercise?

One method for promoting motivation is to design the exercise program so the least complicated or stressful exercises are taught first, thus ensuring early success. Always ending an exercise session with a successful effort also helps maintain a patient's level of motivation. Additional suggestions to enhance motivation and promote adherence to an exercise program are discussed in this section following an overview of the concepts of motor learning and acquisition of simple to complex motor skills. Box 1.18 summarizes some practical suggestions for effective exercise instruction.

## Concepts of Motor Learning: A Foundation for Exercise and Task-Specific Instruction

Integration of motor learning principles into exercise instruction optimizes learning an exercise or functional task. An exercise is simply a motor task (a psychomotor skill) that a therapist teaches and a patient is expected to learn.

*Motor learning* is a complex set of internal processes that involves the acquisition and *relatively permanent* retention of a skilled movement or task through practice.<sup>130,163,164,192,196</sup> In the motor learning literature a distinction is made between motor performance and motor learning. *Performance* involves acquisition of the ability to carry out a skill, whereas *learning* involves both acquisition and retention.<sup>56,154,163</sup> Therefore, a patient's ability to perform an exercise or any skilled movement early in the motor-learning process is not necessarily representative of having learned the new exercise or skill.

It is thought that motor learning probably modifies the way sensory information in the central nervous system is

### BOX 1.18 Practical Suggestions for Effective Exercise Instruction

- Select a nondistracting environment for exercise instruction.
- Initially teach exercises that replicate movement patterns of *simple* functional tasks.
- Demonstrate proper performance of an exercise (safe vs. unsafe movements; correct vs. incorrect movements). Then have the patient model your movements.
- If appropriate or feasible, initially guide the patient through the desired movement.
- Use clear and concise verbal and written directions.
- Complement written instructions for a home exercise program with illustrations (sketches) of the exercise.
- Have the patient demonstrate an exercise to you as you supervise and provide feedback.
- Provide specific, action-related feedback rather than general, nondescriptive feedback. For example, explain *why* the exercise was performed correctly or incorrectly.
- Teach an entire exercise program in small increments to allow time for a patient to practice and learn components of the program over several visits.

organized and processed and affects how motor actions are produced. In addition, because motor learning is not directly observable, it must be measured by observation and analysis of how an individual performs a skill.

### Types of Motor Tasks

There are three basic types of motor tasks: discrete, serial, and continuous.<sup>163,164</sup>

**Discrete task.** A discrete task involves an action or movement with a recognizable beginning and end. Isolating and contracting a specific muscle group (as in a quadriceps setting exercise), grasping an object, doing a push-up, locking a wheelchair, and kicking a ball are examples of discrete motor tasks. Almost all exercises, such as lifting and lowering a weight or performing a self-stretching maneuver, can be categorized as discrete motor tasks.

**Serial task.** A serial task is composed of a series of discrete movements that are combined in a particular sequence. For example, to eat with a fork, a person must be able to grasp the fork, hold it in the correct position, pierce or scoop up the food, and lift the fork to the mouth. Many functional tasks in the work setting, for instance, are serial tasks with simple as well as complex components. Some serial tasks require specific timing between each segment of the task or momentum during the task. Wheelchair transfers are serial tasks. A patient must learn how to position the chair, lock the chair, possibly remove an armrest, scoot forward in the chair, and then transfer from the chair to another surface. Some transfers require momentum, whereas others do not.

**Continuous task.** A continuous task involves repetitive, uninterrupted movements that have no distinct beginning and ending. Examples include walking, ascending and descending stairs, and cycling.

Recognizing the type of skilled movements a patient must learn to do helps a therapist decide which instructional strategies will be most beneficial for acquiring specific functional skills. Consider what must be learned in the following motor tasks of an exercise program. To self-stretch the hamstrings, a patient must learn how to position and align his or her body and how much stretch force to apply to perform the stretching maneuver correctly. As flexibility improves, the patient must then learn how to safely control active movements in the newly gained portion of the range during functional activities. This requires muscles to contract with correct intensity at an unaccustomed length. In another scenario, to prevent recurrence of a shoulder impingement syndrome or back pain, a patient may need to learn through posture training how to maintain correct alignment of the trunk during a variety of reaching or lifting tasks that place slightly different demands on the body.

In both of these situations, motor learning must occur for the exercise program and functional training to be effective. By viewing exercise interventions from this perspective, it becomes apparent why applications of strategies to promote motor learning are an integral component of effective exercise instruction.

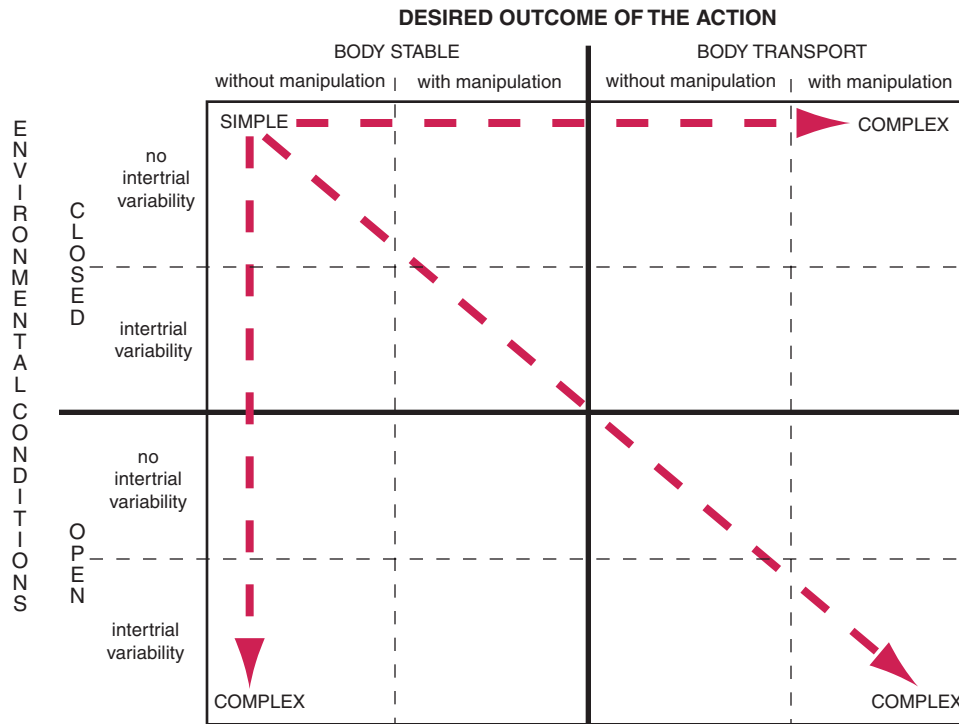

### Conditions and Progression of Motor Tasks

If an exercise program is to improve a patient's function, it must include performing and learning a variety of tasks. If a functional training program is to prepare a patient to meet necessary and desired functional goals, it must place demands on a patient under varying conditions. A taxonomy of motor tasks, proposed by Gentile,<sup>56</sup> is a system for analyzing functional activities and a framework for understanding the conditions under which simple to complex motor tasks can be performed. Figure 1.8 depicts these conditions and the dimensions of difficulty of motor tasks.

An understanding of the components of this taxonomy and the interrelationships among its components is a useful framework for a therapist to identify and increase the difficulty of functional activities systematically for a patient with impaired function.

There are four main task dimensions addressed in the taxonomy: (1) the environment in which the task is performed, (2) the intertrial variability of the environment that is imposed on a task, (3) the need for a person's body to remain stationary or to move during the task, and (4) the presence or absence of manipulation of objects during the task. Examples of simple to complex everyday activities characteristic of each of the 16 different but interrelated task conditions are shown in Figure 1.9.

**Closed or open environment.** Environmental conditions of a task address whether objects or people (around the patient) are stationary or moving during the task and if the surface on

**FIGURE 1.8** Taxonomy of motor tasks: dimensions of task difficulty. (From Dennis, JK, and McKeough, DM: *Mobility*. In May, BJ [ed]: *Home Health and Rehabilitation—Concepts of Care*. Philadelphia: FA Davis, 1993, p 147, with permission.)

		BODY STABLE		BODY TRANSPORT	
		without manipulation	with manipulation	without manipulation	with manipulation
		without intertrial variability	Maintaining balance in sitting on bed while caregiver combs hair Maintaining balance in standing in hallway as caregiver buttons coat	Sitting at the table and eating a meal Sitting doing household accounts Sitting at desk to write a letter	Rolling over in bed Sit <=> stand from bed Tub transfers Bed <=> bathroom, using same route daily
with intertrial variability	Maintaining sitting balance on different chairs in the room e.g., rocker, straight-backed chair, sofa. Maintaining standing balance on different surfaces: carpet, wood	Standing in the kitchen unloading a dishwasher Sitting on a low stool in the yard, bending over to weed the vegetable garden	Rolling over in a twin bed and a queen bed Sit <=> stand from different heights and surfaces Up and down curbs of different heights	Carrying a tray of food or drinks from the kitchen to the living room, using different trays and routes each time	
without intertrial variability	Maintaining balance in a moving elevator	Rearranging packages while standing in a moving elevator	Walking up or down a moving escalator or a moving sidewalk	Rearranging packages while walking up or down the moving escalator	
with intertrial variability	Maintaining sitting or standing balance in a moving bus	Drinking a cocktail on the deck of a cruise ship	Community ambulation Walking through a living room where children are playing	Shopping in the supermarket Walking a precocious pet on a leash	

**FIGURE 1.9** Activities of daily living in the context of the taxonomy of motor tasks. (From Dennis, JK, and McKeough, DM: *Mobility*. In May, BJ [ed]: *Home Health and Rehabilitation—Concepts of Care*, ed. 2. Philadelphia: FA Davis, 1999, p 116, with permission.)

which the task is performed is fixed or moving. A *closed environment* is one in which objects around the patient and the surface on which the task is performed do not move. When a functional task is performed in this type of environment, the patient's complete attention can be focused on performing the task and the task can be self-paced. Examples of tasks performed in a closed environment are drinking or eating while sitting in a chair and maintaining an erect trunk, standing at a sink and washing your hands or combing your hair, and walking in an empty hallway or in a room where furniture placement is consistent.

A more complex environment is an *open environment*. It is one in which objects or other people are in motion or the support surface is unstable during the task. The movement that occurs in the environment is not under the control of the patient. Tasks that occur in open environments include maintaining sitting or standing balance on a movable surface (a balance board or BOSU®; Fig. 1.10), standing on a moving train or bus, ascending or descending stairs in a crowded stairwell, crossing a street at a busy intersection, or returning a serve in a tennis match or volleyball game. During tasks such as these, the patient must predict the speed and directions of movement of people or objects in the environment or must

**FIGURE 1.10** Learning to maintain standing balance on an unstable surface is an example of a motor skill that is performed in an open (moving) environment.

anticipate the need to make postural or balance adjustments as the support surface moves. Consequently, the patient must pace the performance of the tasks to match the imposed environmental conditions.

**Intertrial variability in the environment—absent or present.** When the environment in which a task occurs is constant (unchanging) from one performance of a task to the next, intertrial variability is absent. The environmental conditions for the task are predictable; therefore, little attention to the task is required, which often enables a patient to perform two tasks at one time. Some examples of tasks without intertrial variability are practicing safe lifting techniques using a box of the same dimensions and weight, practicing the tasks of standing up and sitting down from just one height or type of chair, or walking on just one type of surface.

A task becomes more complex when there is intertrial variability in the environmental conditions—that is, when the demands change from one attempt or repetition of a task to the next. With such variability, the patient must continually monitor the changing demands of the environment and adapt to the new circumstances by using a variety of movement strategies to complete the task. Lifting and carrying objects of different sizes and weight, climbing stairs of different heights, or walking over varying terrain are tasks with intertrial variability.

**Body stable or body transport.** In addition to environmental conditions, tasks are analyzed from the perspective of the person doing the task. Tasks that involve maintaining the body in a stable (stationary) position, such as maintaining an upright posture, are considered simple tasks, particularly when performed under closed environmental conditions. When the task requirements involve the patient moving from one place to another (body transport), such as performing a transfer, walking, jumping, or climbing, the task is more complex. When a body transport task is performed in an open environment with intertrial variability, such as walking in a crowded corridor or on different support surfaces, such as grass, gravel, and pavement, the task becomes even more complex and challenging.

**Manipulation of objects—absent or present.** Whether performing a task does or does not require upper extremity manipulation activities also affects the degree of difficulty of the task. When a task is performed without manipulating an object, it is considered less complex than if manipulation is a requirement of the task. Carrying a cup of coffee without spilling it while at home alone and walking from one room to another is a more complex task than walking with hands free. Doing the same task in a busy hallway further increases the complexity and difficulty of the task.

In summary, Gentile's taxonomy of motor tasks can be used to analyze the characteristics of functional tasks in the context of the task conditions. The taxonomy provides a framework to structure individual treatment sessions with a patient or to progress the level of difficulty of motor tasks throughout a functional training program.

## Stages of Motor Learning

There are three stages of motor learning: cognitive, associative, and autonomous.<sup>44,131,163,164</sup> The characteristics of the learner are different at each stage of learning and consequently affect the type of instructional strategies selected by a therapist in an exercise and functional training program.

### Cognitive Stage

When learning a skilled movement, a patient first must figure out *what* to do—that is, the patient must learn the goal or purpose and the requirements of the exercise or functional task. Then the patient must learn *how* to do the motor task safely and correctly. At this stage, the patient needs to think about each component or the sequencing of the skilled movement. The patient often focuses on how his or her body is aligned and how far and with what intensity or speed to move. In other words, the patient tries to get the “feel” of the exercise.

Because all of the patient’s attention is often directed to the correct performance of the motor task, distractions in the environment, such as a busy, noisy exercise room (an open environment), may initially interfere with learning. During this stage of learning, errors in performance are common, but with practice that includes error correction, the patient gradually learns to differentiate correct from incorrect performance, initially with frequent feedback from a therapist and eventually by monitoring his or her own performance (self-evaluation).

### Associative Stage

The patient makes infrequent errors and concentrates on fine-tuning the motor task during the associative stage of learning. Learning focuses on producing the most consistent and efficient movements. The timing of the movements and the distances moved also may be refined. The patient explores slight variations and modifications of movement strategies while doing the task under different environmental conditions (intertrial variability). The patient also uses problem-solving to self-correct errors when they do occur. At this stage, the patient requires infrequent feedback from the therapist and instead begins to anticipate necessary adjustments and make corrections even before errors occur.

### Autonomous Stage

Movements are automatic in this final stage of learning. The patient does not have to pay attention to the movements in the task, thus making it possible to do other tasks simultaneously. Also, the patient easily adapts to variations in task demands and environmental conditions. Little, if any, instruction goes on in this phase of learning unless the patient encounters a recurrence of symptoms or other problems. In fact, most patients are discharged before reaching this stage of learning.

## Variables That Influence Motor Learning—Considerations for Exercise Instruction and Functional Training

Motor learning is influenced by many variables, some of which can be manipulated by a therapist during exercise instruction or functional training to facilitate learning. Some of these variables include pre-practice considerations, physical

or mental practice, and several forms of feedback. An understanding of these variables and their impact on motor learning is necessary to develop strategies for successful exercise instruction and functional training. A brief overview of these key variables that influence the acquisition and retention of skilled movements during each stage of motor learning is presented in this section. Because concepts and principles of motor learning encompass an extensive body of knowledge, the reader is referred to a number of in-depth resources for additional information.<sup>45,56,111,128,130,131,163,164,192</sup>

### Pre-Practice Considerations

A number of variables can influence motor learning during an exercise session even before practice begins. A patient’s *understanding* of the purpose of an exercise or task, as well as interest in the task, affects skill acquisition and retention. The more meaningful a task is to a patient, the more likely it is that learning will occur. Including tasks the patient identified as important during the initial examination promotes a patient’s interest.

*Attention* to the task at hand also affects learning. The ability to focus on the skill to be learned without distracting influences in the environment promotes learning. Instructions given to a patient prior to practice about where his or her attention should be directed during practice also may affect learning. There is evidence in studies of nonimpaired individuals that learning is enhanced if a person attends to the outcomes of performing a task rather than to the details of the task itself.<sup>116,200</sup> This finding is addressed in more detail in a later discussion of feedback as it relates to motor learning.

*Demonstration* of a task prior to commencing practice also enhances learning. It is often helpful for a patient to observe another person, usually the therapist or possibly another patient, perform the exercise or functional task correctly and then model those actions. *Pre-practice verbal instructions* that describe the task also may facilitate skill acquisition, but they should be succinct. Extensive information about the task requirements early in the learning process may actually confuse a patient rather than enhance the learning process.

### Practice

Motor learning occurs as the direct result of practice—that is, repeatedly performing a movement or series of movements in a task.<sup>100,163,164</sup> Practice is probably the single most important variable in learning a motor skill. The *amount*, *type*, and *variability* of practice directly affect the extent of skill acquisition and retention.<sup>128,163,164</sup> In general, the more a patient practices a motor task, the more readily it is learned. In today’s health-care environment, most practice of exercises or functional tasks occurs at home independent of therapist supervision. A therapist often sets the practice conditions for a home program prior to a patient’s discharge by providing guidelines on how to increase the difficulty of newly acquired motor skills during the later stages of learning.

The type of practice strategy selected also has a significant impact on how readily a motor task is learned.<sup>45,100,111,128,131,163,164,196</sup>

Common types of practice are defined in Box 1.19. The type of skill to be learned (discrete, serial, or continuous) and the patient's cognitive status and stage of motor learning determine which practice strategies are more appropriate than others.

**Part versus whole practice.** *Part practice* has been shown to be most effective in the early stage of learning for the acquisition of complex serial skills that have simple and difficult components. Depending on the patient's cognitive status, it is usually necessary to practice only the difficult dimensions of a task before practicing the task as a whole. *Whole practice* is more effective than part practice for acquiring continuous skills, such as walking and climbing stairs, or serial tasks in

which momentum or timing of the components is the central focus of the learning process. Whole practice is also used for acquisition of discrete tasks, such as an exercise that involves repetitions of a single movement pattern.

**Practice order—blocked, random, and random/blocked.**

During the initial phase of rehabilitation, practice usually is directed toward learning just a few exercises or functional motor tasks. During the initial (cognitive) stage of learning in which a new motor skill is acquired, *blocked-order practice* is the appropriate choice because it rapidly improves performance of skilled movements. A transition to *random-order* or *random/blocked-order practice* should be made as soon as possible to introduce variability into the learning process. *Variability of practice* refers to making slight adjustments (variations) in the conditions of a task—for example, by varying the support surface or the surroundings where a task is performed.<sup>56,163,164</sup>

Although blocked-order practice initially improves performance at a faster rate than random-order practice, random practice leads to better skill retention and generalizability of skills than blocked practice.<sup>128</sup> It is thought that varying tasks just slightly, as is done with random-order practice, requires more cognitive processing and problem-solving than blocked-order practice and, hence, culminates in greater retention of a newly acquired skill after practice has ceased. However, blocked-order practice may be preferable for patients with cognitive deficits because random-order practice may pose too great a challenge for the patient and subsequently interfere with the learning process.<sup>103</sup>

Random/blocked-order practice results in faster skill acquisition than random-order practice and better retention than blocked-order practice. Because random/blocked-order practice enables a patient to perform a task at least twice before changing to another variation of the task, this form of practice gives a patient the opportunity to identify and then immediately correct errors in a movement sequence before proceeding to the next variation of the task.<sup>56,163</sup>

**Physical versus mental practice.** Physical practice has long been a hallmark of exercise instruction and functional training in physical therapy, whereas mental practice (motor imagery practice) has its roots in sports psychology and sport-related training.<sup>164,171</sup> Over the past few decades, the applicability of mental practice as a treatment tool in the rehabilitation of patients with movement impairments has been investigated for its potential.<sup>45,195</sup> It is thought that mental rehearsal of a motor task reinforces the cognitive component of motor learning—that is, learning what to do when performing a task and refining how it is executed.

Most studies support the finding that physical practice of motor skills by overtly performing the task is superior to mental practice alone for learning motor tasks.<sup>163,164</sup> However, in sports training and rehabilitation, mental practice, when used in conjunction with physical practice, has been shown to enhance motor skill acquisition at a faster rate than use of physical practice alone.<sup>111,112,128,133</sup>

### BOX 1.19 Types of Practice for Motor Learning

#### Part Versus Whole Practice

- *Part practice.* A task is broken down into separate dimensions. Individual and usually the more difficult components of the task are practiced. After mastery of the individual segments, they are combined in sequence so the whole task can be practiced.
- *Whole practice.* The entire task is performed from beginning to end and is not practiced in separate segments.

#### Blocked, Random, and Random/Blocked Practice Orders

- *Blocked-order practice.* The same task or series of exercises or tasks is performed repeatedly under the same conditions and in a predictable order; for example, the patient may consistently practice walking in the same environment, stepping to and from the same height platform, standing up from the same height chair, or lifting containers of equal size or weight; therefore, the task does not change from one repetition to the next.
- *Random-order practice.* Slight variations of the same task are carried out in an unpredictable order; for example, a patient could practice stepping to and from platforms of different heights or practice standing up from chairs of different heights or styles in a random order; therefore, the task changes with each repetition.
- *Random/blocked-order practice.* Variations of the same task are performed in random order, but each variation of the task is performed more than once; for example, the patient rises from a particular height or style chair and then repeats the same task a second time before moving on to a different height or style chair.

#### Physical Versus Mental Practice

- *Physical practice.* The movements of an exercise or functional task are actually performed.
- *Mental practice.* A cognitive rehearsal of how a motor task is to be performed occurs prior to actually executing the task; the terms *visualization* and *motor imagery practice* are used synonymously with mental practice.

## Feedback

Second only to practicing a motor task, feedback is considered the next most important variable that influences motor learning.<sup>128</sup> *Feedback* is sensory information that is received and processed by the learner during or after performing or attempting to perform a motor skill.<sup>56,128,130,163,164</sup> There are a number of descriptive terms used to differentiate one type of feedback from another. The terms used to describe feedback are based on the source of feedback (*intrinsic* or *augmented/extrinsic*), the focus of feedback (*knowledge of performance* [KP] or *knowledge of results* [KR]), and the timing or frequency of feedback (the *feedback schedule*). Boxes 1.20 and 1.21 identify and define the various terms associated with the types and scheduling of feedback.

Several factors influence the types of feedback that can occur during exercise instruction or functional training and the effectiveness of feedback for skill acquisition (performance) and skill retention (learning). For example, a patient's physical and cognitive status and the stage of motor learning have a significant impact on the type of feedback that is most effective and the timing and frequency of augmented feedback implemented during practice sessions. It has also been suggested that a therapist should encourage a patient to provide input about his or her receptiveness to the type of feedback or feedback schedule used during practice, particularly once the patient has achieved a beginning level of skill acquisition. This active participation may promote a

### BOX 1.20 Types of Feedback for Motor Learning

#### Knowledge of Performance (KP) Versus Knowledge of Results (KR)

- *KP*. Either intrinsic feedback sensed during a task or immediate, posttask, augmented feedback (usually verbal) about the *nature* or *quality* of the performance of a motor task.
- *KR*. Immediate, posttask, augmented feedback about the *outcome* of a motor task.

#### Intrinsic Feedback

- Sensory cues that are inherent in the execution of a motor task.
- Arises directly from performing or attempting to perform the task.
- May immediately follow completion of a task or may occur even before a task has been completed.
- Most often involves proprioceptive, kinesthetic, tactile, visual, or auditory cues.

#### Augmented (Extrinsic) Feedback

- Sensory cues from an external source that are supplemental to intrinsic feedback and that are not inherent in the execution of the task.
- May arise from a mechanical source or from another person.

### BOX 1.21 Feedback Schedules

#### Concurrent Versus Postresponse Feedback

- *Concurrent*. Occurs during the performance of a task; also known as “real-time” feedback.
- *Postresponse (terminal)*. Occurs after completing or attempting to complete a motor skill.

#### Immediate, Delayed, and Summary Postresponse Feedback

- *Immediate*. Information that is given directly after a task is completed.
- *Delayed*. Information that is given after a short interval of time has elapsed, allowing time for the learner to reflect on how well or poorly a task was executed.
- *Summary*. Information that is given about the average performance of several repetitions of a motor skill.

#### Variable Versus Constant Feedback

- *Variable (intermittent)*. Occurs irregularly, randomly during practice of a motor task.
- *Constant*. Occurs on a regularly recurring, continuous basis during practice of a motor task.

sense of self-control in the patient and is thought to have a positive impact on learning.<sup>116</sup>

In order to provide the most effective forms of feedback during exercise instruction and functional training, it is useful for a therapist to understand the benefits and limitations of several types and schedules of feedback for skill acquisition and skill retention.

***Intrinsic feedback.*** Intrinsic feedback comes from all of the sensory systems of the learner, not from the therapist, and is derived from performing or attempting to perform any movement. Intrinsic feedback is inherent in the movement itself—that is, it occurs naturally during or after a task is performed.<sup>56,128,163</sup> It provides ongoing information about the quality of movement during a task and information about the outcomes (results) of a task, specifically if the goal of a task was achieved. In everyday life, intrinsic feedback is a continuous source of information that provides KP and KR as a person performs routine activities or tries to learn new motor skills.

***Augmented feedback.*** Information about the performance or results of a task that is *supplemental* to intrinsic feedback is known as augmented feedback.<sup>128,163,164,198</sup> It is also referred to as *extrinsic feedback*.<sup>56,131</sup> Unlike intrinsic feedback, a therapist has control of the type, timing, and frequency of augmented feedback a patient receives during practice. Augmented/extrinsic feedback can be provided during or at the conclusion of a task to give information about the quality of the performance (KP) or the quality of the outcome of a task (KR).

**NOTE:** Although augmented feedback is a commonly used instructional tool to facilitate motor learning in healthy individuals,

it is thought to be particularly necessary when teaching motor skills to patients who may receive inadequate or inaccurate intrinsic feedback as the result of impaired sensory systems from injury or disease.<sup>56,128</sup>

Therapists have many forms of augmented/extrinsic feedback from which to select for exercise instruction and functional training.<sup>56,69,130,198</sup> Some examples include *verbal* or *tactile* feedback directly from a therapist who is interacting with a patient during practice and *visual* or *auditory* feedback from a rehabilitative ultrasound imaging device (Fig. 1.11) or an electromyography (EMG) biofeedback unit. A videotaped replay of a previous performance is another source of augmented visual feedback.

**FIGURE 1.11 (A, B)** Use of rehabilitative ultrasound imaging provides augmented (visual) feedback on the screen during exercise instruction to help the patient learn how to activate the transversus abdominis and internal oblique muscles.

**KP versus KR.** Over the past few decades, the selection and application of feedback have changed in the clinical setting. Traditionally, a therapist would have a patient focus on sensory information inherent in a motor task (intrinsic feedback)

to “get the feel” of movements in the task, such as how it felt to weight shift from side to side while controlling the knees and maintaining standing balance. At the same time the therapist would provide ongoing feedback—usually verbal—about the quality of the patient’s posture or knee control (KP) during the weight-shifting activity.

However, research, primarily with nonimpaired subjects, has shown that directing a person’s attention to the outcomes of movements (KR) rather than to the details of the movements themselves enhances learning (retention of a motor skill) more effectively.<sup>200</sup> Consequently, therapists now tend to place greater emphasis on providing feedback about the outcomes (results) of performing a motor skill.<sup>198</sup>

Going back to the weight-shifting example—to employ KR during functional training, a therapist should have a patient perform weight shifts by reaching for objects placed in various positions just outside the patient’s base of support. By giving the patient a target, the task becomes goal directed as the patient focuses on the intended results of the movement. The patient, therefore, learns to judge the effectiveness of his or her movements based on feedback received from external cues.<sup>116,200</sup>

**The feedback schedule—timing and frequency of augmented feedback.** The scheduling of feedback (see Box 1.21) during practice sessions involves the timing and frequency with which augmented/extrinsic feedback is provided. Feedback schedules affect motor skill acquisition and retention and should be adjusted during the learning process.

*Concurrent feedback* is a form of augmented feedback that occurs in “real time” as a patient is performing or attempting to perform a motor task. Visual feedback from a rehabilitative ultrasound-imaging unit (see Fig. 1.11) is an example of concurrent feedback and is useful when a patient is first learning how to perform an isometric contraction of the trunk stabilizing muscles because no observable movement of the body occurs.

Another form of concurrent feedback, the use of *manual guidance*, which provides tactile cues to the patient, may be necessary for patient safety and may help a patient understand the required movements of an exercise or functional task. However, excessive or long-term use of manual guidance may hamper motor learning in that it may not allow a patient to make “safe mistakes” while figuring out how to perform a movement. As mentioned in the discussion of the stages of motor learning, self-detection and self-correction of errors are absolutely necessary for learning to occur. The key is to use the least amount of concurrent feedback for the shortest time possible, so the patient does not become reliant on it to carry out a task.<sup>56</sup>

*Immediate, postresponse feedback* is another form of augmented/extrinsic feedback often used during the initial stage of learning. The therapist provides information, often verbally, about the outcome of the task (KR) immediately after each trial. Although immediate feedback after each trial may enhance early skill acquisition, it too does not allow time for problem-solving by the patient and detection of errors without input from the therapist. Consequently, although initial

skill acquisition may occur rather quickly, learning, which includes retention, is delayed.<sup>163</sup>

As alternatives to immediate feedback, *delayed feedback* from the therapist after each repetition of a task or exercise or *summary feedback* after several trials have been completed gives the patient time for self-evaluation and problem-solving as to how the task was performed during practice, which in turn promotes retention and generalizability of the learned skills. Although use of delayed or summary schedules of feedback is associated with slower skill acquisition than concurrent or immediate feedback after every trial, it is thought that delaying the timing of feedback makes the patient pay attention to intrinsic feedback inherent in the task.<sup>56,163,197</sup>

### FOCUS ON EVIDENCE

The impact of concurrent, immediate postresponse, and summary feedback schedules was investigated in a study of non-impaired individuals.<sup>197</sup> When subjects practiced a partial weight-bearing activity, those who received concurrent visual feedback (by looking at a scale) achieved the skill more quickly than the subjects who received postresponse feedback (either immediate or summary). However, subjects who received concurrent feedback performed least well on a retention test 2 days after practice ended than the subjects in the two other groups who received postresponse feedback. In addition, summary feedback was found to enhance retention to a greater extent than immediate postresponse feedback.

The frequency with which a therapist provides augmented feedback also should be considered. A basic principle about augmented feedback is that “less is better.” Although the greatest frequency of feedback is necessary during the cognitive (initial) stage of learning when a patient is first learning how to perform an exercise or a functional task, excessive or extended use of any form of augmented feedback can create dependence on the feedback and can be a deterrent to self-detection and correction of errors.<sup>56,163,164</sup> Excessive verbal feedback, for example, provided by a therapist after every trial also can be distracting and may interrupt a patient’s attention to the task.

Rather than providing feedback after each repetition of an exercise, a therapist may want to consider varying the frequency of feedback (a variable feedback schedule) by giving the patient input following more than a single repetition and on a variable, less predictable basis. *Variable (intermittent)* feedback during practice has been shown to promote retention of a learned motor skill more effectively than *constant (continuous)* feedback given during or after each repetition.<sup>69</sup> A therapist must keep in mind, however, that constant (continuous) feedback improves skill acquisition (performance) more quickly during the initial stage of learning than variable (intermittent) feedback.<sup>56</sup>

It is also important to fade (decrease) the frequency of feedback over time to avoid the extended use of feedback. *Summary feedback*, particularly during the associative stage

of learning, is an effective strategy to reduce the total amount of feedback given in a practice session. As augmented feedback is faded, a patient must explore slight modifications of a movement strategy and analyze the results. This promotes problem-solving, self-monitoring, and self-correction, all of which enable a patient to perform tasks independently and safely and to transfer learning to new task conditions.

### Application of Motor-Learning Principles for Exercise Instruction Summarized

Box 1.22 summarizes the information discussed in this section with regard to qualities of the learner and effective strategies for exercise instruction and functional training founded on the principles and stages of motor learning.<sup>44,130</sup>

## Adherence to Exercise

Effective patient-related instruction for a functionally oriented exercise program must include methods to foster *adherence*. This is particularly challenging when a patient is unaccustomed to regular exercise or when an exercise program must be carried out for an extended period of time. Positive outcomes from treatment are contingent not so much on designing the “ideal” exercise program for a patient, but rather on designing a program that a patient or family will actually follow.<sup>81,82,186</sup>

**NOTE:** Although the terms *adherence* and *compliance* are often used interchangeably by clinicians and in the literature, the term *adherence* has been selected for this discussion because it has a stronger connotation of active involvement of the patient and patient-therapist collaboration. In contrast, *compliance* tends to imply a more passive connotation with respect to a patient’s behavior.

### Factors that Influence Adherence to an Exercise Program

Many factors influence adherence to an exercise program.<sup>28,60,64,81,82,110,116,127,168,186</sup> These factors can be grouped into several categories: a patient’s characteristics, factors related to a patient’s health condition or impairments, and program-related variables.

#### Patient-Related Factors

The following patient-related factors can have a positive or negative impact on adherence: understanding the health condition, impairments, or exercise program; level of motivation, self-discipline, attentiveness, memory, and willingness and receptivity to change; degree of fatigue or stress; the availability of time to devote to an exercise program; the patient’s self-perception of his or her compatibility with the therapist or the degree of control in the exercise program; socioeconomic and cultural background; the beliefs and attitudes about exercise and the value the patient places on the exercise program; and the patient’s access to resources. The patient’s age and sex also influence adherence to an exercise program, with men having higher adherence rates than women. The association between age and adherence is less clear.

## BOX 1.22 Characteristics of the Learner and Instructional Strategies for the Three Stages of Motor Learning

### COGNITIVE STAGE

#### Characteristics of the Learner

Must attend only to the task at hand; must think about each step or component; easily distractible; begins to understand the demands of the motor task; starts to get a "feel" for the exercise; makes errors and alters performance, particularly when given augmented feedback; and begins to differentiate correct versus incorrect and safe versus unsafe performance.

#### Instructional Strategies

- Initiate instruction in a nondistracting (closed) environment.
- Identify the purpose and functional relevance of the exercise or functional task.
- Demonstrate the ideal execution of the movements (modeling).
- Initially, guide or assist the patient through the movements. Reduce manual guidance feedback as soon as a patient can safely control movements.
- Point out the distance and speed of the movement (how far or fast to move).
- Emphasize the importance of controlled movements.
- Break complex movements into parts when appropriate.
- Have the patient verbally describe the sequence of component motions.
- Have the patient demonstrate each exercise or task but practice only a few motor tasks. Keep repetitions low and alternate tasks to ensure safety and avoid fatigue.
- Point out sensory cues (intrinsic feedback) to which the patient should attend.
- Provide frequent and explicit positive feedback related to KP and KR.
- Use a variety of forms of feedback (verbal, tactile, and visual) and vary.
- Initially use feedback after each repetition to improve performance (acquisition); gradually transition to variable and delayed feedback to enhance learning (retention).
- Introduce the concept of self-evaluation and self-correction of movements.
- Initially, use blocked-order practice; gradually introduce random-order practice.
- Allow trial and error to occur within safe limits.

### ASSOCIATIVE STAGE

#### Characteristics of the Learner

Performs movements more consistently with fewer errors or extraneous movements; executes movements in a well-organized manner; refines the movements in the exercise or functional task; detects and self-corrects movement errors when they occur; is less dependent on augmented/extrinsic feedback from the therapist; and uses prospective cues and anticipates errors before they occur.

#### Instructional Strategies

- Emphasize practice of a greater number and variety of movements or tasks.
- Increase the complexity of the exercise or task.
- Vary the sequence of exercise or tasks practiced (random-order practice).
- Allow the patient to practice independently, emphasizing problem-solving and use of proprioceptive cues (intrinsic feedback) for error detection.
- Introduce simulation of functional tasks into the practice session.
- Continue to provide augmented feedback regarding KP and KR, but avoid the use of manual guidance.
- Delay feedback or use a variable feedback schedule to give the learner an opportunity to detect movement errors and self-correct them.
- Gradually fade feedback by decreasing the total amount of feedback but increase the specificity of feedback.
- Allow the learner to perform a full set of exercises or several repetitions of a functional task before providing feedback (summary feedback).
- Increase the level of distraction in the exercise environment.
- Prepare the patient to carry out the exercise program in the home or community setting.

### AUTONOMOUS STAGE

#### Characteristics of the Learner

Performs the exercise program or functional tasks consistently and automatically and while doing other tasks; applies the learned movement strategies to increasingly more difficult tasks or new environmental situations; and, if appropriate, performs the task more quickly or for an extended period of time at a lower energy cost.

#### Instructional Strategies

- Set up a series of progressively more difficult activities the learner can do independently, such as increasing the speed, distance, and complexity of the exercises or task.
- Suggest ways the learner can vary the original exercise or task and use the task in more challenging situations encountered in everyday activities.
- If the patient is still in therapy, which at most is usually for just a recheck, incorporate little to no feedback unless a significant movement error is noted or a potentially unsafe situation arises.
- Provide assistance, as needed, to integrate the learned motor skills into fitness or sports activities.

### Factors Related to the Health Condition or Impairments

The acuity, chronicity, severity, or stability of the primary health condition and related impairments and the presence of comorbidities all have an impact on adherence. Pain is obviously a deterrent to adherence and therefore must be minimized in an exercise program. When impairments are severe or long-standing, setting short-term goals that can be achieved regularly fosters adherence to an exercise program that must be followed over a long period of time.

### Program-Related Variables

The complexity and necessary duration of an exercise program; the adequacy of instruction, supervision, and feedback from the therapist; whether the patient has had input into the plan of care; and the continuity of care from an inpatient to a home setting all can have an impact on adherence. Programs that address the interest level and motivational needs of a patient have higher adherence rates. In the outpatient setting, logistics, such as location and scheduling, the program's atmosphere created by the therapist/exercise instructor, and the availability of social support and individualized attention or counselling from personnel also are important factors that foster adherence.

### Strategies to Foster Adherence

A therapist should expect that most patients will not dutifully adhere to any treatment program, particularly if regular exercise has not been a part of the patient's life prior to the occurrence of disease or injury. The most a therapist can hope to do is implement strategies that foster adherence. Some suggestions from a number of resources in the literature are noted in Box 1.23.<sup>28,60,64,81,82,99,116,127,168,186</sup>

#### BOX 1.23 Strategies to Foster Adherence to an Exercise Program

- Explore and try to appreciate the patient's beliefs about exercising or the value the patient places on exercising as a means to "get better."
- Help the patient identify personal benefits derived from adhering to the exercise program.
- Explain the rationale and importance of each exercise and functional activity.
- Identify how specific exercises are designed to meet specific patient-centered goals or functional outcomes.
- Allow and encourage the patient to have input into the nature and scope of the exercise program, the selection and scheduling of practice and feedback, and decisions of when and to what extent exercises are progressively made more difficult to enhance a patient's sense of self-control.
- Keep the exercise program as brief as possible.
- Identify practical and functionally oriented ways to do selected exercises during everyday tasks.
- Have the patient keep an exercise log.
- If possible, schedule follow-up visit(s) to review or modify exercises.
- Point out specific exercise-related progress.
- Identify barriers to adherence (not enough time in the day to do the exercises, discomfort during the exercises, and lack of necessary equipment); then suggest solutions or modify the exercise program.

## Independent Learning Activities

### Critical Thinking and Discussion

1. Critically analyze your own, an acquaintance's, or a family member's exercise history. Then identify how a regular regimen of exercise could improve your quality of life or theirs.
2. Research four health conditions (diseases, injuries, or disorders) that result in primary impairments of the (1) musculoskeletal, (2) neuromuscular, (3) cardiovascular/pulmonary, and (4) integumentary systems. Identify characteristic impairments (signs and symptoms) associated with each health condition and hypothesize what activity limitations and participation restrictions are most likely to develop.
3. Why is it essential for a physical therapist to understand and be able to articulate (verbally or in written form) the interrelationships among impairments typically exhibited by patients with various health conditions, activity limitations, and participation restrictions?
4. Last month, you sprained your ankle (inversion sprain). You had to use crutches for several days, but since then you have been walking independently. Pain and swelling still return after vigorous activity, and your ankle feels unstable on uneven terrain. Using a model of functioning and disability as your frame of reference, identify specific activity limitations and at least one participation restriction that would most likely develop in your life as the result of your history and current problems.
5. Using your current knowledge of examination procedures, develop a list of specific tests and measures you would most likely choose to use when examining a patient whose primary impairments affect the (1) musculoskeletal, (2) neuromuscular, (3) cardiovascular and/or pulmonary, and (4) integumentary systems.

6. You have been asked to make recommendations for the adoption of one or more new measurement instruments to be used at your facility for data collection and analysis of patient-centered functional outcomes. Review the literature on musculoskeletal assessment and identify and summarize key features of five instruments that measure activity limitations associated with musculoskeletal impairments of the extremities, neck, or trunk. In addition, identify and summarize key features of five measurement instruments that assess a patient's restricted participation in societal, family, or work roles.
7. Three individuals just recently sustained similar fractures of the hip. All underwent an open reduction with internal fixation. The patients are an otherwise healthy 19-year-old college student who was in an automobile accident and wants to return to campus after discharge from the hospital; a 60-year-old person with a somewhat sedentary lifestyle who plans to return home after postoperative rehabilitation and wishes to return to work in an office as soon as possible; and an 85-year-old individual with severe age-related osteoporosis who has been residing in an assisted living facility for the past year. What issues must be considered when identifying anticipated goals and expected outcomes and determining appropriate interventions in the plans of care for these patients? In what ways would goals and expected outcomes differ for these patients?
8. Identify the key components of the patient management model described in this chapter and discuss how each of those components relates to the potential use of therapeutic exercise interventions.
9. Using the taxonomy of motor tasks discussed in this chapter, identify simple to complex activities that are necessary or important in your daily life. Identify at least 3 activities that fall within each of the 16 condition variables described in the taxonomy.
10. You are seeing a patient in the home setting for follow-up of a postoperative exercise program and progression of functional activities initiated in the hospital. The patient is a 55-year-old computer analyst who had a (L) total knee arthroplasty 10 days ago. You have completed your examination and evaluation. Other than a long-standing history of degenerative arthritis of the (L) knee, the patient has no other significant health-related problems. As you would expect, the patient has pain and limited ROM of the (L) knee and decreased strength of the (L) lower extremity. The patient is currently ambulating with axillary crutches, weight bearing as tolerated on the (L) lower extremity. As the patient recovers strength and ROM, design a series of progressively more challenging functional motor tasks the patient could practice with your supervision or independently at home based on the taxonomy of motor tasks described in this chapter.

*Transforming society by optimizing movement to improve the human experience.*

*APTA Vision Statement<sup>8</sup>*

Physical therapists have long been advocates for prevention, health, and wellness. They not only work with patients in a rehabilitation environment, but they also have opportunity to work with clients to improve fitness, wellness, and overall health.<sup>6,38</sup> Their roles include education, direct intervention, research, advocacy, and collaborative consultation, as well as identification of risk factors and provision of services to mitigate those risks,<sup>7</sup> thus helping individuals bridge the gap between illness and wellness. Physical therapists and physical therapist assistants also work within their communities to influence and advocate for adapting environments to promote healthy lifestyles for all. In these ways, they can achieve the profession's vision of "transforming society by optimizing movement to improve the human experience."<sup>8</sup>

## Key Terms and Concepts

**Health.** "A state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity."<sup>84</sup> "A state of being associated with freedom from disease, injury,

and illness that also includes a positive component (wellness) that is associated with a quality of life and positive well-being."<sup>4</sup>

**Wellness.** "A state of being that incorporates all facets and dimensions of human existence, including physical health, emotional health, spirituality, and social connectivity."<sup>4</sup> "An active process through which people become aware of, and make choices toward, a more successful existence."<sup>48</sup>

**Health literacy.** "The degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions."<sup>70</sup>

**Health promotion.** "Any effort taken to allow an individual, group, or community to achieve awareness of—and empowerment to pursue—prevention and wellness."<sup>4</sup>

**Public health.** "The practice of preventing disease and promoting good health by providing the resources and creating environments that help people stay healthy."<sup>9</sup>

**Health-related quality of life.** "A broad multidimensional concept that usually includes self-reported measures of physical and mental health."<sup>16</sup>

**Well-being.** “A positive outcome that is meaningful for people and for many sectors of society, because it tells us that people perceive that their lives are going well.”<sup>19</sup>

**Fitness and physical activity.** Refer to Chapter 7.

## Chronic Disease, Prevention, and Health Care

Noncommunicable chronic diseases are primary causes of death and illness in the United States, with chronic diseases accounting for 7 of the top 10 causes of death.<sup>34,83</sup> The top four chronic conditions in terms of mortality include cardiovascular disease, cancers, chronic respiratory diseases, and diabetes. According to the Centers for Disease Control and Prevention (CDC), chronic diseases account for about two-thirds of deaths globally.<sup>18</sup>

### Chronic Conditions Related to Behaviors

Chronic conditions are often attributable to behaviors. Some common risky behaviors include tobacco use and second-hand smoke exposure, physical inactivity and lack of regular exercise, poor diet and nutrition, and excessive alcohol use. These behaviors often lead to a cascade of health problems, including hypertension and stroke, obesity, and diabetes, among others. Approximately 78 million Americans are at increased risk for heart disease, diabetes, and cancer as a result of obesity alone.<sup>69</sup> In 2013, more than 76% of adults had at least one chronic condition, 19% had two to three chronic conditions, and 4% had more than four chronic conditions.<sup>17</sup> These conditions are common in the patients/clients with whom physical therapists intervene; therefore, risk factor assessment must be an integral part of physical therapist practice.

### Health-Care Costs Due to Risky Behaviors

The risky life-style behaviors noted above result in increased costs for health care. In 2014, the US spent approximately \$3.0 trillion dollars on health care, averaging about \$9,523 per person, which was about 17.5% of the gross domestic product for that year.<sup>20</sup> According to the CDC, treating people with chronic disease accounts for about 86% of US health-care costs.<sup>15</sup> Although the health-care spending level is about twice as much as other industrialized nations, the US ranks 24th among those 30 nations in life expectancy.<sup>9</sup> Spending on prevention in the US is only about 3% of all health-care spending, while about 75% of health-care costs are related to treatment of largely preventable conditions.<sup>37</sup>

### Investment in Prevention

To facilitate change and improve health behaviors, and thereby reduce health-care costs and spending, investment in prevention is critical. A 2009 report by the Trust for America's

Health found that an investment of \$10 per person per year on prevention and wellness programs could yield a net savings in health-care costs of more than \$2.8 billion annually within 1 to 2 years and more than \$16 billion annually within 5 years,<sup>68</sup> a significant return on investment. To that end, the Prevention and Public Health Fund (Prevention Fund) was created as a part of the Patient Protection and Affordable Care Act.<sup>9</sup> The purpose of the Prevention Fund is to provide money for investment in public health programs to improve the health of communities and the nation.<sup>9</sup> More than \$4.7 billion has been allocated for prevention and public health programs since the inception of the Prevention Fund in 2012.<sup>54</sup> These activities and programs are typically community-based programs aimed to improve health, including those that reduce or prevent tobacco use, increase immunization rates, improve access to care, reduce transmission of HIV, and those that generally encourage healthy living.<sup>9</sup> Physical therapists have opportunity to facilitate behavior change to reduce risk factors in the individuals with whom they work, thereby reducing not only the economic burden of these conditions for the individual and society, but also improving the health of the individuals and the communities in which they live.

## Wellness

There are varying definitions of wellness and models of the components of wellness, but there is general agreement on the multidimensional, interdependent nature of the concept of wellness.<sup>2,13,24,48</sup> The various components are summarized in Table 2.1. The National Wellness Institute utilizes The Six Dimensions of Health Model (SDH), which includes social, occupational, spiritual, physical, intellectual, and emotional dimensions.<sup>48</sup> Adams, Bezner, and Steinhardt describe six domains of wellness, including emotional, intellectual, physical, psychological, societal, and spiritual.<sup>2</sup> They developed the Perceived Wellness Survey (PWS) to assess wellness across and within those six domains of wellness. This tool is easy to administer and score, increasing its clinical utility for the physical therapist.<sup>1</sup> The Model for Healthy Living developed by the Church Health Center in Memphis, Tennessee, includes the domains of faith life, movement, medical, work, emotional, nutrition, and family and friends.<sup>24</sup> The Model of Healthy Living Assessment Wheel, shown in Figure 2.1, provides a description of each domain, as well as a rating system for self-assessment for individuals.<sup>23</sup> This tool is easily administered and has been used in community and faith-based settings.

## Healthy People 2020

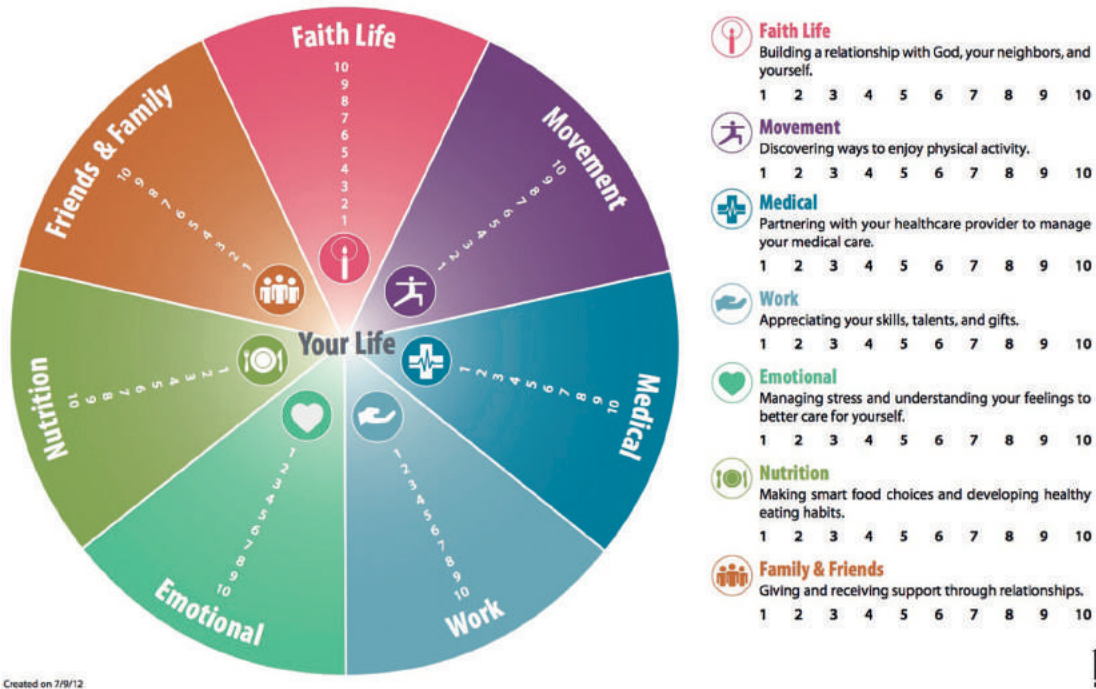

In 1979, following the Surgeon General's report on the health of the nation, the US government developed a national prevention agenda. Currently, the Office of Disease Prevention

**TABLE 2.1** Domains of Wellness by Model—cont'd

Domain	Description	Model
<b>Emotional</b>	Accepting and managing our feelings in all personal interactions	Six Dimensions of Health <sup>48</sup>
<b>Emotional</b>	The possession of a secure sense of self-identity and a positive sense of self-regard	Perceived Wellness Model <sup>2,13</sup>
<b>Emotional</b>	Managing stress and understanding your feelings to better care for yourself	Model for Healthy Living <sup>24</sup>
<b>Psychological</b>	A general perception that one will experience positive outcomes to the events and circumstances of life	Perceived Wellness Model <sup>2,13</sup>
<b>Medical</b>	Partnering with your health-care provider to manage your medical care	Model for Healthy Living <sup>24</sup>
<b>Nutrition</b>	Making smart food choices and developing healthy eating habits	Model for Healthy Living <sup>24</sup>

and Health Promotion in the Department of Health and Human Services oversees this agenda through *Healthy People 2020*.<sup>1,23,50,68</sup> The vision for *Healthy People 2020* is “a society in which all people live long, healthy lives.”<sup>72</sup> The four overarching goals of this agenda are the following:

- Attain high-quality, longer lives free of preventable disease, disability, injury, and premature death.
- Achieve health equity, eliminate disparities, and improve health of all groups.
- Create social and physical environments that promote health for all.
- Promote quality of life, healthy development, and healthy behaviors across all life stages.

**Leading health indicators.** *Healthy People 2020* contains 42 topic areas and more than 1,200 objectives. Leading Health Indicators (LHI), a subset of *Healthy People 2020* objectives, have been identified since *Healthy People 2010*. LHIs were selected to communicate high-priority areas and actions to address the 26 identified objectives. The current LHI topic areas include access to care; clinical preventative services; environmental quality; injury and violence; maternal, infant, and child health; mental health; nutrition, physical activity, and obesity; oral health; reproductive and sexual health; social determinants of health; substance abuse; and tobacco use.<sup>73</sup> A progress update from March 2014 indicates that progress has been generally positive for the LHI, with 14 of the 26 indicators/objectives (53.9%) having either met their target or shown improvement.<sup>74,75</sup>

## Role of Physical Therapists in Health Promotion and Wellness

Consider the American Physical Therapy Association (APTA) vision statement, “Transforming society by optimizing movement to improve the human experience.”<sup>8</sup> Optimal movement

is purposeful, efficient—especially in terms of energy expenditure, and reduces risk of injury or onset of impairments or disability. Quality of life is improved with the ability to move well. Physical therapists have unique expertise in the evaluation of and interventions for dysfunction of the movement system.

### Facilitating Transformation

Physical therapists can facilitate transformation of society through the typical practice of working with patients in rehabilitation after onset of injury or illness or after surgery. Physical therapists can also facilitate this transformation by educating patients/clients to enhance health and wellness; identifying community resources available to the client to support a healthy lifestyle; advocating for community systems and resources to support health-enhancing behaviors and environments; influencing public policy at the local, state, and national levels; and advocating for reduction in health disparities. Through use of clinical reasoning, knowledge, and skills, and as experts in the human movement system, physical therapists can transform society by helping patients/clients optimize movement to promote health and wellness, prevent or reduce impairments, and reduce and/or prevent disability.

### Promoting Health and Behavior Change

Due to the nature of physical therapist practice, with extended patient/client visits over a period of time, physical therapists are “uniquely qualified to lead the assault on lifestyle conditions.”<sup>32</sup> Physical therapists have the opportunity to not only address patient/client specific impairments and functional limitations, but also to promote health and influence behavior change so that the outcome is improved individual health and function and improved health of the community. Through assessment of risk factors, education regarding impact of risk factors and behaviors, and interventions designed for the individual to address multiple components of wellness, the physical therapist can assist the patient/client in achieving better health and better health-related quality of life. Helpful

resources for counseling patients and clients about nutrition and weight management can be found at [myplate.gov](http://myplate.gov) and in the *2015-2020 Dietary Guidelines for Americans*.<sup>71</sup> Physical therapists can and should encourage their patients/clients to increase physical activity, eat a nutritious diet and manage weight, and have a positive outlook.

### Assess State of Wellness

Physical therapists should take the opportunity to assess patient/client current state of wellness using an assessment tool, such as the Perceived Wellness Survey or the Model for Health Living Assessment Wheel (see Fig. 2.1).<sup>1,23</sup> These tools are easy to administer and provide insight in terms of perceived

wellness in each category as well as across the domains. Balance across the domains is desired. Outcomes of interventions for these domains can be assessed with repeat administration. When obtaining the patient/client history, include questions about general health status and social and health habits, including current level of physical activity, tobacco use, nutrition and weight management, adequacy of sleep, and level of stress.<sup>13</sup> In addition to asking about these behaviors, discuss options for intervention with the patient/client, such as identifying smoking cessation or nutritional counseling and weight loss programs available in the area. Table 2.2 describes physical therapists' behaviors, knowledge, and skills needed for incorporating health and wellness into practice.<sup>13</sup>

**TABLE 2.2** Health and Wellness Knowledge and Skills for Physical Therapists<sup>13</sup>

For all behaviors: normal and abnormal pathophysiology, epidemiology of injury and disease, risk factors, protective health behaviors, theories of health behavior change, ecological approaches to behavior change, counseling skills, local and community resources, history taking, rapport building, and ability to assess readiness to change

## Function of the Physical Therapist

Roles of the physical therapist in prevention, health promotion, and wellness include:<sup>4</sup>

- Identifying risk factors and interventions to reduce risk in individuals and communities.
- Preventing or slowing progression of functional decline and disability and enhancing activity in those with a diagnosed condition.
- Reducing disability by restoring skills and independence in those with chronic conditions.
- Screening: Identifying individuals or groups who would benefit from education, intervention, or referral to an appropriate health-care provider.
- Intervention: Providing interventions as identified from screening sessions.
- Consultation: Providing expertise and knowledge.
- Education: Providing information on prevention, health, wellness, and fitness topics.
- Critical Inquiry: Obtaining, synthesizing, and utilizing current research; interpreting data; and/or participating in research.
- Administration: Planning, developing, and managing all aspects of a prevention or wellness project including budget, human resources, and space.

## Prevention Activities

Examples for various prevention activities can be found in Table 2.3. When developing prevention activities, it is important to note that there are three types of prevention:<sup>4</sup>

- Primary prevention:** Preventing a target problem or condition in an individual or in a community at risk; for example,

developing fitness programs for children to prevent obesity or a back injury prevention program for warehouse workers.

- Secondary prevention:** Decreasing the duration and severity of disease; for example, developing resistance programs for individuals with osteoporosis.
- Tertiary prevention:** Decreasing the degree of disability and promoting rehabilitation for individuals with chronic or irreversible diseases; for example, developing fitness programs for individuals with spinal cord injury.

## FOCUS ON EVIDENCE

Norman and her coauthors<sup>50</sup> assessed psychological well-being (Positive Affect Balance Scale), depression symptoms (Edinburgh Postnatal Depressions Scale), and physical activity (minutes per week) in postpartum women. The intervention group (n = 62) participated in an exercise and education program for 8 weeks led by a women’s health physical therapist, while the control group (n = 73) was mailed the same educational material over the 8 weeks. The intervention group had a significant difference in well-being (improvement p = 0.007) and a reduced risk of developing postpartum depression (P < 0.001) compared with the control group but no difference in amount of physical activity.

## Identifying Risk Factors

When developing specific programs related to health, wellness, and fitness, it is important to conduct risk assessments and preparticipation screenings. The reader is referred to the

**TABLE 2.3** Prevention Activities

Screening Risk Assessment	Health Promotion, Wellness, and Fitness
<b>Scoliosis</b>	Education: Information flyer for parents on identification and treatment for idiopathic scoliosis.
<b>Obesity</b>	Intervention: Develop exercise/fitness program for overweight teens and adults. Include education on nutrition and weight management. Use myplate.gov for education and tracking tools.
<b>Osteoporosis</b>	Education: Develop community education programs related to osteoporosis (importance of exercise, reducing falls in the home). Administration: Develop a resistance and weight-bearing exercise class for individuals with osteoporosis. Screening: Perform Falls Risk Assessment at community health fair.
<b>Falls</b>	Critical Inquiry: Complete a literature review and identify the most appropriate measures of fall risk. Intervention: Develop exercise program to increase strength, balance, and coordination in older adults.
<b>Work site assessment</b>	Consultation: Work with human resource department of a company to identify ways to reduce workplace injuries. Educate: Educate employees and management on proper body mechanics, work station redesign, and ways to reduce injury risk.

American College of Sports Medicine (ACSM)<sup>3</sup> for several tools to assess these factors.

### Preparticipation Screening

Prior to participation in moderate-intensity physical activity, the individual should be asked several questions as summarized in Box 2.1.<sup>65</sup> Individuals who answer yes to one or more questions should be evaluated further and may require consultation with their physician before starting some activities (see the appendix following Chapter 24). For higher-performing clients, the Functional Movement Screen (FMS) and the Selective Functional Movement Assessment (SFMA) can be used to assess movement patterns with seven activities.<sup>25, 26</sup>

#### BOX 2.1 Activity Prescreening Questions

1. Have you ever been diagnosed with a heart condition?
2. Have you ever been advised that you should only do physical activity under the direction of a physician?
3. Do you experience chest pain when you do physical activity?
4. Have you experienced chest pain during this past month when not physically active?
5. Have you been diagnosed with arthritis or osteoporosis, or have you experienced increased pain in your joints when physically active?
6. Are you currently taking prescription drugs for blood pressure or a heart condition?
7. Do you ever lose your balance or lose consciousness?
8. Are you aware of any condition that would prohibit you from doing physical activity?

The FMS has been used to assess athletes, fireman, and military personnel. The SFMA is a similar assessment but is used with those with known musculoskeletal pain.<sup>22,28,41,51</sup>

### Risk Assessment

The participant should be assessed for risk factors associated with specific conditions such as coronary artery disease (CAD) and osteoporosis, as shown in Box 2.2.<sup>3, 47</sup> Identification of risk factors guides the therapist when deciding how to proceed. If multiple risk factors, such as those associated with CAD, are identified, a participant may need to be referred to a physician prior to initiating a program. However, if the risk factors are minimal, the therapist should monitor and progress the chosen activities or exercises within established guidelines. (See Chapter 7 for guidelines related to aerobic exercise.)

An individual with identified risk factors for osteoporosis may require additional screening for balance and strength. The therapist can then develop an appropriate exercise program that reduces the risk of injury. (See Chapter 6 for precautions during resistance training and Chapter 8 for balance programs.)

### Determining Readiness to Change

Once the preparticipation screenings and risk assessments are completed, but prior to individualized program development, it is important to know where the person is in terms of readiness for behavior change. There are multiple theories and models related to health promotion interventions that explain how behavior change occurs. Understanding several of these behavioral change theories can help guide the therapist and client toward the desired outcome.

### BOX 2.2 Risk Factors for Coronary Artery Disease and Osteoporosis

#### Coronary Artery Disease Risk Factors

- Family history
- Cigarette smoking
- Hypertension
- Hypercholesterolemia
- Impaired fasting glucose level
- Obesity
- Sedentary lifestyle

#### Osteoporosis Risk Factors

- Bone mineral density score of  $-2.5$  or less
- Postmenopausal
- Caucasian or Asian descent
- Family history of osteoporosis
- Low body weight
- Inactive lifestyle
- Insufficient calcium and vitamin E
- Insufficient fruits and vegetables in diet
- Smoking
- Excessive consumption of alcohol
- Prolonged bed rest
- Prolonged use of corticosteroids and other medications, including selective serotonin reuptake inhibitors, proton pump inhibitors, and some antacids

## Behavioral Change Theories

**Social cognitive theory.** The underlying premise of the social cognitive theory is that learning occurs within a social context with a dynamic and reciprocal interaction between cognitive processes, environment, and behavior.<sup>11,12</sup> An individual must believe that he or she can change a particular behavior and that changing that behavior will lead to positive outcomes that outweigh possible negative outcomes one might experience.<sup>27,33,42,44,67</sup> For example, a patient/client may want to lose weight. In addition to the desire to change the behavior(s) causing the increased weight, the patient/client needs to believe that he or she is capable of succeeding (self-efficacy) and that the outcome will improve his or her health. If the patient/client decides to use exercise to lose weight, clear instructions on how to perform and progress the exercise program must be given. Feedback on performance must then occur to achieve the final outcome of weight reduction. Self-efficacy is one construct within this model. Many researchers have identified positive self-efficacy as the key to successful participation in physical activity.<sup>56,64,80</sup>

**Health belief model.** The health belief model (HBM), one of the most influential and widely used psychosocial approaches to explaining health-related behavior, was initially created to explain the failure of people to participate in programs to prevent or to detect disease.<sup>27,59</sup> The HBM has six constructs: perceived susceptibility, perceived severity, perceived benefits, perceived barriers, cues to action, and self-efficacy.<sup>59</sup> An individual must

have sufficient concern about developing an illness (perceived threat, mediated by perceived susceptibility and perceived severity of disease). Next, the individual needs to believe that they can be successful following the health recommendations (self-efficacy) and that by doing so, it is possible to achieve the desired outcome (perceived benefit). The likelihood of taking the preventative action is mediated by the perceived benefits minus the perceived barriers of such action. Modifying factors to perceived threat include cues to action, such as a reminder card from the dentist, media campaigns, or illness of a loved one.<sup>27</sup> Using the example of losing weight, an individual would have to believe that being overweight puts him or herself at a greater risk for developing heart disease (perceived threat). This threat may be greater because of a family history. The individual may understand that modifying the diet can help with weight loss but is not sure of the best way to proceed or if they can even be successful with dieting. The person may consider joining a weight loss program but may not be sure he or she can afford the weekly fee (perceived barrier). If the perceived threat is sufficiently high, the individual may choose to join the weight loss program to obtain the desired benefit or may choose a different method of weight loss that does not have the same cost, such as using Internet resources, like [myplate.gov](http://myplate.gov).

**Transtheoretical model.** The transtheoretical model (TTM), also known as the stages of change model, was first described by Prochaska in 1979. The TTM “is an integrative framework for understanding how individuals and populations progress toward adopting and maintaining health behavior change for optimal health.”<sup>55</sup>

The TTM has five stages of change:<sup>27, 44,55,59,67</sup>

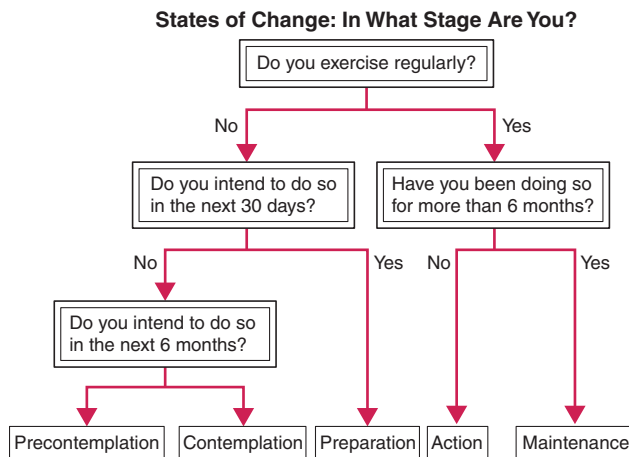

1. Precontemplation—no intention of making any changes within the next 6 months.
2. Contemplation—intend to make changes within the next 6 months.
3. Preparation—has begun to take steps toward making the desired change in behavior and plans to make the changes within the next 30 days.
4. Action—has changed the behavior for less than 6 months.
5. Maintenance—has changed the behavior for more than 6 months.

By knowing what stage an individual is in and knowing the beliefs they have regarding the need to change, the physical therapist can assist in planning the intervention, particularly if individuals are not ready to make any changes. It allows the therapist to give information needed at the appropriate time. Figure 2.2 depicts an algorithm for determining what stage of change an individual is in, using exercise as an example.

## FOCUS ON EVIDENCE

Using the HBM, Chen<sup>21</sup> assessed older adults in a long-term care (LTC) facility about barriers to participating in physical activity. The residents interviewed identified five main barriers: (1) physical frailty and health problems, (2) fear of falling

**FIGURE 2.2** Transtheoretical Model Algorithm. (Adapted from Reed et al: *What makes a good staging algorithm: Examples from regular exercise*. *Am J Health Promot* 12(2):57-66, 1997)<sup>57</sup>

and being injured, (3) past history of little to no physical activity, (4) limited knowledge about physical activity, and (5) restrictions within their environment. The author recommended addressing these modifiable barriers through careful planning, education, and interventions to increase physical activity in older adults living in LTC facilities to prevent further declines in function and mobility.

### Motivation Affecting the Ability to Change

By definition, motivation is how we move ourselves or others to act.<sup>64,67</sup> When attempting to motivate an individual or group, several dimensions of motivation need to be considered. What is the *intrinsic* motivation? Is it the goal or expectation to do one's personal best? Is it the level of difficulty of the task and any potential incentives? Does the individual have the ability to learn and act on what they learn to be successful?

Next, what is the *performance* motivation? Positive and negative reinforcement or rewards can improve performance, as can success or failure. Generally, the best performance motivators are low failure and/or high successes.

Finally, what is the *task* motivation? This relates to knowledge and feedback on the performance and should include information on how to improve.

## Physical Activity Guidelines

In October 2008, the US Department of Health and Human Services published *Physical Activity Guidelines for Americans*, which provides physical activity recommendations for persons 6 years and older and for specific subgroups.<sup>78</sup> This document is based on the findings of the Physical Activity Guidelines Advisory Committee, which conducted an extensive analysis

of the scientific information on physical activity and health. Their findings suggest that some physical activity is better than none and that more activity is better than some. The guidelines include the minimal level of recommended physical activity to achieve most health benefits, although additional benefits occur with more activity. These health benefits include the reduction in risk for many chronic diseases. The Physical Activity Guidelines Advisory Committee also found that muscle strengthening and aerobic activities are beneficial and that the benefits of physical activity far outweigh the risks. A process is currently in place to update the guidelines.

## Physical Activity Recommendations

In order to achieve the most health benefits, the following are identified for each age group.

### Children and Adolescents

Children and adolescents (aged 6 years and older) should participate in at least 60 minutes of moderate to vigorous physical activity daily.

- At least 3 days a week, the activity level should be vigorous
- Both bone and muscle strengthening activities should be included in daily activity at least 3 days per week.
- Activities should be both age appropriate and fun.

### Adults

Adults should participate in moderate intensity physical activity for a minimum of 150 minutes or vigorous intensity for 75 minutes per week.

- Episodes of at least 10 minutes count toward daily total.
- Muscles strengthening activities should be included at least 2 days per week.

### Older Adults

Older adults (65 years and older) should follow adult guidelines as able.

- Participate in moderate intensity physical activity for a minimum of 150 minutes or vigorous intensity for 75 minutes per week.
- Include balance exercises to reduce risk of falls.
- Episodes of at least 10 minutes count toward daily total.
- Muscles strengthening activities should be included at least 2 days per week.

### Adults With Disabilities

Adults with disabilities should follow adult guidelines as able. Those unable to meet the guidelines should:

- Engage in regular physical activity according to their abilities and should avoid inactivity.
- Consult with their health-care provider for an individualized program that is appropriate for their abilities.

## Considerations for People With Disabilities

Individuals with disability encompass almost 19% of the US population.<sup>14</sup> The World Health Organization (WHO) defines disability as an “umbrella term, covering impairments, activity limitations, and participation restrictions. Disability is the interaction between individuals with a health condition (e.g., cerebral palsy, Down syndrome, and depression) and personal and environmental factors (e.g., negative attitudes, inaccessible transportation and public buildings, and limited social supports).”<sup>82</sup> In the WHO’s ICF, disability and function are viewed as multifactorial and biopsychosocial phenomena, with both affected at the body, person, and society levels.<sup>49</sup>

### Health Disparities and Risks

As a group, individuals with disability experience greater health disparities than those without disability.<sup>60</sup> Adults with disabilities and chronic conditions generally receive fewer preventive services and have poorer health status than those without disabilities with the same conditions.<sup>58</sup> These individuals are at higher risk of secondary conditions, including obesity, hypertension, cardiac disease, stroke, diabetes, arthritis, asthma, and depression, and are more likely to engage in unhealthy behaviors like smoking, poor diet, and inadequate physical activity.<sup>58,60,61,79,82</sup> According to the WHO, while people with disabilities have the same health-care needs as those without disabilities, those with disabilities are two times more likely to find health-care provider’s with inadequate skill and facilities, 3 times more likely to be denied health care, and 4 times more likely to be treated poorly in the health-care system.<sup>81</sup>

People with disabilities, especially those with intellectual disabilities, have been described as having a “thinner margin of health,”<sup>53</sup> and therefore, physical activity is especially important. It is important to remember that individuals with disability are not “sick” but are more commonly in good health. However, their impairments of body functions and structures, activity limitations, and participation restrictions often put them at risk for and more vulnerable to health problems. Caretaker and family member attitudes of the individual’s abilities and disability can contribute to learned helplessness, creating further barriers to physical activity. Additionally, individuals with disabilities typically have fewer opportunities to participate in health promoting behaviors, as facilities are often not designed to be inclusive or adaptive.

Children with disabilities often have individualized education plans and routinely work with physical therapists both within and outside of school systems. As these individuals become adults, access to physical therapy may be limited. Too often, health and fitness professionals lack adequate training and/or comfort level in working with persons with disabilities, especially intellectual disabilities. Often, attitudes of family and caregivers about their own levels of fitness can affect

the attitude and fitness level of the person with disability, and education of those caregivers may also be necessary to facilitate fitness for the individual.

### Achieving Health Equity for Those with Disabilities

*Healthy People 2020* affirms that disparities are present for this population, and one of the four overarching goals of *Healthy People 2020* is to achieve health equity, eliminate disparities, and improve the health of all groups, including those with disabilities.<sup>73</sup> Some objectives in *Healthy People 2020* for people with disabilities are (1) inclusion in public health activities, (2) receiving well-timed intervention and services, (3) interaction with their environment without barriers, and (4) participation in everyday life activities. In order to meet these objectives, ways must be developed to include those with disabilities in public health programs.<sup>79</sup> Physical activity has a key role in increasing quality of years of healthy life and eliminating health disparities. As noted above in the *Physical Activity Guidelines for Americans*, those with disabilities should be physically active and avoid inactivity. Some objectives of a wellness program for people with disabilities are found in Box 2.3.

**Resources.** The National Center on Health, Physical Activity, and Disability (NCHPAD) is an excellent resource; it provides information on physical activity, health promotion, and disability, and it provides health promotion resources for professionals and for those with disabilities who want to achieve a healthy lifestyle.<sup>46</sup> The NCHPAD primarily serves persons with physical, sensory, and cognitive disabilities across the life span. Resources for professionals include tools for building inclusive communities, accessible fitness, inclusive fitness (i-Fit Tips), and a guidebook for healthy living with a spinal cord injury. There are also resources for individuals relating to living healthy with a variety of disabilities and ways to improve access in communities. The “Get the Facts” publication provides general exercise guidelines for individuals with disabilities, as well as a description of the NCHPAD’s 14-week fitness program. Box 2.4 provides preliminary steps to exercise for persons with disabilities, taken from the NCHPAD.

#### BOX 2.3 Sample Objectives of a Wellness Program for Individuals With Disabilities

1. Reduce secondary conditions
2. Maintain functional independence throughout life span
3. Provide an opportunity for leisure and enjoyment
4. Enhance overall quality of life by reducing environmental barriers to good health

### BOX 2.4 Preliminary Steps to Exercise (NCHPAD)<sup>46</sup>

1. Inform your physician, other health-care provider, or primary caregiver that you are considering starting an exercise program.
2. If possible, participate in a graded exercise test to determine your current level of fitness.
3. Find out the effects, if any, of your medication on exercise.
4. If possible, consult a trained exercise professional for an individualized exercise prescription.
5. Determine your goals and make sure they are S.M.A.R.T.\*\*

\*\*S.M.A.R.T. goals are Specific, Measurable, Attainable, Relevant, and Time Bound.

**Role of physical therapist.** Physical therapist interventions have a positive impact on overall health and wellness, primarily through patient/client education and movement. Physical therapists have opportunity to consult with individuals with disability and help them develop fitness programs to facilitate wellness. This is accomplished through interventions designed to improve muscle strength, flexibility, and endurance, as well as cardiovascular and pulmonary endurance. Major goals of fitness programs for individuals with developmental delay are provided in Box 2.5.<sup>62</sup>

**Exercise adherence.** Physical activity is important for all, especially so for those with disabilities, but adherence to a structured exercise program can be an issue. Some suggestions to

### BOX 2.5 Major Goals of a Fitness Program for Individuals With Developmental Delay<sup>62</sup>

1. Aim to expend 200 to 400 calories a day. Fittest persons aim for 400 kcal/day while less fit aim for 200 kcal/day, working up to 300 kcal/day after 6 months of training.
2. Use the 3-2-1 principle when developing your fitness program:
  - 30 minutes of cardiovascular training (starting at 45%-55% max heart rate)
  - 20 minutes of strength training (may take longer to master; stress safety)
  - 10 minutes of flexibility exercises
3. Include a variety of activities; have one program for M/W/F, another for Tu/Th, and different activities for the weekend.
4. Aim for 30 to 60 minutes a day. This can be broken up into 4 sets of 15 minute bouts, 3 sets of 20 minute bouts, or 2 sets of 30 minute bouts. Do what works for the individual.
5. For a structured program, get physician clearance.

improve exercise adherence in this population include using a buddy system to be physically active with a friend or caregiver, keeping an exercise log, and using a reward system (preferably not with food) when goals are achieved.<sup>62</sup> Remember, a “one size fits all” approach to physical activity does not work for individuals with disability. Consideration must be made for disability specific variability, an individual’s comorbidities, and personal and environmental barriers to participation. By addressing these concerns with a fitness program and achieving improved physical activity and fitness levels, impairments of body functions and structures, activity limitations, and participation restrictions may be prevented, remediated, and improved.<sup>5</sup>

## Mindfulness: Implications for Health and Wellness

Chronic or persistent pain, as well as chronic musculoskeletal conditions, have an effect on overall wellness. In the presence of chronic conditions, neurophysiological changes occur in the peripheral and central nervous systems. Integrating the principles of mindfulness with traditional exercise is an approach physical therapists can use to address these neuroplastic changes to help patients and clients with persistent symptoms deal with associated stress and anxiety.<sup>45,52</sup> Physical therapists routinely work on body and movement awareness, and the addition of mindful awareness may prove highly beneficial. Mindfulness can help a patient/client learn to separate the self from the illness and improve quality of life. Applications of mindful awareness include prevention of injury, rehabilitation, and increased tolerance of uncomfortable or painful medical treatments.

### Mindfulness Defined

*Mindfulness* has been defined as “paying attention in a particular way: on purpose, in the present moment, and non-judgementally.”<sup>39</sup> Simply, it means paying full attention. Mindfulness has also been described as “... the non-judgmental observation of the ongoing stream of internal and external stimuli as they arise.”<sup>10</sup> That is, recognizing that thoughts, perceptions, sensations, and emotions that enter one’s awareness are observed, but are not judged in any way—not good or bad, not helpful or detrimental, and not important or unimportant. With distraction being a dominant condition of modern Western culture, mindfulness is a logical response. Mindfulness is one way to focus attention on the here and now, and this approach meets people where they are, viewing them as whole rather than broken. McManus describes seven qualities of mindful awareness based on the work of Kabat-Zinn.<sup>40,45</sup> These seven qualities include present moment awareness, fundamental kindness, nonjudging, acceptance, nonstriving, not knowing, and letting go. These are further described in Box 2.6.

**BOX 2.6 Qualities of Mindful Awareness<sup>45</sup>**

1. *Present Moment.* Mindfulness invites one to be in the moment and experience peace and well-being in the here and now.
2. *Fundamental Kindness.* Meeting oneself with kindness; being friendly toward ourselves.
3. *Nonjudging.* Judging experiences as good or bad results in triggers for automatic behaviors based on past experiences and can limit understanding of the self. Mindfulness allows one to be an impartial witness without those automatic behaviors.
4. *Acceptance.* Accepting one's thoughts, feelings, and actions just as they are.
5. *Nonstriving.* Efforts are directed at being fully aware of one's experience just as it is, without trying to force or change that experience.
6. *Not Knowing.* Mindfulness allows the temporary suspension of preconceived ideas, concepts, and expectations so that new learning can occur and life can be revealed rather than forced. It is meeting the world with a "beginner's mind."
7. *Letting Go.* Recognizing that life is change, mindfulness allows one to let go and be open to those changes.

**Mindfulness Meditation**

*Mindfulness meditation* is defined as "the deliberate training of the mind in present moment awareness" and generally results in increased compassion, understanding, inner peace, and well-being.<sup>45</sup> Mindfulness based stress reduction (MBSR) was first developed by Jon Kabat-Zinn in 1979 at the University of Massachusetts Medical Center and was originally housed in the Department of Physical Therapy there before moving to the College of Medicine.<sup>45</sup> The effects of MBSR and mindfulness meditation have been studied in persons with chronic pain, multiple sclerosis, depression and anxiety, cancer, and psoriasis and in high school, college, and elite athletes.

Research suggests that mindfulness meditation has a positive effect on attention regulation, body awareness, and emotional regulation.<sup>36</sup> MBSR programs promote acceptance without judgment to minimize anxiety and its effects on pain processing as well as encouraging movement and relaxation and translation of these skills to daily life.<sup>35,52</sup> Mindfulness meditation has been shown to have positive influence on immune response,<sup>31</sup> reduction in stress response,<sup>30</sup> reduction in serum cortisol levels, increased serum protein, and reduction in heart rate and blood pressure.<sup>66</sup> There is increasing evidence that mindfulness meditation can significantly attenuate the subjective experience of pain.<sup>84</sup> It has been suggested that mindfulness meditation-related pain relief may share a common final pathway with other cognitive techniques in pain modulation, with resultant reappraisal of faulty beliefs and restructuring of negative conditions.<sup>84</sup> MBSR has also been shown to decrease stress, anxiety, and depression associated with persistent

pain, improve pain acceptance, and it shows promise in the treatment of central sensitization in those with chronic musculoskeletal disorders.<sup>29,35,52,63</sup>

**Mindful Breathing**

Mindful breathing is one method to integrate mindfulness in physical therapist interventions. Patients and clients often hold their breath when performing a painful movement or exercise that is very challenging. McManus advocates that every wellness program should include instruction in mindful breathing. She suggests that the practice of mindful breathing allows one to observe automatic mental, physical, and emotional reactions, which can play a role in symptom severity and distress.<sup>45</sup>

Mindful breathing involves observing the breath and breathing deeply during distress, and it can be taught as a part of mindfulness meditation (15 to 60 minutes) or as brief (5-minute) practices. One example of mindful breathing is found in Box 2.7. Further examples can be found in the McManus text,<sup>45</sup> or one can Google "mindful breathing exercises" for a host of examples. Other exercises in mindfulness meditation can be found by searching Google or YouTube. Numerous apps are also now available for use on mobile phones and tablets for the practice of mindfulness.

**Mindful Eating**

One often cited exercise to learn the skill of mindfulness, described by Kabat-Zinn, is the mindful eating exercise.<sup>40</sup> With this exercise, which lasts approximately 5 minutes or more, one practices mindful eating with a raisin. As with other mindfulness exercises, provide the instruction that when one finds the mind wandering from the task at hand, gently return one's attention to the raisin and what is being done with it. The raisin is first held in the hand and observed, examining the color and details of the raisin. One considers how the raisin came to be in one's hand, from its planting and growth, to its harvesting, and to its placement in the hand. It is moved in the hand, appreciating the texture, and it is smelled, noticing any response of the salivary glands or the stomach. It is placed in the mouth, with the sensation of that appreciated. It is then chewed, appreciating the sensation of that and both the texture and taste of the raisin and the body's response to it. Finally, the raisin is swallowed. The experience is then considered.

## Developing and Implementing a Wellness Program

In general, there are several steps to follow when developing and implementing prevention, health, and wellness programs.<sup>27,44</sup> These steps are summarized in Box 2.8. The following case example illustrates the process.

**BOX 2.7 Mindful Breathing Exercise (from McManus<sup>45</sup>)**

- Sit comfortably and avoid slouching. Sit so that your shoulders are aligned over your hips and both feet are on the floor. Close your eyes. Consider the quality of awareness you might bring to something in nature, such as how you might look at the ocean or mountains. This quality of awareness is open and nonjudging.
- Now bring this same quality of awareness to your inner landscape and observe your breathing. As you inhale, simply feel what part of your body moves. As you exhale, simply feel what part of your body moves as you exhale. Do not try to consciously change your breathing. Simply observe your breathing just as it is.
- You can experience the movement of your breathe in different places in your body. You might notice your belly move, your rib cage rising and falling, or your chest moving as you breathe. Each breath is unique. Simply experience the movement of your body as it occurs, moment to moment.

(Pause to allow participants to practice.)

- Now place one hand on your upper chest. Draw your stomach in slightly and breathe into your hand. Allow your breath to be of average size. You should feel your upper chest and rib cage rise and fall. Observe these sensations as they are. This is called upper chest or shallow breathing.

(Pause to allow for practice.)

- Observe how you feel.
- Now place your hand on your stomach at the level of your navel. As you inhale, imagine breathing into your hand. You

should experience your stomach pushing forward into your hand as you breathe in. You may also feel your lower ribs flare out slightly. As you exhale, your stomach should gently fall. This is called diaphragmatic or abdominal breathing.

(Pause to allow for practice.)

- Observe how you feel.
- Now allow our breathing to return to whatever feels comfortable and natural for you. Simply observe your experience just as it is.

(Brief pause)

- Now, slightly round your shoulders and assume a slouched position. Notice how this affects your breathing.

(Pause to allow for practice.)

- Return to sitting upright and draw your shoulders blades back and down and your chest up slightly. This movement should be small and gentle. Notice how this movement affects your breathing.

(Pause to allow for practice.)

- Now, return to a comfortable position and breathing pattern that feels natural for you. Once again, observe your breath in and your breath out.

(Pause to allow for practice.)

- And now, gradually return your awareness to the room and let your eyes open.

**BOX 2.8 Steps to Develop and Implement Prevention, Health, Wellness, and Fitness Programs****Step 1: Identify a Need**

- Identify the intended audience
  - Children
  - Adults
  - Older adults
  - Industry/business
  - School system
  - Community
  - Specific population (e.g., individuals with Parkinson's disease)

**Step 2: Set Goals and Objectives**

- Identify the purpose of the program
- Identify the goals to be achieved
  - Screening
  - Education
  - Exercise program
- Identify the objectives of the program

**Step 3: Develop the Intervention**

- Screenings: Identify valid and reliable right tools to use for the screening
- Education: Develop the program including handouts for participants
- Exercise: Develop the plan for each class

**Logistics**

- Secure a location for the program
- Consider parking and access to the facility
- Determine the time and length of the program
- Determine the number of people who can attend based on the space
- Identify who will do the program (self or with assistance)
- Develop the presentation/program; include handouts for the participants
- Develop a budget; determine costs and charge to the participants

**Step 4: Implement the Intervention**

- Recognize that even with the best of plans it is important to be adaptable and to be prepared for the unexpected

**Step 5: Evaluate the Results**

- For an educational session, ask the participants to evaluate the program; consider an additional follow-up assessment
- For an exercise class, record baseline data and assess progress during the program and at the end
- Ask participants to evaluate the exercise program
- Ask for feedback on what could be done to improve the program (e.g., different time, smaller class, longer sessions, etc.)

## Case Example: Exercise and Osteoporosis

### Step 1: Assessing the Need

- Gretchen, a physical therapist at ABC Hospital, completed an educational session for a local osteoporosis support group on the most recent research related to resistance training and weight-bearing exercise for increasing bone density.
- The women contacted Gretchen and asked her to develop a resistance training exercise class that included free weights and exercise equipment (as found in a fitness club).

NEED: An exercise class that educates women with osteoporosis about the safe way to perform resistance exercise.

### Step 2: Set Goals and Objectives

#### Goal

Develop two education and exercise classes (level 1 and level 2) for women with osteoporosis that emphasize prevention of fractures and proper technique for resistance exercise and weight-bearing activities.

#### Objectives

1. Educate the participants on the effects of resistance training and weight-bearing exercise on bone health.
2. Educate the participants on the indications and contraindications of certain exercises for individuals with osteoporosis.
3. Educate the participants on the correct techniques for resistance exercise including free weights, resistance band and tubing, and exercise machines.
4. Have participants demonstrate the correct technique when performing resistance exercise.
5. Review implications related to posture and body mechanics during daily activities and during exercise.

### Step 3: Develop the Intervention

Gretchen decided to develop two exercise classes: level 1 and level 2. To attend level 2 classes, participants had to complete the level 1 class. The level 1 exercise and education class consisted of four sessions as outlined in Table 2.4.

Gretchen decided to work collaboratively with the Occupational Therapy Department and together they conducted the final class, which emphasized the correct techniques for posture and body mechanics during daily activities. Once the number of classes and general content was decided, Gretchen started planning and developing the program.

- She reserved a medium-sized, open room in ABC hospital for 4 weeks and scheduled the class for Tuesday evenings from 6:00 p.m. to 8:30 p.m.
- She determined that the room be set up with tables and chairs in the front for lecture and discussion and with open space in the back for exercising. Classes would be limited to 20 people.
- She developed the content and objectives for each exercise/education session including handouts for participants. She

**TABLE 2.4** Sample: Level 1 Exercise and Educational Class Content for Osteoporosis

Session	Content/Plan
1	<ul style="list-style-type: none"> <li>■ Introduction</li> <li>■ Discussion about yearly height measurement</li> <li>■ Assessment of balance and flexibility of ankles, falls risk assessment</li> <li>■ Review and discussion of good posture</li> <li>■ Discussion on benefits of resistance training</li> <li>■ Perform exercises—shoulder blade retraction, chin tucks, sit to stand from a chair, pelvic tilt, heel/toe raises</li> </ul>
2	<ul style="list-style-type: none"> <li>■ Brief review and questions related to material from first class</li> <li>■ Discussion on prevention of falls</li> <li>■ Discussion and demonstration of correct technique for performing strengthening exercises</li> <li>■ Perform exercises with resistance band: arms—bilateral horizontal abduction, rhomboids (band in doorway), leg press</li> <li>■ Perform exercises without band—standing hip abduction and step-ups</li> </ul>
3	<ul style="list-style-type: none"> <li>■ Brief review and questions related to previous material</li> <li>■ Discussion of types of exercise to avoid (increase stress on vertebral bodies)</li> <li>■ Discussion and demonstration on how to lift weights correctly and how to determine starting weight</li> <li>■ Discussion on how to increase repetitions and weight during exercise</li> <li>■ Perform exercises with and without free weights—overhead press, seated fly, standing hip extension, prone bilateral scapular retraction, prone opposite arm and leg lift, lunges</li> </ul>
4	<ul style="list-style-type: none"> <li>■ Review and questions over previous material</li> <li>■ Occupational therapy reviewed various adaptive equipment</li> <li>■ Demonstrated correct posture and body mechanics for brushing teeth, making bed, vacuuming</li> <li>■ Final questions</li> <li>■ Evaluation of program</li> </ul>

- put all developed material in a binder by week, including a presenter's checklist of what had to be brought to each class.
- She developed a brochure with times and location of the class and sent it to the osteoporosis support group. The cost of the level 1 exercise and education program was \$25. Interested participants were to call and reserve a spot in the class.

### Step 4: Implement the Program

The program had 10 participants and took place as scheduled for 4 weeks.

### Step 5: Evaluate the Program

Participants were given a course evaluation sheet to complete regarding the location, time, content, and overall satisfaction with the program. In addition, Gretchen evaluated the participants' interest in the proposed level 2 class that would take place in a fitness center with equipment and consist of three sessions.

The overall evaluation of the program was positive, with a few individuals preferring a different day of the week or time of day for attendance. Altogether, 8 of the 10 participants were interested in participating in the level 2 class.

## Additional Considerations for Developing Prevention, Health, and Wellness Programs

The following are additional points to consider:<sup>43</sup>

- The exercise or activity has to be specific to the goals of the individual. An individual training to run a marathon needs to run, not ride a bike. Specific principles and procedures for resistance training and aerobic exercise training can be found in Chapters 6 and 7, respectively.
- Consider asking the participants during the “assessing the need” component about what would motivate individuals to participate and then incorporate some of their suggestions.
- For children, the program should be fun and less structured but should take place for a specified period of time. The recommended amount of physical activity for children is 60 minutes (moderate and vigorous) every day.<sup>76</sup>
- For older adults, the program should start slowly to allow the participants to experience success. Consideration should be given to how the individuals can incorporate the various exercises or activities into their daily routines. The facility where the program is conducted should be well lit and easily accessible. The physical activity guidelines are

the same for adults and older adults, 30 minutes a day of moderate intensity aerobic activity at least 5 days per week for a minimum of 10-minute bouts, unless they are unable because of chronic conditions. Older adults should also do exercises to maintain or improve balance to reduce fall risk.<sup>77</sup> Additional information on exercises in the older population in Chapter 24.

- If screenings are conducted, take-home materials with the results and with follow-up recommendations should be given to the participants.
- When making handouts for participants, keep in mind the audience. For children, make them colorful and fun. For older adults, make the print larger. Keep the language simple. Limit the amount of medical terminology used. Write information as clearly as possible.
- Include pictures of exercises whenever possible.
- Consider the time commitment for you and the participants and the cost involved.

Table 2.5 lists issues related to exercise adherence.

**TABLE 2.5** Issues Affecting Exercise Adherence

Poor	Good
Poor or limited leadership	Effective leadership
Inconvenient class time or location	Part of regular routine or program
Injury	No injury
Boredom with exercise	Enjoyment—fun—variety
Poor individual commitment	Social support from group
Unaware of any progress being made	Regular updates on progress
Poor family support—disapproval	Family approval; positive reinforcement

## Independent Learning Activities

### Critical Thinking and Discussion

1. In the case example for developing an exercise program for women with osteoporosis, a second class (level 2) was proposed. Develop the level 2 class. Follow the steps outlined for developing and implementing this program including the content of each exercise session, use of fitness equipment for individuals with osteoporosis, and any handouts needed.
2. In this chapter, the differences in primary, secondary, and tertiary prevention were reviewed. For each of these categories, describe one screening program and one wellness program (exercise or education) that a physical therapist could provide.
3. One of the *Healthy People 2020* goals is to reduce the activity limitations (functional limitations) of individuals with chronic low back pain. Describe the limitations to

achieving this goal using one of the behavioral change theories. Identify strategies for obtaining this goal.

- Using the five steps identified in this chapter, develop a prevention and wellness program for a group of fifth and sixth

grade boys and girls (10 to 12 years of age) who have been identified as being at risk for type 2 diabetes because of obesity and sedentary lifestyle. Refer to Chapter 6 for special considerations when developing exercise programs for children.

## ROM Through Functional Patterns 80

Independent Learning Activities 80

**Range of motion** is a basic technique used for the examination of movement and for initiating movement into a program of therapeutic intervention. Movement that is necessary to accomplish functional activities can be viewed, in its simplest form, as muscles or external forces moving bones in various patterns or ranges of motions. When a person moves, the intricate control of the muscle activity that causes or controls the motion comes from the central nervous system. Bones move with respect to each other at the connecting joints. The structure of the joints, as well as the integrity and flexibility of the soft tissues that pass over the joints, affects the amount of motion that can occur between any two bones. The full motion possible is called the **range of motion** (ROM). When moving a segment through its ROM, all structures in the region are affected: muscles, joint surfaces, synovial fluid, joint capsules, ligaments, fasciae, vessels, and nerves. ROM activities are most easily described in terms of joint range and muscle range. To describe joint range, terms such as flexion, extension, abduction, adduction, and rotation are used. Ranges of available joint motion are usually measured with a goniometer and recorded in degrees.<sup>21</sup> Muscle range is related to the functional excursion of muscles.

**Functional excursion** is the distance that a muscle is capable of shortening after it has been elongated to its maximum.<sup>13</sup> In some cases the functional excursion, or range of a muscle, is directly influenced by the joint it crosses. For example, the range for the brachialis muscle is limited by the range available at the elbow joint. This is true of one-joint muscles (muscles with their proximal and distal attachments

on the bones on either side of one joint). For two-joint or multijoint muscles (those muscles that cross over two or more joints), their range goes beyond the limits of any one joint they cross. An example of a two-joint muscle functioning at the hip and knee is the hamstring muscle group. If it contracts and moves the knee into flexion while simultaneously moving the hip into extension, it shortens to a point known as *active insufficiency*, where it is too short to produce much tension. This is one end of its range. When it is fully lengthened and limits motion at one of the joints it crosses, it is known as *passive insufficiency*. This occurs in the hamstring muscle when the knee is extended and full range of hip flexion is limited (or conversely, when the hip is flexed full range and knee extension is limited). Two-joint or multijoint muscles normally function in the midportion of their functional excursion where ideal length-tension relations exist.<sup>13</sup>

To maintain normal ROM, the segments must be moved through their available ranges periodically, whether it is the available joint range or muscle range. It is recognized that many factors, such as systemic, joint, neurological, or muscular diseases; surgical or traumatic insults; or simply inactivity or immobilization for any reason, can lead to decreased ROM. Therapeutically, ROM activities are administered to maintain joint and soft tissue mobility to minimize loss of tissue flexibility and contracture formation.<sup>7</sup> Extensive research by Robert Salter has provided evidence of the benefits of movement on the healing of tissues in various pathological conditions in both the laboratory and clinical settings.<sup>28-34</sup>

The principles of ROM described in this chapter do not encompass stretching to increase range. Principles and techniques of stretching and joint manipulation for treating impaired mobility are described in Chapters 4 and 5.

## Types of ROM Exercises

**Passive ROM.** Passive ROM (PROM) is movement of a segment within the unrestricted ROM that is produced entirely by an *external force*; there is little to no voluntary muscle contraction. The external force may be from gravity, a machine, another individual, or another part of the individual's own body.<sup>9</sup> PROM and passive stretching are not synonymous. (See Chapter 4 for definitions and descriptions of passive stretching.)

**Active ROM.** Active ROM (AROM) is movement of a segment within the unrestricted ROM that is produced by active contraction of the *muscles* crossing that joint.

**Active-assistive ROM.** Active-assistive ROM (A-AROM) is a type of AROM in which assistance is provided manually or mechanically by an outside force because the prime mover muscles need assistance to complete the motion.

## Indications, Goals, and Limitations of ROM

### Passive ROM

#### Indications for PROM

- In the region where there is acute, inflamed tissue, passive motion is beneficial; active motion would be detrimental to the healing process. Inflammation after injury or surgery usually lasts 2 to 6 days.
- When a patient is not able to or not supposed to actively move a segment(s) of the body, as when comatose, paralyzed, or on complete bed rest, movement is provided by an external source.
- PROM is indicated after surgical repair of contractile tissue when active motion would compromise the repaired muscle.

#### Goals for PROM

The primary goal for PROM is to decrease the complications that would occur with immobilization, such as cartilage degeneration, adhesion and contracture formation, and sluggish circulation.<sup>9,27,33</sup> Specifically, the goals are to:

- Maintain joint and connective tissue mobility.
- Minimize the effects of the formation of contractures.
- Maintain mechanical elasticity of muscle.
- Assist circulation and vascular dynamics.
- Enhance synovial movement for cartilage nutrition and diffusion of materials in the joint.
- Decrease or inhibit pain.

- Assist with the healing process after injury or surgery.
- Help maintain the patient's awareness of movement.

#### Other Uses for PROM

- When a therapist is examining inert structures, PROM is used to determine limitations of motion, joint stability, muscle flexibility, and other soft tissue elasticity.
- When a therapist is teaching an active exercise program, PROM is used to demonstrate the desired motion.
- When a therapist is preparing a patient for stretching, PROM is often used preceding the passive stretching techniques.

#### Limitations of Passive Motion

True passive, relaxed ROM may be difficult to obtain when muscle is innervated and the patient is conscious. Passive motion *does not*:

- Prevent muscle atrophy
- Increase strength or endurance
- Assist circulation to the extent that active, voluntary muscle contraction does

### Active and Active-Assistive ROM

#### Indications for AROM

- When a patient is able to contract the muscles actively and move a segment with or without assistance, AROM is used.
- When a patient has weak musculature and is unable to move a joint through the desired range (usually against gravity), A-AROM is used to provide enough assistance to the muscles in a carefully controlled manner so the muscle can function at its maximum level and be progressively strengthened. Once patients gain control of their ROM, they are progressed to manual or mechanical resistance exercises to improve muscle performance for a return to functional activities (see Chapter 6).
- When a segment of the body is immobilized for a period of time, AROM is used on the regions above and below the immobilized segment to maintain the areas in as normal a condition as possible and to prepare for new activities such as walking with crutches.
- AROM can be used for aerobic conditioning programs (see Chapter 7) and is used to relieve stress from sustained postures (see Chapter 14).

#### Goals for AROM

If there is no inflammation or contraindication to active motion, the same goals of PROM can be met with AROM. In addition, there are physiological benefits that result from active muscle contraction and motor learning from voluntary muscle control. Specific goals are to:

- Maintain physiological elasticity and contractility of the participating muscles.
- Provide sensory feedback from the contracting muscles.
- Provide a stimulus for bone and joint tissue integrity.
- Increase circulation and prevent thrombus formation.
- Develop coordination and motor skills for functional activities.

### Limitations of Active ROM

For strong muscles, AROM *does not* maintain or increase strength. It also *does not* develop skill or coordination except in the movement patterns used.

## Precautions and Contraindications to ROM Exercises

Although both PROM and AROM are contraindicated under any circumstance when motion to a part is disruptive to the healing process (Box 3.1), complete immobility leads to adhesion and contracture formation, sluggish circulation, and a prolonged recovery time. In light of research by Salter<sup>30</sup> and others,<sup>18</sup> early, continuous PROM within a pain-free range has been shown to be beneficial to the healing and early recovery of many soft tissue and joint lesions (discussed later in the chapter). Historically, ROM has been contraindicated immediately after acute tears, fractures, and surgery, but because the benefits of controlled motion have demonstrated decreased pain and an increased rate of recovery, early controlled motion is used as long as the patient's tolerance is monitored.

It is imperative that the therapist recognizes the value as well as potential abuse of motion and stays within the range, speed, and tolerance of the patient during the acute recovery

stage.<sup>9</sup> Additional trauma to the part is contraindicated. Signs of too much or the wrong motion include increased pain and increased inflammation (greater swelling, heat, and redness). See Chapter 10 for principles of when to use the various types of passive and active motion therapeutically.

Usually, AROM of the upper extremities and limited walking near the bed are tolerated as early exercises after myocardial infarction, coronary artery bypass surgery, and percutaneous transluminal coronary angioplasty. Careful monitoring of symptoms, perceived exertion, and blood pressure is necessary.<sup>8,24</sup> If the patient's response or the condition is life-threatening, PROM may be carefully initiated to the major joints along with some AROM to the ankles and feet to avoid venous stasis and thrombus formation. Individualized activities are initiated and progress gradually based on the patient's tolerance.<sup>8,24</sup>

Early mobility for patients on mechanical ventilation (initiated 1 to 2 days after intubation in one study<sup>25</sup> or less than 3 days in another study<sup>35</sup>) that includes sedative interruption followed by AROM, with progression to the activities of daily living (ADLs) of sitting, standing, and walking has been shown to improve patient status when compared with standard care as measured by duration of delirium, ventilator-free days, and functional outcome at hospital discharge.

## Principles and Procedures for Applying ROM Techniques

### Examination, Evaluation, and Treatment Planning

1. Examine and evaluate the patient's impairments and level of function, determine any precautions and their prognosis, and plan the intervention.
2. Determine the ability of the patient to participate in the ROM activity and whether PROM, A-AROM, or AROM can meet the immediate goals.
3. Determine the amount of motion that can be applied safely for the condition of the tissues and health of the individual.
4. Decide what patterns can best meet the goals. ROM techniques may be performed in the:
  - a. *Anatomic planes of motion*: frontal, sagittal, and transverse
  - b. *Muscle range of elongation*: antagonistic to the line of pull of the muscle
  - c. *Combined patterns*: diagonal motions or movements that incorporate several planes of motion
  - d. *Functional patterns*: motions used in ADLs
5. Monitor the patient's general condition and responses during and after the examination and intervention; note any change in vital signs; in the warmth and color of the segment; and in the ROM, pain, or quality of movement.
6. Document and communicate findings and intervention.
7. Re-evaluate and modify the intervention as necessary.

#### BOX 3.1 Summary of Precautions and Contraindications to ROM Exercises

ROM should not be done when motion is disruptive to the healing process.

- Carefully controlled motion within the limits of pain-free motion during early phases of healing has been shown to benefit healing and early recovery.
- Signs of too much or the wrong motion include increased pain and inflammation.
- ROM should not be done when patient response or the condition is life-threatening.
- PROM may be carefully initiated to major joints and AROM to ankles and feet to minimize venous stasis and thrombus formation.
- After myocardial infarction, coronary artery bypass surgery, or percutaneous transluminal coronary angioplasty, AROM of upper extremities and limited walking are usually tolerated under careful monitoring of symptoms.
- Sedative interruption followed by AROM with progression to sitting, standing, and walking may be initiated early on mechanically ventilated patients

Note: ROM is not synonymous with stretching. For precautions and contraindications to passive and active stretching techniques, see Chapters 4 and 5.

## Patient Preparation

1. Communicate with the patient. Describe the plan and method of intervention to meet the goals.
2. Free the region from restrictive clothing, linen, splints, and dressings. Drape the patient as necessary.
3. Position the patient in a comfortable position with proper body alignment and stabilization but that also allows you to move the segment through the available ROM.
4. Position yourself so proper body mechanics can be used.

## Application of Techniques

1. To control movement, grasp the extremity around the joints. If the joints are painful, modify the grip, still providing support necessary for control.
2. Support areas of poor structural integrity, such as a hypermobile joint, recent fracture site, or paralyzed limb segment.
3. Move the segment through its complete pain-free range to the point of tissue resistance. Do not force beyond the available range. If you force motion, it becomes a stretching technique.
4. Perform the motions smoothly and rhythmically, with 5 to 10 repetitions. The number of repetitions depends on the objectives of the program and the patient's condition and response to the treatment.

## Application of PROM

1. During PROM, the force for movement is external; it is provided by a therapist or mechanical device. When appropriate, a patient may provide the force and be taught to move the part with a normal extremity.
2. No active resistance or assistance is given by the patient's muscles that cross the joint. If the muscles contract, it becomes an active exercise.
3. The motion is carried out within the free ROM—that is, the range that is available without forced motion or pain.

## Application of AROM

1. Demonstrate the motion desired using PROM; then ask the patient to perform the motion. Have your hands in position to assist or guide the patient if needed.
2. Provide assistance only as needed for smooth motion. When there is weakness, assistance may be required only at the beginning or the end of the ROM or when the effect of gravity has the greatest moment arm (torque).
3. The motion is performed within the available ROM.

## ROM Techniques

The descriptions of positions and ROM techniques in this section may be used for PROM as well as A-AROM and AROM. When making the transition from PROM to AROM, gravity has

a significant impact, especially in individuals with weak musculature. When the segment moves up against gravity, it may be necessary to provide assistance to the patient. However, when moving parallel to the ground (gravity eliminated or gravity neutral), the part may need only to be supported while the muscles take the part through the range. When the part moves downward, with gravity causing the motion, muscles antagonist to the motion become active and may need assistance in controlling the descent of the part. The therapist must be aware of these effects and modify the patient's position if needed to meet desired goals for A-AROM and AROM. Principles and techniques for progression to manual and mechanical resistance ROM to develop strength are described in Chapter 6.

### CLINICAL TIP

- When transitioning from PROM to AROM, vary patient position to use gravity to either assist or resist the motion.
- Functional activities that are antigavity will require assistance when the muscle test grades are less than 3/5.

The following descriptions are, for the most part, with the patient in the supine position. Alternate positions for many motions are possible and, for some motions, necessary. For efficiency, perform all motions possible in one position; then change the patient's position and perform all appropriate motions in that position, progressing the treatment with minimal turning of the patient. Individual body types or environmental limitations might necessitate variations of the suggested hand placements. Use of good body mechanics by the therapist while applying proper stabilization and motion to the patient to accomplish the goals and avoid injury to weakened structures is the primary consideration.

**NOTE:** The term *upper hand*, or *top hand*, means the hand of the therapist that is toward the patient's head; the *bottom hand*, or *lower hand*, refers to the hand toward the patient's foot. Antagonistic ROMs are grouped together for ease of application.

## Upper Extremity

### Shoulder: Flexion and Extension (Fig. 3.1)

#### VIDEO 3.2

#### Hand Placement and Procedure

- Grasp the patient's arm under the elbow with your lower hand.
- With the top hand, cross over and grasp the wrist and palm of the patient's hand.
- Lift the arm through the available range and return.

**NOTE:** For normal motion, the scapula should be free to rotate upward as the shoulder flexes. If motion of only the glenohumeral joint is desired, the scapula is stabilized as described in the chapter on stretching (see Chapter 4).

**FIGURE 3.1** Hand placement and positions for (A) initiating and (B) completing shoulder flexion.

### Shoulder: Extension (Hyperextension) (Fig. 3.2)

To obtain extension past zero, position the patient's shoulder at the edge of the bed when supine or position the patient side-lying, prone, or sitting.

**FIGURE 3.2** Hyperextension of the shoulder (A) with the patient at the edge of the bed and (B) with the patient side-lying.

### Shoulder: Abduction and Adduction (Fig. 3.3)

#### Hand Placement and Procedure

Use the same hand placement as with flexion, but move the arm out to the side. The elbow may be flexed for ease in completing the arc of motion.

**NOTE:** To reach full range of abduction, there must be external rotation of the humerus and upward rotation of the scapula.

**FIGURE 3.3** Abduction of the shoulder with the elbow flexed.

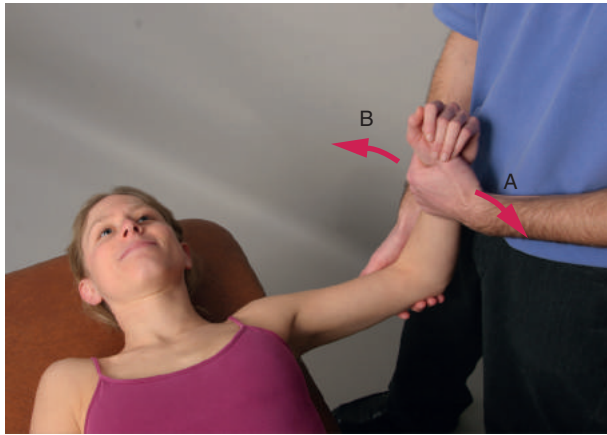

### Shoulder: Internal (Medial) and External (Lateral) Rotation (Fig. 3.4)

If possible, the arm is abducted to 90°, the elbow is flexed to 90°, and the forearm is held in neutral position. Rotation may also be performed with the patient's arm at the side of the thorax, but full internal rotation is not possible in this position.

#### Hand Placement and Procedure

- Grasp the hand and the wrist with your index finger between the patient's thumb and index finger.
- Place your thumb and the rest of your fingers on either side of the patient's wrist, thereby stabilizing the wrist.

**FIGURE 3.4** The 90/90 position for initiating (A) internal and (B) external rotation of the shoulder.

- With the other hand, stabilize the elbow.
- Rotate the humerus by moving the forearm like a spoke on a wheel.

### Shoulder: Horizontal Abduction (Extension) and Adduction (Flexion) (Fig. 3.5)

To reach full horizontal abduction, position the patient's shoulder at the edge of the table. Begin with the arm either adducted or abducted 90°.

**FIGURE 3.5** Horizontal (A) abduction and (B) adduction of the shoulder.

### Hand Placement and Procedure

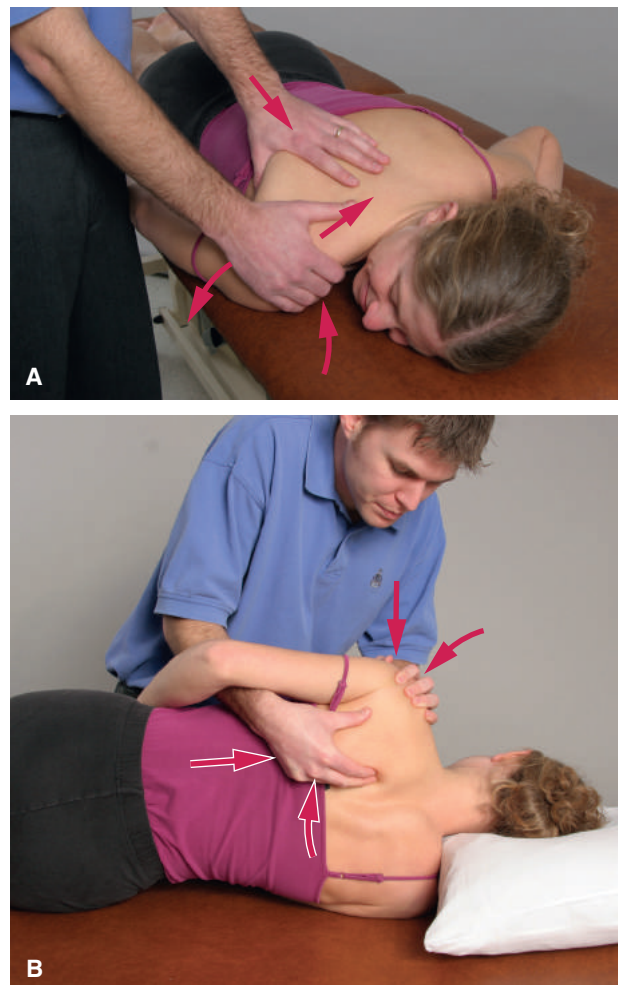

Hand placement is the same as with flexion, but turn your body and face the patient's head as you move the patient's arm out to the side and then across the body.

### Scapula: Elevation/Depression, Protraction/Retraction, and Upward/Downward Rotation (Fig. 3.6)

Position the patient prone with his or her arm at the side (Fig. 3.6A) or side-lying facing toward you with the patient's arm draped over your bottom arm (Fig. 3.6B).

### Hand Placement and Procedure

- Cup the top hand over the acromion process and place the other hand around the inferior angle of the scapula.
- For elevation, depression, protraction, and retraction, the clavicle also moves as the scapular motions are directed at the acromion process.
- For rotation, direct the scapular motions at the inferior angle of the scapula while simultaneously pushing the acromion in the opposite direction to create a force couple turning effect.

**FIGURE 3.6** ROM of the scapula with the patient (A) prone and with the patient (B) side-lying.

## Elbow: Flexion and Extension (Fig. 3.7)

### VIDEO 3.3

#### Hand Placement and Procedure

- Grasp the distal forearm and support the wrist with one hand. This hand also controls forearm supination and pronation.
- With the other hand, support the elbow.
- Flex and extend the elbow with the forearm supinated and also with the forearm pronated.

**NOTE:** The scapula should not tip forward when the elbow extends, as it disguises the true range.

**FIGURE 3.7** Elbow (A) flexion and (B) extension with the forearm supinated.

### Elongation of Two-Joint Biceps Brachii Muscle

To extend the shoulder beyond zero, position the patient's shoulder at the edge of the table when supine or position the patient prone lying, sitting, or standing.

#### Hand Placement and Procedure

- First, pronate the patient's forearm by grasping the wrist and extend the elbow while supporting it.
- Then, extend (hyperextend) the shoulder to the point of tissue resistance in the anterior arm region. At this point, full available lengthening of the two-joint muscle is reached.

### Elongation of Two-Joint Long Head of the Triceps Brachii Muscle (Fig. 3.8)

When the near-normal range of the triceps brachii muscle is available, the patient must be sitting or standing to reach the full ROM. With marked limitation in muscle range, ROM can be performed in the supine position.

#### Hand Placement and Procedure

- First, fully flex the patient's elbow with one hand on the distal forearm.
- Then, flex the shoulder by lifting up on the humerus with the other hand under the elbow.
- Full available range is reached when discomfort is experienced in the posterior arm region.

**FIGURE 3.8** End ROM for the long head of the triceps brachii muscle.

## Forearm: Pronation and Supination (Fig. 3.9)

#### Hand Placement and Procedure

Perform pronation and supination with the elbow flexed as well as extended. When the elbow is extended, prevent the shoulder from rotating by stabilizing the elbow.

- Grasp the patient's wrist, supporting the hand with the index finger and placing the thumb and the rest of the fingers on either side of the distal forearm.
- Stabilize the elbow with the other hand.
- The motion is a rolling of the radius around the ulna at the distal radius.

#### Alternate Hand Placement

Sandwich the patient's distal forearm between the palms of both hands.

**FIGURE 3.9** Pronation of the forearm.

**PRECAUTION:** Do not stress the wrist by twisting the hand; control the pronation and supination motion by moving the radius around the ulna.

### Wrist: Flexion (Palmar Flexion) and Extension (Dorsiflexion); Radial (Abduction) and Ulnar (Adduction) Deviation (Fig. 3.10) VIDEO 3.4 🌐

#### Hand Placement and Procedure

For all wrist motions, grasp the patient's hand just distal to the joint with one hand and stabilize the forearm with your other hand.

**NOTE:** The range of the extrinsic muscles to the fingers affects the range at the wrist if tension is placed on the tendons as they cross into the fingers. To obtain full range of the wrist joint, allow the fingers to move freely as you move the wrist.

**FIGURE 3.10** ROM at the wrist. Shown is wrist flexion; note that the fingers are free to move in response to passive tension in the extrinsic tendons.

### Hand: Cupping and Flattening the Arch of the Hand at the Carpometacarpal and Intermetacarpal Joints (Fig. 3.11)

#### Hand Placement and Procedure

- Face the patient's hand; place the fingers of both of your hands in the palms of the patient's hand and your thenar eminences on the posterior aspect.
- Roll the metacarpals palmarward to increase the arch and dorsalward to flatten it.

#### Alternate Hand Placement

One hand is placed on the posterior aspect of the patient's hand with the fingers and thumb cupping the metacarpals.

**FIGURE 3.11** ROM to the arch of the hand.

**NOTE:** Extension and abduction of the thumb at the carpometacarpal joint are important for maintaining the web space for functional movement of the hand. Isolated flexion-extension and abduction-adduction ROM of this joint should be performed by moving the first metacarpal while stabilizing the trapezium.

### Joints of the Thumb and Fingers: Flexion and Extension and Abduction and Adduction (Fig. 3.12) VIDEO 3.5 🌐

The joints of the thumbs and fingers include the metacarpophalangeal and interphalangeal joints.

#### Hand Placement and Procedure

- Depending on the position of the patient, stabilize the forearm and hand on the bed or table or against your body.

**FIGURE 3.12** ROM to the metacarpophalangeal joint of the thumb.

- Move each joint of the patient's hand individually by stabilizing the proximal bone with the index finger and thumb of one hand and moving the distal bone with the index finger and thumb of the other hand.

#### Alternate Procedure

Several joints can be moved simultaneously if proper stabilization is provided. Example: To move all the metacarpophalangeal joints of digits 2 through 5, stabilize the metacarpals with one hand and move all the proximal phalanges with the other hand.

**NOTE:** To accomplish full joint ROM, do not place tension on the extrinsic muscles going to the fingers. Tension on the muscles can be relieved by altering the wrist position as the fingers are moved.

### Elongation of Extrinsic Muscles of the Wrist and Hand: Flexor and Extensor Digitorum Muscles (Fig. 3.13)

#### General Technique

##### Hand Placement and Procedure

- First, move the distal interphalangeal joint and stabilize it; then move the proximal interphalangeal joint.
- Hold both these joints at the end of their range; then move the metacarpophalangeal joint to the end of the available range.
- Stabilize all the finger joints and begin to extend the wrist. When the patient feels discomfort in the forearm, the muscles are fully elongated.

**NOTE:** Motion is initiated in the distal-most joint of each digit to minimize compression of the small joints. Full joint ROM will not be possible when the extrinsic muscles are elongated.

FIGURE 3.13 End of range for the extrinsic finger (A) flexors and

FIGURE 3.13 (B) extensors.

## Lower Extremity

### Combined Hip and Knee: Flexion and Extension (Fig. 3.14) VIDEO 3.6

To reach full range of hip flexion, the knee must also be flexed to release tension on the hamstring muscle group. To reach full range of knee flexion, the hip must be flexed to release tension on the rectus femoris muscle.

#### Hand Placement and Procedure

- Support and lift the patient's leg with the palm and fingers of the top hand under the patient's knee and the lower hand under the heel.
- As the knee flexes full range, swing the fingers to the side of the thigh.

FIGURE 3.14 (A) Initiating and

**FIGURE 3.14—cont'd (B)** completing combined hip and knee flexion.

### Hip: Extension (Hyperextension) (Fig. 3.15)

Prone or side-lying must be used if the patient has near-normal or normal motion.

#### Hand Placement and Procedure

- If the patient is prone, lift the thigh with the bottom hand under the patient's knee; stabilize the pelvis with the top hand or arm.
- If the patient is side-lying, bring the bottom hand under the thigh and place the hand on the anterior surface; stabilize the pelvis with the top hand. For full range of hip extension, do not flex the knee full range, as the two-joint rectus femoris would then restrict the range.

**FIGURE 3.15** Hip extension with the patient side-lying.

### Elongation of the Two-Joint Hamstring Muscle Group (Fig. 3.16)

#### Hand Placement and Procedure

- Place the lower hand under the patient's heel and the upper hand across the anterior aspect of the patient's knee.

**FIGURE 3.16** ROM to the hamstring muscle group.

- Keep the knee in extension as the hip is flexed.
- If the knee requires support, cradle the patient's leg in your lower arm with your elbow flexed under the calf and your hand across the anterior aspect of the patient's knee. The other hand provides support or stabilization where needed.

**NOTE:** If the hamstrings are so tight as to limit the knee from going into extension, the available range of the muscle is reached simply by extending the knee as far as the muscle allows and not moving the hip.

### Elongation of the Two-Joint Rectus Femoris Muscle

Position the patient supine with knee flexed over the edge of the treatment table or position prone.

#### Hand Placement and Procedure

- When supine, stabilize the lumbar spine by flexing the hip and knee of the opposite lower extremity and placing the foot on the treatment table (hook-lying).
- When prone, stabilize the pelvis with the top hand (see Fig. 4.31).
- Flex the patient's knee until tissue resistance is felt in the anterior thigh, which means the full available range is reached.

### Hip: Abduction and Adduction (Fig. 3.17)

#### Hand Placement and Procedure

- Support the patient's leg with the upper hand under the knee and the lower hand under the ankle.
- For full range of adduction, the opposite leg needs to be in a partially abducted position.
- Keep the patient's hip and knee in extension and neutral to rotation as abduction and adduction are performed.

**FIGURE 3.17** Abduction of the hip, maintaining the hip in extension and neutral to rotation.

### Hip: Internal (Medial) and External (Lateral) Rotation

#### Hand Placement and Procedure With the Hip and Knee Extended

- Grasp just proximal to the patient's knee with the top hand and just proximal to the ankle with the bottom hand.
- Roll the thigh inward and outward.

#### Hand Placement and Procedure for Rotation With the Hip and Knee Flexed (Fig. 3.18)

- Flex the patient's hip and knee to 90°; support the knee with the top hand.
- If the knee is unstable, cradle the thigh and support the proximal calf and knee with the bottom hand.
- Rotate the femur by moving the leg like a pendulum.
- This hand placement provides some support to the knee but should be used with caution if there is knee instability.

**FIGURE 3.18** Rotation of the hip with the hip positioned in 90° of flexion.

### Ankle: Dorsiflexion (Fig. 3.19) VIDEO 3.7

#### Hand Placement and Procedure

- Stabilize around the malleoli with the top hand.
- Cup the patient's heel with the bottom hand and place the forearm along the bottom of the foot.
- Pull the calcaneus distalward with the thumb and fingers while pushing upward with the forearm.

**NOTE:** If the knee is flexed, full range of the ankle joint can be obtained. If the knee is extended, the lengthened range of the two-joint gastrocnemius muscle can be obtained, but the gastrocnemius limits full range of dorsiflexion. Apply dorsiflexion in both positions of the knee to provide range to both the joint and the muscle.

**FIGURE 3.19** Dorsiflexion of the ankle.

### Ankle: Plantarflexion

#### Hand Placement and Procedure

- Support the heel with the bottom hand.
- Place the top hand on the dorsum of the foot and push it into plantarflexion.

**NOTE:** In bed-bound patients, the ankle tends to assume a plantarflexed position from the weight of the blankets and the pull of gravity, so this motion may not need to be performed.

### Subtalar (Lower Ankle) Joint: Inversion and Eversion (Fig. 3.20)

#### Hand Placement and Procedure

- Using the bottom hand, place the thumb medial and the fingers lateral to the joint on either side of the heel.
- Turn the heel inward and outward.

**NOTE:** Supination of the foot may be combined with inversion, and pronation may be combined with eversion.

**FIGURE 3.20** Inversion of the subtalar joint.

### Transverse Tarsal Joint

#### Hand Placement and Procedure

- Stabilize the patient's talus and calcaneus with one hand.
- With the other hand, grasp around the navicular and cuboid.
- Gently rotate the midfoot by lifting and lowering the arch.

### Joints of the Toes: Flexion and Extension and Abduction and Adduction (Metatarsophalangeal and Interphalangeal Joints) (Fig. 3.21)

#### Hand Placement and Procedure

- Stabilize the bone proximal to the joint that is to be moved with one hand, and move the distal bone with the other hand.
- The technique is the same as for ROM of the fingers.
- Several joints of the toes can be moved simultaneously if care is taken not to stress any structure.

**FIGURE 3.21** Extension of the metatarsophalangeal joint of the large toe.

### Cervical Spine VIDEO 3.8

Stand at the end of the treatment table; securely grasp the patient's head by placing both hands under the occipital region.

### Flexion (Forward Bending) (Fig. 3.22A)

#### Procedure

- Lift the head as though it were nodding (chin toward larynx) to flex the head on the neck.
- Once full nodding is complete, continue to flex the cervical spine and lift the head toward the sternum.

**FIGURE 3.22** Cervical (A) flexion and

### Extension (Backward Bending or Hyperextension)

#### Procedure

Tip the head backward.

**NOTE:** If the patient is supine, only the head and upper cervical spine can be extended; the head must clear the end of the table to extend the entire cervical spine. The patient may also be prone or sitting.

### Lateral Flexion (Side Bending) and Rotation (Fig. 3.22B)

#### Procedure

Maintain the cervical spine neutral to flexion and extension as you direct the head and neck into side bending (approximate the ear toward the shoulder) and rotation (rotate from side to side).

**FIGURE 3.22** (B) rotation.

## Lumbar Spine VIDEO 3.9

### Flexion (Fig. 3.23)

#### Hand Placement and Procedure

- Bring both of the patient's knees to the chest by lifting under the knees (hip and knee flexion).
- Flexion of the spine occurs as the hips are flexed full range and the pelvis starts to rotate posteriorly.
- Greater range of flexion can be obtained by lifting under the patient's sacrum with the lower hand.

**FIGURE 3.23** Lumbar flexion is achieved by bringing the patient's hips into flexion until the pelvis rotates posteriorly.

### Extension

Position the patient prone for full extension (hyperextension).

#### Hand Placement and Procedure

With hands under the thighs, lift the thighs upward until the pelvis rotates anteriorly and the lumbar spine extends.

### Rotation (Fig. 3.24)

Position the patient in the hook-lying position with hips and knees flexed and feet resting on the table.

#### Hand Placement and Procedure

- Push both of the patient's knees laterally in one direction until the pelvis on the opposite side comes up off the treatment table.
- Stabilize the patient's thorax with the top hand.
- Repeat in the opposite direction.

**FIGURE 3.24** Rotation of the lumbar spine results when the thorax is stabilized and the pelvis lifts off the table as far as allowed.

### CLINICAL TIP

Effective and efficient ROM can be administered by combining several joint motions that transect several planes resulting in oblique, functional, or diagonal patterns.

- For example, wrist flexion may be combined with ulnar deviation or shoulder flexion may be combined with abduction and lateral rotation.
- Use patterns that mimic functional activities such as moving hand behind head as in combing hair—add rotation of the neck. See also Box 3.3 at the end of the chapter.
- Proprioceptive neuromuscular facilitation (PNF) patterns of movement may be effectively used for PROM, AROM, or A-AROM techniques. See Chapter 6 for descriptions of these patterns.

## Self-Assisted ROM

Patient involvement in self-care should begin as soon as the individual is able to understand and learn what to do. Even with weakness or paralysis, the patient can learn how to move the involved part and be instructed in the importance of movement within safe parameters. After surgery or traumatic injury, self-assisted ROM (S-AROM) is used to protect the healing tissues when more intensive muscle contraction is contraindicated. A variety of devices as well as use of a normal extremity may be used to meet the goals of PROM or A-AROM. Incorporation of S-AROM then becomes a part of the home exercise program (Box 3.2).

### Manual Assistance

With cases of unilateral weakness or paralysis or during early stages of recovery after trauma or surgery, the patient can be taught to use the uninvolved extremity to move the involved

### BOX 3.2 Self-assisted ROM Techniques

#### Forms of Self-assisted ROM

- Manual
- Equipment
  - Wand or T-bar
  - Finger ladder, wall climbing, ball rolling
  - Pulleys
  - Skate board/powder board
  - Reciprocal exercise devices

#### Guidelines for Teaching Self-assisted ROM

- Educate the patient on the value of the motion.
- Teach the patient correct body alignment and stabilization.
- Observe patient performance and correct any substitute or unsafe motions.
- If equipment is used, make sure all hazards are eliminated so application will be safe.
- Provide drawings and clear guidelines for number of repetitions and frequency.

Review the exercises at a follow-up session. Modify or progress the exercise program based on the patient response and treatment plan for meeting the outcome goals.

extremity through ranges of motion. These exercises may be done supine, sitting, or standing. The effects of gravity change with patient positioning, so when lifting the part against gravity, gravity provides a resistive force against the prime motion and, therefore, the prime mover requires assistance. When the extremity moves downward, gravity causes the motion, and the antagonists need assistance to control the motion eccentrically.

### Arm and Forearm

Instruct the patient to reach across the body with the uninjured (or assisting) extremity and grasp the involved extremity around the wrist, supporting the wrist and hand.

- **Shoulder flexion and extension.** The patient lifts the involved extremity over the head and returns it to the side (Fig. 3.25).
- **Shoulder horizontal abduction and adduction.** Beginning with the arm abducted 90°, the patient pulls the extremity across the chest and returns it to the side.
- **Shoulder rotation.** Beginning with the arm at the patient's side in slight abduction and with the elbow resting on a small pillow to elevate it or abducted 90° and elbow flexed 90°, the patient moves the forearm "like a spoke on a wheel" with the uninjured extremity (Fig. 3.26). It is important to emphasize rotating the humerus, not merely flexing and extending the elbow.
- **Elbow flexion and extension.** The patient bends the elbow until the hand is near the shoulder and then moves the hand down toward the side of the leg.

**FIGURE 3.25** Patient giving self-assisted ROM to shoulder flexion and extension. Horizontal abduction and adduction can be applied with the same hand placement.

**FIGURE 3.26** Arm position of patient for giving self-assisted ROM to internal and external rotation of shoulder.

- **Pronation and supination of the forearm.** Beginning with the forearm resting across the body, the patient rotates the radius around the ulna. Emphasize to the patient not to twist the hand at the wrist joint.

### Wrist and Hand

The patient moves the uninjured fingers to the dorsum of the hand and the thumb into the palm of the hand.

- **Wrist flexion and extension and radial and ulnar deviation.** The patient moves the wrist in all directions, applying no pressure against the fingers (Fig. 3.27).

**FIGURE 3.27** Patient applying self-assisted wrist flexion and extension with no pressure against the fingers.

- **Finger flexion and extension.** The patient uses the uninvolved thumb to extend the involved fingers and cups the normal fingers over the dorsum of the involved fingers to flex them (Fig. 3.28).

**FIGURE 3.28** Patient applying self-assisted finger flexion and extension.

- **Thumb flexion with opposition and extension with reposition.** The patient cups the uninvolved fingers around the radial border of the thenar eminence of the involved thumb and places the uninvolved thumb along the palmar surface of the involved thumb to extend it (Fig. 3.29). To flex and oppose the thumb, the patient cups the normal hand around the dorsal surface of the involved hand and pushes the first metacarpal toward the little finger.

**FIGURE 3.29** Patient applying self-assisted thumb extension.

### Hip and Knee

- **Hip and knee flexion.** With the patient supine, instruct the patient to initiate the motion by lifting the involved knee by slipping his or her normal foot under the knee or with a strap or belt under the involved knee (Fig. 3.30). The patient can then grasp the knee with one or both hands to bring the knee up toward the chest to complete the range. With the patient sitting, he or she may lift the thigh with the hands and flex the knee to the end of its available range.

**FIGURE 3.30** Self-assisted flexion of the hip.

- **Hip abduction and adduction.** It is difficult for the weak patient to assist the lower extremities into abduction and adduction when supine owing to the weight of the leg and the friction of the bed surface. It is necessary, though, for the individual to move a weak lower extremity from side to side for bed mobility. To practice this functional activity as an exercise, instruct the patient to slide the normal foot from the knee down to the ankle and then move the involved extremity from side-to-side. S-AROM can be performed sitting by using the hands to assist moving the thigh outward and inward.

- **Combined hip abduction with external rotation.** The patient sits on the floor or on a bed with the back supported, the involved hip and knee flexed, and the foot resting on the surface. The knee is moved outward (toward the table/bed) and back inward, with assistance from the upper extremities (Fig. 3.31).

**FIGURE 3.31** Self-assisted hip abduction and external rotation.

### Ankle and Toes

- The patient sits with the involved extremity crossed over the uninvolved one so the distal leg rests on the normal knee. The uninvolved hand moves the involved ankle into dorsiflexion, plantarflexion, inversion, and eversion and toe flexion and extension (Fig. 3.32).

### Wand (T-Bar) Exercises

When a patient has voluntary muscle control in an involved upper extremity but needs guidance or motivation to complete the ROM in the shoulder or elbow, a wand (dowel rod, cane, wooden stick, T-bar, or similar object) can be used to provide assistance (Fig. 3.33).

The choice of position is based on the patient's level of function. Most of the techniques can be performed supine if maximum protection is needed. Sitting or standing requires greater control. Choice of position is also guided by the effects of gravity on the weak muscles. Initially, guide the patient through the proper motion for each activity to ensure that he or she does not use substitute motions. The patient grasps the wand with both hands, and the normal extremity guides and controls the motions.

- **Shoulder flexion and return.** The wand is grasped with the hands a shoulder width apart. The wand is lifted forward

**FIGURE 3.32** Position of patient and hand placement for self-assisted ankle and toe motions; shown is inversion and eversion.

and upward through the available range, with the elbows kept in extension if possible (Fig. 3.33A). Scapulohumeral motion should be smooth; do not allow substitute motions such as scapular elevation or trunk movement.

- **Shoulder horizontal abduction and adduction.** The wand is lifted to 90° shoulder flexion. Keeping the elbows extended, the patient pushes and pulls the wand back and forth across the chest through the available range (Fig. 3.33B). Do not allow trunk rotation.
- **Shoulder internal and external rotation.** The patient's arms are at the sides, and the elbows are flexed 90°. Rotation of the arms is accomplished by moving the wand from side to side across the trunk while maintaining the elbows at the side (Fig. 3.33C). The rotation should occur in the humerus; do not allow elbow flexion and extension. To prevent substitute motions as well as provide a slight distraction force to the glenohumeral joint, a small towel roll may be placed in the axilla with instruction to the patient to "keep the roll in place."
- **Shoulder internal and external rotation—alternate position.** The patient's shoulders are abducted 90°, and the elbows are flexed 90°. For external rotation, the wand is moved toward the patient's head; for internal rotation, the wand is moved toward the waistline.
- **Elbow flexion and extension.** The patient's forearms may be pronated or supinated; the hands grasp the wand a shoulder-width apart. Instruct the patient to flex and extend the elbows.
- **Shoulder hyperextension.** The patient may be standing or prone. He or she places the wand behind the buttocks, grasps the wand with hands a shoulder width apart, and

**FIGURE 3.33** Patient using a wand for self-assisted shoulder (A) flexion, (B) horizontal abduction/adduction, and (C) rotation.

then lifts the wand backward away from the trunk. The patient should avoid trunk motion.

- **Variations and combinations of movements.** For example, the patient begins with the wand behind the buttocks and then moves the wand up the back to achieve scapular winging, shoulder internal rotation, and elbow flexion.

## Wall Climbing

Wall climbing (or use of a device such as a finger ladder) can provide the patient with objective reinforcement and, therefore, motivation for performing shoulder ROM. Wall markings may

also be used to provide visual feedback for the height reached. The arm may be moved into flexion or abduction (Fig. 3.34). The patient steps closer to the wall as the arm is elevated.

**PRECAUTION:** The patient must be taught the proper motions and not allowed to substitute with trunk side bending, toe raising, or shoulder shrugging.

**FIGURE 3.34** Wall climbing for shoulder elevation.

## Overhead Pulleys

If properly taught, pulley systems can be effectively used to assist an involved extremity in performing ROM. The pulley has been demonstrated to utilize significantly more muscle activity than therapist-assisted ROM and continuous passive motion machines (described later in the chapter), so this form of assistance should be used only when muscle activity is desired.<sup>6</sup>

For home use, a single pulley may be attached to a strap that is held in place by closing the strap in a door. A pulley may also be attached to an overhead bar or affixed to the ceiling. The patient should be set up so the pulley is directly over the joint that is moving or so the line of pull is effectively moving the extremity and not just compressing the joint surfaces together. The patient may be sitting, standing, or supine.

## Shoulder ROM (Fig. 3.35)

Instruct the patient to hold one handle in each hand, and with the normal hand, pull the rope and lift the involved extremity forward (flexion), out to the side (abduction), or in the plane of the scapula (scaption is 30° forward of the frontal plane). The patient should not shrug the shoulder (scapular elevation) or lean the trunk. Guide and instruct the patient so there is smooth motion.

**FIGURE 3.35** Use of overhead pulleys to assist shoulder elevation.

**PRECAUTION:** Assistive pulley activities for the shoulder are easily misused by the patient, resulting in compression of the humerus against the acromion process. Continual compression leads to pain and decreased function. Proper patient selection and appropriate instruction can avoid this problem. If a patient cannot learn to use the pulley with proper shoulder mechanics, these exercises should not be performed. Discontinue this activity if there is increased pain or decreased mobility.

### Elbow Flexion

With the arm stabilized along the side of the trunk, the patient lifts the forearm and bends the elbow.

### Skate Board/Powder Board

Use of a friction-free surface may encourage movement without the resistance of gravity or friction. If available, a skate with rollers may be used. Other methods include using powder on the surface or placing a towel under the extremity so it can slide along the smooth surface of the board. Any motion can be done, but most common are abduction/adduction of the hip while supine and horizontal abduction/adduction of the shoulder while sitting.

### Reciprocal Exercise Unit

Several devices, such as a bicycle, upper body or lower body ergometer, or a reciprocal exercise unit, can be set up to provide some flexion and extension to an involved extremity using the strength of the normal extremity. Movable devices that can be attached to a patient's bed, wheelchair, or standard chair are available. The circumference of motion as well as

excursion of the extremities can be adjusted. A reciprocal exercise unit has additional exercise benefits in that it can be used for reciprocal patterning, endurance training, and strengthening by changing the parameters of the exercise and monitoring the heart rate and fatigue. See Chapter 6 for principles of resistance exercise and Chapter 7 for principles of aerobic exercise.

## Continuous Passive Motion

**Continuous passive motion (CPM)** refers to passive motion performed by a mechanical device that moves a joint slowly and continuously through a controlled ROM. The mechanical devices that exist for nearly every joint in the body (Fig. 3.36) were developed as a result of research by Robert Salter, who demonstrated that continual passive motion has beneficial healing effects on diseased or injured joint structures and soft tissues in animal and clinical studies.<sup>28-34</sup> Since the development of CPM, many studies have been done to determine the

**FIGURE 3.36** Continuous motion devices for (A) the shoulder and (B) the knee.

parameters of application, but because the devices are used for many conditions and studies have used various protocols with varying research designs, no definitive delineation has been established.<sup>4,16,22</sup>

## Benefits of CPM

CPM has been reported to be effective in lessening the negative effects of joint immobilization in conditions such as arthritis, contractures, and intra-articular fractures<sup>23</sup>; some studies report improved recovery rate and ROM, particularly early in the recovery period after a variety of surgical procedures,<sup>3,16,22,28-34,36</sup> although other studies question the need for its use when long-term measures show little or no difference in outcomes compared with traditional therapy.<sup>11,17,19</sup> Suggested benefits of CPM include:

- Preventing development of adhesions and contractures and thus joint stiffness
- Providing a stimulating effect on the healing of tendons and ligaments
- Enhancing the healing of incisions over the moving joint
- Increasing synovial fluid lubrication of the joint and thus increasing the rate of intra-articular cartilage healing and regeneration
- Preventing the degrading effects of immobilization
- Providing a quicker return of ROM
- Decreasing postoperative pain

### FOCUS ON EVIDENCE

Studies have compared short- and long-term outcomes of CPM use after various types of surgery using various parameters as well as CPM with other methods of early movement and positioning.<sup>1,5,6,11,14,15,22,17,26,27,37,39</sup> Some studies have shown no significant difference between patients undergoing CPM and those undergoing PROM or other forms of early motion.<sup>5,14,15,27,38</sup> Reports of the short-term benefits of CPM use after surgery were that patients gained ROM more quickly and therefore experienced earlier discharge from the hospital when CPM was used compared with other forms of intervention.<sup>3</sup> However, long-term functional gains are reported to be no different from those in patients who underwent other forms of early motion.<sup>4,17,37,39</sup>

The authors of an updated Cochrane Review of 24 randomized controlled trials in which CPM was used following total knee arthroplasty summarized that for patients who had CPM combined with physical therapy, the clinical effects on active knee flexion ROM, pain, function, and quality of life were not significant enough to justify its use as a routine intervention. There was no significant difference in passive knee flexion or passive or active knee extension.<sup>11</sup>

Another Cochrane Review looked at the use of CPM for the prevention of venous thromboembolism after total knee arthroplasty using 11 randomized controlled trials involving 808 patients. The authors concluded that there was insufficient

evidence to state that CPM reduces thromboembolism after total knee arthroplasty.<sup>12</sup> They suggested that additional quality studies are needed.

Some studies have identified detrimental effects such as the need for greater analgesic intervention and increased postoperative blood drainage when using CPM<sup>26,38</sup> in contrast to claims that CPM decreases postoperative pain and complications.<sup>29-33,36</sup> The cost-effectiveness of the CPM equipment, patient compliance, utilization and supervision of equipment by trained personnel, length of hospital stay, speed of recovery, and determination of appropriate patient populations become issues to consider when making the choice of whether or not to utilize CPM devices.<sup>15,20</sup>

## General Guidelines for CPM

General guidelines for CPM are as follows:<sup>2,4,10,16,18,28,33</sup>

1. The device may be applied to the involved extremity immediately after surgery while the patient is still under anesthesia or as soon as possible if bulky dressings prevent early motion.
2. The arc of motion for the joint is determined. A low arc of 20° to 30° is often used initially and progressed 10° to 15° per day as tolerated. The portion of the range used initially is based on the range available and patient tolerance. One study that looked at accelerating the range of knee flexion after total knee arthroplasty found that a greater range and earlier discharge were attained for that group of patients,<sup>39</sup> although there was no difference between the groups at 4 weeks.
3. The rate of motion is determined; usually 1 cycle/45 sec or 2 min is well tolerated.
4. The length of time on the CPM machine varies for different protocols—anywhere from continuous for 24 hours to continuous for 1 hour three times a day.<sup>10,18,33</sup> The longer periods of time per day reportedly result in a shorter hospital stay, fewer postoperative complications, and greater ROM at discharge,<sup>10</sup> although no significant difference was found in a study comparing CPM for 5 hr/day with CPM for 20 hr/day.<sup>2</sup> A study that compared short-duration CPM (3 to 5 hr/day) with long-duration CPM (10 to 12 hr/day) found that patient compliance and the most gained range occurred with a CPM duration of 4 to 8 hours.<sup>4</sup>
5. Physical therapy treatments are usually initiated during periods when the patient is not on CPM, including active-assistive and muscle-setting exercises. It is important that patients learn to use and develop motor control of the ROM as motion improves.
6. The duration minimum for CPM is usually less than 1 week or when a satisfactory range of motion is reached. Because CPM devices are portable, home use is possible in cases in which the therapist or physician deems that additional time would be beneficial. In these cases, the patient, a family member, or a caregiver is instructed in proper application.

7. CPM machines are designed to be adjustable, easily controlled, versatile, and portable. Some are battery operated (with rechargeable batteries) to allow the individual to wear the device for up to 8 hours while functioning with daily activities.

## ROM Through Functional Patterns

To accomplish motion through functional patterns, first determine what pattern of movement is desired and then move the extremity through that pattern using manual

assistance, mechanical assistance if it is appropriate, or self-assistance from the patient. Functional patterning can be beneficial in initiating the teaching of ADLs and instrumental activities of daily living (IADLs) as well as in instructing patients with visual impairments in functional activities. Utilizing functional patterns helps the patient recognize the purpose and value of ROM exercises and develop motor patterns that can be used in daily activities as strength and endurance improves. Box 3.3 identifies some examples and the basic motions that are utilized. When the patient no longer requires assistance to perform the pattern safely and correctly, the activity is incorporated into his or her daily activities so motor learning is reinforced and the motion becomes functional.

### BOX 3.3 Functional ROM Activities

Early ROM training for functional upper extremity and neck patterns may include activities such as:

- Grasping an eating utensil: utilizing finger extension and flexion
- Eating (hand to mouth): utilizing elbow flexion and forearm supination and some shoulder flexion, abduction, and lateral rotation
- Reaching to various shelf heights: utilizing shoulder flexion and elbow extension
- Brushing or combing back of hair: utilizing shoulder abduction and lateral rotation, elbow flexion, and cervical rotation
- Holding a phone to the ear: utilizing shoulder lateral rotation, forearm supination, and cervical side bend
- Donning or doffing a shirt or jacket: utilizing shoulder extension, lateral rotation, and elbow flexion and extension

- Reaching out a car window to an ATM machine: utilizing shoulder abduction, lateral rotation, elbow extension, and some lateral bending of the trunk

Early ROM training for functional lower extremity and trunk patterns may include activities such as:

- Going from supine to sitting at the side of a bed: utilizing hip abduction and adduction followed by hip and knee flexion
- Standing up/sitting down and walking: utilizing hip and knee flexion and extension, ankle dorsi and plantarflexion, and some hip rotation
- Putting on socks and shoes: utilizing hip external rotation and abduction, knee flexion and ankle dorsi and plantarflexion, and trunk flexion

## Independent Learning Activities

### Critical Thinking and Discussion

1. Analyze a variety of functional activities, such as grooming, dressing, bathing, raising up from a chair, and getting in and out of a car; determine the functional ranges needed to perform each task.
2. Look at the effects of gravity or other forces on the ROM for each activity listed in #1. If you have a patient who is unable to do the activity because of an inability to control the range needed, determine how you would establish an exercise program to begin preparing the individual to develop the desired function.

- a. and hip extension, knee flexion with the hip extended, and rotation of the hip?
  - b. Progress the PROM to A-AROM and AROM, and determine the effects of gravity and the effort required in these positions compared with that in the supine position.
2. Compare the ROMs of the hip, knee, and ankle when each of the two joint muscles is elongated over its respective joint versus when each of the muscles is slack.

### Laboratory Practice

1. Perform PROM of the upper and lower extremities with your partner placed in a prone, side-lying, and sitting position.
  - a. What are the advantages and disadvantages of each of the positions for some of the ranges, such as shoulder

## Independent Learning Activities 123

The term *mobility* is often defined as the ability of body structures or segments to move so that range of motion (ROM) for functional activities is allowed (*functional ROM*).<sup>3</sup> It can also be defined as the ability of an individual to initiate, control, or sustain active movements of the body to perform motor tasks (*functional mobility*).<sup>41,116</sup> Mobility, as it relates to functional ROM, is associated with both joint integrity and soft tissue *flexibility*. In this context, the soft tissues that cross or surround joints must have sufficient extensibility to allow an individual to perform their functional tasks and activities. Importantly, the ROM needed to perform functional activities does not necessarily mean full or “normal” ROM.

Sufficient soft tissue mobility and joint ROM must also be supported by a requisite level of muscle function, including strength, endurance, and neuromuscular control. Not only

does adequate muscle function enable functional mobility, it also helps manage imposed physical loads and may help prevent musculoskeletal injury.<sup>58,66,71,120,132,159</sup>

*Hypomobility*, or reduced functional motion, is often caused by adaptive shortening or decreased extensibility in soft tissues. Potential factors leading to hypomobility include (1) prolonged immobilization of a body segment, (2) sedentary lifestyle, (3) postural malalignment with muscle length alterations, (4) impaired muscle performance (weakness) associated with musculoskeletal or neuromuscular disorders, (5) tissue trauma resulting in inflammation and pain, and (6) congenital or acquired deformities. Any factor that limits mobility by decreasing the extensibility of soft tissues may also lead to impaired muscular performance.<sup>82</sup> Hypomobility can contribute to activity limitations and participation restrictions in a person’s life.<sup>10,18</sup>

Stretching interventions become an integral component of an individualized rehabilitation program when restricted mobility adversely affects function or increases the risk of injury. Stretching exercises also are considered an important element of fitness and sport-specific conditioning programs designed to promote wellness and reduce the risk of injury or re-injury.<sup>58,120,132,159</sup> *Stretching* is a general term used to describe any therapeutic maneuver designed to *increase* soft tissue extensibility with the intent of improving flexibility and ROM by elongating (lengthening) structures that have adaptively shortened and have become hypomobile.<sup>70,155</sup>

Only through a systematic examination, evaluation, and diagnosis of a patient's problems can a therapist determine what structures are restricting motion and if, when, and what types of stretching procedures are indicated. Early in the rehabilitation process, manual stretching and joint mobilization/manipulation, which involve direct, "hands-on" intervention by a practitioner, may be the most appropriate techniques. Later, self-stretching exercises performed independently by a patient after careful instruction and close supervision may be a more suitable intervention. In some situations the use of a mechanical stretching device is indicated, particularly when manual therapies have been ineffective. Regardless of the types of stretching used as an intervention, any gains in ROM should be used regularly during functional activities and strengthening exercises. The stretching interventions described in this chapter are designed to improve the extensibility of the contractile and noncontractile components of muscle-tendon units and periarticular structures. The efficacy of these interventions is explored throughout the chapter. In addition to the stretching procedures for the extremities illustrated in this chapter, self-stretching exercises for each region of the body are described and illustrated in Chapters 16 through 22. Joint mobilization/manipulation procedures for extremity joints are described and illustrated in Chapter 5 and for the temporomandibular joints, ribs, and sacrum in Chapter 15. Spinal manipulative techniques are presented in Chapter 16.

## Definition of Terms Associated With Mobility and Stretching

### Flexibility

*Flexibility* is the ability to rotate a single joint or series of joints smoothly and easily through an unrestricted, pain-free ROM.<sup>82,100</sup> Muscle length, joint integrity, and periarticular soft tissue extensibility all interact to determine flexibility.<sup>3</sup> Flexibility is maximized when the muscle-tendon units that cross a joint have adequate extensibility to deform and yield

to a stretch force. In addition, the arthrokinematics of the moving joint (the ability of the joint surfaces to roll and slide) and the ability of periarticular connective tissues to deform also affect joint ROM and flexibility.

### Dynamic and Passive Flexibility

**Dynamic flexibility.** This form of flexibility, also referred to as active mobility or active ROM, is the extent to which an active muscle contraction can rotate a joint through its available ROM. Dynamic flexibility depends on the ability of a muscle to contract through the ROM and on the degree and quality of tissue extensibility

**Passive flexibility.** This type of flexibility, also referred to as passive mobility or passive ROM, is the extent to which a joint can be passively rotated through its available ROM and depends on the extensibility of soft tissues that cross and surround a joint. Passive flexibility is a prerequisite for—but does not ensure—dynamic flexibility.

### Hypomobility

*Hypomobility* refers to decreased mobility or restricted motion at a single joint or series of joints. Many pathological processes are associated with hypomobility, and there are many factors that may contribute to motion limitations. These factors are summarized in Table 4.1.

### Contracture

Restricted motion can range from mild tightness to irreversible contractures. *Contracture* is defined as the adaptive shortening of the muscle-tendon unit and other soft tissues that cross or surround a joint, resulting in significant resistance to passive or active stretch and limited ROM.<sup>12,33,51,82,104</sup> The limitations associated with contractures can significantly compromise functional abilities.

There is no clear delineation of the extent of motion loss required due to decreased soft tissue extensibility to designate the limitation as a contracture. Contracture is most often defined as an almost complete loss of motion, whereas the term *shortness* is used to denote partial loss of motion.<sup>82</sup> *Tightness* is commonly used in the clinical and fitness settings to describe restricted motion due to adaptive shortening of soft tissue, in particular mild muscle shortening. *Muscle tightness* is also used to denote adaptive shortening of the contractile and noncontractile elements of muscle.<sup>70</sup>

### Designation of Contractures by Location

Contractures are described as the side of the joint that has the tissue tightness. If the tightness is on the flexion side of the flexion/extension joint axis, it is called a flexion contracture. For the patient with shortened elbow flexors who cannot fully extend the elbow, they are said to have an elbow flexion contracture. The patient with tight hip adductors

**TABLE 4.1** Factors Contributing to Restricted Motion

Contributing Factors	Examples
Prolonged immobilization: extrinsic factors <ul style="list-style-type: none"> <li>■ Casts and orthotics</li> <li>■ Skeletal traction</li> </ul>	Fractures, osteotomy, soft tissue trauma or repair
Prolonged immobilization: intrinsic factors <ul style="list-style-type: none"> <li>■ Pain</li> <li>■ Joint inflammation and effusion</li> <li>■ Muscle, tendon, or fascial disorders</li> <li>■ Skin disorders</li> <li>■ Bony block</li> <li>■ Vascular disorders</li> </ul>	Microtrauma or macrotrauma; degenerative diseases Joint diseases or trauma Myositis, tendonitis, fasciitis Burns, skin grafts, scleroderma Osteophytes, ankylosis, surgical fusion Peripheral lymphedema
Sedentary lifestyle and habitual faulty or asymmetrical postures	Confinement to bed or a wheelchair; prolonged positioning associated with occupation or work environment
Paralysis, tonal abnormalities, and muscle imbalances	Neuromuscular disorders and diseases: CNS or PNS dysfunction (spasticity, rigidity, flaccidity, weakness, muscle guarding, spasm)
Postural malalignment: congenital or acquired	Scoliosis, kyphosis

who cannot fully abduct the leg is said to have a hip adduction contracture.

### Contracture Versus Contraction

The terms *contracture* and *contraction* (the process of active tension developing in a muscle during shortening or lengthening) are not synonymous and not to be used interchangeably.

### Types of Contracture

One way to further define the term *contracture* is to describe contractures by the pathological changes in the different types of soft tissues involved.<sup>32</sup>

**Myostatic contracture.** In a myostatic (myogenic) contracture, although the musculotendinous unit has adaptively shortened and there is a significant loss of ROM, there is no specific muscle pathology present.<sup>32</sup> From a morphological perspective, although there may be a reduction in the number of sarcomere units in series, there is no decrease in individual sarcomere length. Myostatic contractures can be resolved in a relatively short time with stretching exercises.<sup>32,51</sup>

**Pseudomyostatic contracture.** Impaired mobility and limited ROM may also be the result of hypertonicity (i.e., spasticity or rigidity) associated with a central nervous system lesion, such as a cerebrovascular accident, a spinal cord injury, or traumatic brain injury.<sup>32,51</sup> Muscle spasm or guarding and pain may also cause a pseudomyostatic contracture. In both situations, the involved muscles appear to be in a constant state of contraction, giving rise to excessive resistance to passive stretch. Hence, the terms pseudomyostatic contracture

or apparent contracture are used. If neuromuscular inhibition procedures to reduce muscle tension temporarily are applied, full, passive elongation of the apparently shortened muscle is then possible.

**Arthrogenic and periarticular contracture.** An arthrogenic contracture is the result of intra-articular pathology. These changes may include adhesions, synovial proliferation, joint effusion, irregularities in articular cartilage, or osteophyte formation.<sup>51</sup> A periarticular contracture develops when connective tissues that cross or attach to a joint or the joint capsule lose mobility, restricting normal arthrokinematic motion.

**Fibrotic contracture and irreversible contracture.** Fibrous changes in the connective tissue of muscle and periarticular structures can cause adherence of these tissues and subsequent development of a fibrotic contracture.<sup>160</sup> Although it is possible to stretch a fibrotic contracture and eventually increase ROM, it is often difficult to re-establish optimal tissue length.<sup>33</sup>

Permanent loss of soft tissue extensibility that cannot be reversed by nonsurgical intervention may occur when normal muscle and organized connective tissue are replaced with a large amount of relatively nonextensible fibrotic adhesions, scar tissue,<sup>33</sup> or heterotopic bone. These changes can occur after long periods of immobilization with tissues in a shortened position or after tissue trauma and the subsequent inflammatory response. The longer a fibrotic contracture exists or the more extensive the tissue replacement, the more difficult it becomes to regain optimal mobility and the more likely it is that the contracture will become irreversible.<sup>33,145</sup>

## Selective Stretching

*Selective stretching* is a process whereby the overall function of a patient may be improved by applying stretching techniques to some muscles and joints while allowing motion limitations to develop in other muscles or joints. When determining which muscles to stretch and which to allow to become slightly shortened, the therapist must always keep in mind the functional needs of the patient and the importance of maintaining a balance between mobility and stability for maximum functional performance.

The decision to allow restrictions to develop in selected muscle-tendon units and joints typically is made in patients with permanent paralysis. For example:

- In a patient with spinal cord injury, stability of the trunk is necessary for independence in sitting. With thoracic and cervical lesions, the patient does not have active control of the back extensors. If the hamstrings are routinely stretched to improve or maintain their extensibility and moderate hypomobility is allowed to develop in the extensors of the low back, this enables a patient to lean into the slightly shortened structures and have some degree of trunk stability for long-term sitting. However, the patient must still have enough flexibility for independence in dressing and transfers. Too much limitation of motion in the low back can decrease function.
- Allowing slight hypomobility to develop in the long flexors of the fingers while maintaining mobility of the wrist extensors enables the patient with spinal cord injury, who lacks innervation of the intrinsic finger muscles, to regain the ability to grasp by using a tenodesis action.

## Overstretching and Hypermobility

*Overstretching* is a stretch well beyond the normal length of muscle and ROM of a joint and the surrounding soft tissues,<sup>82</sup> resulting in *hypermobility* (excessive mobility).

- Creating selective hypermobility by overstretching may be necessary for certain healthy individuals with normal strength and stability who participate in sports that require extensive flexibility.
- Hypermobility can create detrimental joint *instability* if the static supporting structures and/or the dynamic muscular control of the joint are unable to maintain the joint in a stable, functional position during activities. Instability of a joint often causes pain and may predispose a person to musculoskeletal injury.

## Overview of Interventions to Increase Mobility of Soft Tissues

Many therapeutic interventions are designed to improve the mobility of soft tissues to increase ROM and flexibility. Stretching and mobilization/manipulation are general terms that describe any therapeutic maneuver that increases the extensibility of restricted soft tissues.

The following terms describe techniques designed to increase soft tissue extensibility and joint mobility, some of which are addressed in depth later in this chapter.

### Stretching: Manual or Mechanical/Passive or Assisted

An end-range stretch force will elongate shortened muscle-tendon units and/or periarticular connective tissues when a restricted joint is rotated just beyond its available ROM. The force can be applied by manual contact or a mechanical device and can be sustained or intermittent. When the patient is as relaxed as possible during the stretch, it is called *passive stretching*. If the patient assists in moving the joint through a greater range, it is called *assisted stretching*.

### Self-Stretching

Any stretching exercise that is carried out independently by a patient after instruction and supervision by a therapist is referred to as *self-stretching*. In this case forces are applied by the patient at the end of available ROM for the purpose of elongating hypomobile soft tissues. Flexibility exercises are also performed independently, but this term usually indicates stretching that is part of a general conditioning and fitness program by individuals without mobility impairments.

### Neuromuscular Facilitation and Inhibition Techniques

Neuromuscular facilitation and inhibition procedures are founded on the concept of reflexively decreasing tension in shortened muscles prior to or during the stretch. Because the use of inhibition or facilitation techniques to assist with muscle elongation is associated with an approach to exercise known as proprioceptive neuromuscular facilitation (PNF),<sup>136,148</sup> many clinicians and some authors refer to these procedures as PNF stretching,<sup>29,36,131</sup> active inhibition,<sup>70</sup> active stretching,<sup>158</sup> or facilitated stretching.<sup>117</sup> Stretching procedures based on principles of PNF are discussed in a later section of this chapter.

### Muscle Energy Techniques

Muscle energy techniques are manipulative procedures that evolved out of osteopathic medicine designed to lengthen muscle and fascia and to mobilize joints.<sup>21,26,157</sup> The procedures employ voluntary muscle contractions by the patient in a precisely controlled direction and intensity against a counterforce applied by the practitioner (see additional information in Chapter 5 and a description of specific techniques for the sacroiliac (SI) joint in Chapter 15 and subcranial region in Chapter 16). Because principles of neuromuscular inhibition are incorporated into this approach, another term used to describe these techniques is *postisometric relaxation*.

### Joint Mobilization/Manipulation

Joint manipulative techniques are skilled manual therapy interventions specifically applied to joint structures by the clinician to modulate pain and treat joint impairments that limit ROM.<sup>64,78</sup> Principles of use and basic techniques for the

extremity joints are described and illustrated in detail in Chapter 5, and mobilization with movement techniques for the extremities are described and illustrated in the regional chapters (see Chapters 17 to 22). Techniques for the ribs, sacrum, and temporomandibular joints are presented in Chapter 15 and for the spinal joints in Chapter 16.

### Soft Tissue Mobilization/Manipulation

Soft tissue manipulative techniques are designed to improve the extensibility of any soft tissue that limits mobility. These techniques involve the application of specific and progressive manual forces using sustained manual pressure or slow, deep stroking. Specially crafted instruments can also be used by clinicians to apply these forces. Many techniques, including friction massage,<sup>70,138</sup> myofascial release,<sup>20,63,93,138</sup> acupressure,<sup>70,138,147</sup> and trigger point therapy,<sup>93,138,147</sup> are designed to improve tissue mobility by manipulating connective tissue that binds soft tissues. Although they are useful adjuncts to manual stretching procedures, specific techniques are not described in this textbook.

### Neural Tissue Mobilization (Neuromeningeal Mobilization)

Neural mobilization techniques are used to improve or restore nerve tissue mobility. Neural tissue mobility may become restricted by tissue adhesions or scar tissue following trauma or surgical procedures. Increased tension placed on nerve tissue by these adhesions during joint motion can lead to pain or neurological symptoms. After specific tests are conducted to determine neural tissue mobility, the neural pathway is mobilized through selective procedures.<sup>19,70</sup> These techniques are described in Chapter 13.

## Indications, Contraindications, and Potential Outcomes of Stretching Exercises

### Indications and Contraindications for Stretching

There are situations in which stretching exercises are appropriate and safe; however, there are also instances when stretching should not be implemented. Boxes 4.1 and 4.2 list indications and contraindications for the use of stretching interventions.

### Potential Benefits and Outcomes of Stretching

#### Increased Flexibility and ROM

The expected outcome of stretching exercises is to restore or increase muscle-tendon unit extensibility to regain or achieve the flexibility and ROM required for functional activities. As

#### BOX 4.1 Indications for Stretching

- ROM is limited because soft tissues have lost their extensibility as the result of adhesions, contractures, and scar tissue formation, causing activity limitations or participation restrictions.
- Restricted motion may lead to structural deformities that are otherwise preventable.
- Muscle weakness and shortening of opposing tissue have led to limited ROM.
- May be a component of a total fitness or sport-specific conditioning program designed to prevent or reduce the risk of musculoskeletal injuries.
- May be used prior to and after vigorous exercise.

#### BOX 4.2 Contraindications to Stretching

- A bony block limits joint motion.
- There was a recent fracture, and bony union is incomplete.
- There is evidence of an acute inflammatory or infectious process (heat and swelling), or soft tissue healing could be disrupted in the restricted tissues and surrounding region.
- There is sharp, acute pain with joint movement or muscle elongation.
- A hematoma or other indication of tissue trauma is observed.
- Joint hypermobility already exists.
- Shortened soft tissues provide necessary joint stability in lieu of normal structural stability or neuromuscular control.
- Shortened soft tissues enable a patient with paralysis or severe muscle weakness to perform specific functional skills otherwise not possible.

discussed throughout this chapter, a considerable body of evidence has shown that stretching, particularly static and PNF stretching procedures, improves flexibility and increases ROM. (The parameters of stretching exercises that determine effectiveness, such as intensity, duration, and frequency, are discussed later in this chapter.)

The underlying mechanisms for stretch-induced gains in ROM include biomechanical and neural changes in the contractile and noncontractile elements of the muscle-tendon unit and surrounding fascia. These changes are thought to be the result of increased muscle extensibility and length or decreased muscle stiffness (passive muscle-tendon tension).<sup>56,97,99,105,125</sup> (These underlying effects are discussed in the next section of this chapter.) Fascia may respond to the heat and mechanical stress generated during stretching by increasing its compliance.<sup>128</sup> There is also speculation that increased ROM following stretching may result from a change in an individual's perception or tolerance of the sensation associated with stretching.<sup>87,152</sup> This is supported by evidence showing that

static stretching improves dorsiflexion ROM without changing the structure of the musculotendinous unit, a result attributed to improved tolerance to 6 weeks of stretching.<sup>85</sup>

### General Fitness

In addition to improving flexibility and ROM, stretching exercises routinely are recommended for warm-up prior to or cool-down following strenuous physical activity. They are also considered to be an essential part of conditioning programs for general fitness, for recreational or workplace activities, and for training in preparation for competitive sports.

### Other Potential Benefits

Potential benefits and outcomes traditionally attributed to stretching exercises include the prevention or reduced risk of soft tissue injuries, reduced post-exercise (delayed onset) muscle soreness, and enhanced physical performance.<sup>47,66,71,132</sup> However, the evidence to support these potential benefits is inconclusive.

**Injury prevention and reduced post-exercise muscle soreness.** Although decreased flexibility has been associated with a greater risk of lower extremity musculotendinous injuries,<sup>159</sup> it is not likely that stretching exercises prevent or reduce injury risk. The vast majority of studies, analyzed in several critical reviews of the literature, indicate little, if any, link between an acute bout of stretching for warm-up prior to a strenuous event and the prevention or reduction in the likelihood of soft tissue injuries<sup>67,120,125,140</sup> or the severity or duration of post-exercise, delayed-onset muscle soreness.<sup>67,68</sup>

**Enhanced performance.** Another potential benefit attributed to stretching is enhanced physical performance—such as increased muscular strength, power, or endurance—or improvements in physical functioning such as walking or running speed and jumping abilities.

Consequently, it is common for an individual who is participating in a fitness or sport-related training program to perform stretching exercises prior to a strength training session. Stretching is also commonly performed just before participation in an athletic event requiring strength or power, such as sprinting or performing a vertical jump.

To effectively evaluate the impact of stretching on physical performance, a distinction must be made between a bout of stretching carried out just before a strenuous activity (*acute or pre-event stretching*) and a program of stretching exercises performed on a regular basis over a period of weeks (*chronic stretching*). A systematic review of the literature<sup>124</sup> and subsequent studies<sup>30</sup> indicate that acute static stretching either has no effect or decreases—rather than enhances—muscle performance (strength, power, or endurance) immediately following the stretching session. Acute stretching also provides no benefit or has a negative effect on the performance of activities that require strength, such as sprinting or jumping.<sup>9,56,109,124,133</sup> These performance decrements are greatest when static stretches are held for longer than 90 seconds. To the contrary, acute *dynamic* stretching appears to lead to

enhanced performance, especially with longer duration stretches (>90 seconds).<sup>9</sup> *Dynamic stretching* is defined as a controlled movement through the active ROM for each joint.<sup>54</sup> Similarly, performing stretching exercises as part of a comprehensive conditioning program on a regular basis over a period of weeks (*chronic stretching*) not only increases flexibility, but also appears to have beneficial effects on physical performance. This approach to stretching has been found to improve strength or power,<sup>59,84,124,133</sup> perhaps because of an alteration in the length-tension relationships of the stretched muscles. Participating in a stretching program on a regular basis also has been shown to improve gait economy<sup>59</sup> and enhance the performance of physical activities, such as sprinting and jumping abilities.<sup>124,133</sup>

## Properties of Soft Tissue: Response to Immobilization and Stretch

The ability of the body to move without restriction during functional activities depends on active neuromuscular control and the passive extensibility of soft tissues. As noted above, the soft tissues that can become restricted and impair mobility include muscles with their contractile and noncontractile elements and various types of connective tissue (tendons, ligaments, joint capsules, fascia, and skin). In most instances, decreased extensibility of connective tissue is the primary cause of restricted mobility in both healthy individuals and patients after injury, disease, or surgery.

A period of immobilization is often used to protect joints or tissues after injury or surgery, which may result in soft tissue morphological adaptations. Each type of soft tissue has unique properties that affect its response to immobilization and its ability to regain extensibility after immobilization. When stretching procedures are applied to these soft tissues, the direction, velocity, intensity (magnitude), duration, and frequency of the stretch force, as well as tissue temperature, tension, and stiffness, all interact to affect the unique soft tissue responses and outcomes. Specifically, mechanical characteristics of contractile and noncontractile soft tissue and the neurophysiological properties of contractile tissue will affect tissue lengthening. In addition, increased extensibility of the muscle-tendon unit following stretching may result from a modification of the stretch sensation, such as the onset of end-range discomfort, perceived by an individual.<sup>99,152</sup>

Most of the information on the biomechanical, biochemical, and neurophysiological responses of soft tissues to immobilization and remobilization is derived from animal studies; as such, the exact physiological mechanism by which stretching increases the extensibility of human tissues is still unclear. However, studies using ultrasound imaging on musculotendinous tissue in humans have provided confirmation of previous experiments on tendon adaptability to stress using isolated material.<sup>86,96</sup> Specifically, decreased muscle stiffness, quantified as a decrease

in shear elastic modulus using ultrasound elastography, has been identified as the likely mechanism for increased extensibility.<sup>1,108</sup> An understanding of the properties of these tissues and their responses to immobilization and stretch is the basis for selecting and applying the safest, most effective stretching procedures for patients with impaired mobility.<sup>59</sup>

When soft tissue is stretched, elastic, viscoelastic, or plastic changes occur. Both contractile and noncontractile tissues have elastic and plastic qualities, while only noncontractile connective tissues have viscoelastic properties.

- A stretched soft tissue is *elastic* if it returns to its prestretch resting length directly after a short-duration stretch force is removed.<sup>24,39,90,91,111</sup>
- *Viscoelasticity*, or viscoelastic deformation, is a time-dependent property of soft tissue. A viscoelastic tissue initially resists deformation, such as a change in length, when a stretch force is applied but will slowly lengthen if the force is sustained. The viscoelastic tissue will gradually return to its prestretch configuration after the stretch force is removed.<sup>90,97,98,111,152</sup>
- *Plasticity*, or plastic deformation, is the tendency of soft tissue to assume a new and greater length after a stretch force is removed.<sup>90,145,152</sup>

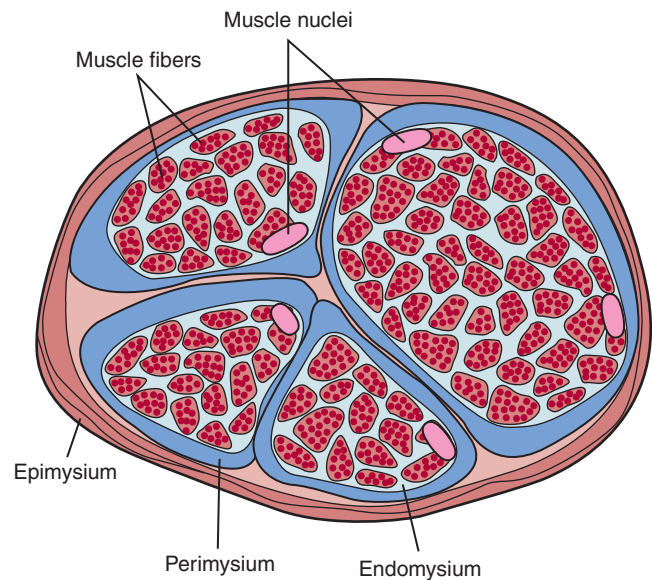

## Mechanical Properties of Noncontractile Soft Tissue

Noncontractile soft tissue permeates the entire body and is organized into various types of connective tissue to support the structures of the body. Ligaments, tendons, joint capsules, fascia, noncontractile tissue in muscles (Fig. 4.1), and skin all possess connective tissue characteristics that can lead to the development of adhesions and contractures. Any of these tissues can lose extensibility and contribute to reduced mobility. When these tissues restrict joint ROM and require stretching, it is important to understand how they respond to the intensity and duration of stretch forces and to recognize that the only way to increase the extensibility of connective tissue is to remodel its basic architecture.<sup>33</sup>

### Composition of Connective Tissue

Connective tissue is composed of three types of fiber: collagen, elastin and reticulin, and nonfibrous ground substance consisting of proteoglycans and glycoproteins.<sup>34,145</sup>

**Collagen fibers.** Collagen fibers are responsible for the strength and stiffness of tissue and resist tensile deformation. Tropocollagen crystals form the building blocks of collagen microfibrils. Each additional level of composition of the fibers is arranged in an organized relationship and dimension (Fig. 4.2). There are six classes with 19 types<sup>29</sup> of collagen. As collagen fibers develop and mature, they bind together, initially with unstable hydrogen bonding, then convert to stable covalent bonding. The stronger these bonds, the greater the mechanical stability of the tissue. Tissue with a larger proportion of collagen provides greater stability.

**FIGURE 4.1** Muscular connective tissue. Cross-sectional view of the connective tissue in a muscle shows how the perimysium is continuous with the outer layer of epimysium. (From Chleboun, G: *Muscle structure and function*. In Levangie, PK, and Norkin, CC [eds]: *Joint Structure and Function: A Comprehensive Analysis*, ed. 5. Philadelphia: FA Davis, 2011, p 117, with permission.)

**FIGURE 4.2** Composition of collagen fibers showing the aggregation of tropocollagen crystals as the building blocks of collagen. Organization of the fibers in connective tissue is related to the function of the tissue. Tissues with parallel fiber orientation, such as tendons, are able to withstand greater tensile loads than tissue, such as skin, in which the fiber orientation appears more random.

**Elastin fibers.** Elastin fibers provide extensibility. They show a great deal of elongation with small loads and fail abruptly without deformation at higher loads. Tissues with higher amounts of elastin have greater flexibility.

**Reticulin fibers.** Reticulin fibers provide tissue with bulk.

**Ground substance.** Ground substance is an organic gel containing water and is made up of proteoglycans (PGs) and glycoproteins. The PGs function to hydrate the matrix, stabilize the collagen networks, and resist compressive forces—especially important in cartilage and intervertebral discs. The type and amount of PGs are proportional to the types of compressive and tensile stress that the tissue is functionally subjected to.<sup>34</sup> Glycoproteins provide linkage between the main tissue matrix components and between the cells and the matrix opponents. The ground substance functions to reduce friction between fibers, transport nutrients and metabolites within the tissue, and maintain space between fibers to help prevent excessive cross-linking between them.<sup>44,145</sup>

### Mechanical Behavior of Noncontractile Tissue

The mechanical behavior of the various noncontractile tissues is determined by the proportion of collagen and elastin fibers, the proportion of PGs, and by the structural orientation of the fibers. Those tissues that withstand high tensile loads are high in collagen fibers; those that withstand greater compressive loads have greater concentrations of PGs. The composition of the tissue changes when the loading environment changes.<sup>34</sup>

Collagen is the structural element that absorbs most of the tensile stress. Its mechanical behavior is explained with reference to the stress-strain curve described in the following paragraphs. With an externally applied load, collagen fibers elongate quickly as wavy fibers align and straighten. With increased loading, tension increases and the fibers stiffen. Continued loading will progressively increase fiber strain until a point where bonds between collagen fibers begin to break. When a substantial number of bonds are broken, the fibers themselves will ultimately fail. Failure of collagen due to tensile loading occurs at less than 10% increase in fiber length, whereas elastin may lengthen 150% without failure. However, collagen is five times as strong as elastin. The alignment and orientation of collagen fibers in a particular tissue reflects the typical tensile loading pattern acting on that tissue (see Fig. 4.2):

- In tendons, collagen fibers are parallel and can resist the greatest tensile load. Their fiber alignment is in series with muscle fibers to transmit muscle forces to the bone.
- In skin, collagen fibers have a random orientation and so are limited in resisting higher levels of tension.
- In ligaments, joint capsules, and fascia, collagen fiber alignment varies so that they can resist multidirectional forces. Ligaments that resist major joint stresses have a more parallel orientation of collagen fibers and a larger cross-sectional area.<sup>113</sup>

### Interpreting Mechanical Behavior of Connective Tissue: The Stress-Strain Curve

The stress-strain curve illustrates the mechanical strength of structures (Fig. 4.3) and is used to interpret what is happening to connective tissue under stress from an externally applied load.<sup>34,143,145</sup> When a tensile load is applied to a structure, it produces elongation; the stress-strain curve illustrates the strength properties, stiffness, and amount of energy the material can store before failure of the structure.

- **Stress** is force (or load) per unit area. Mechanical stress is the internal reaction or resistance to an externally applied load.
- **Strain** is the amount of deformation or lengthening that occurs when an external load (such as a stretch force) is applied to a structure.

**FIGURE 4.3** Stress-strain curve. When stressed, the wavy collagen fibers straighten (toe region). With additional stress, recoverable deformation occurs in the elastic range. Once the elastic limit is reached, sequential failure of the collagen fibers and tissue occurs in the plastic range, resulting in release of heat and new length when the stress is released. The length from the stress point (X) results in a new length when released (X'); the heat released is represented by the area under the curve between these two points. Y to Y' represents additional length from additional stress into the plastic region with more heat released. Necking is the region in which there is considerable weakening of the tissue, and less force is needed for deformation. Total failure quickly follows even under small loads.

### Types of Stress

There are three kinds of stress that develop in a structure in response to an applied load:

- **Tension**—the resistance to a force applied in a manner that will lengthen the tissue. A stretching force results in tension stress.
- **Compression**—resistance to a force applied in a manner that approximates tissue. Weight bearing through a joint will produce compression stresses.
- **Shear**—resistance to two or more forces that are applied in opposing directions.

### Regions of the Stress-Strain Curve

**Toe region.** Because collagen fibers are wavy and within a three-dimensional matrix at rest, their first response to loading is to straighten and align. This response occurs with minimally

applied force and results in small increases in tissue stress. The toe region of the stress-strain curve represents this behavior and is the range in which most functional activity normally occurs.

**Elastic range/linear phase.** Adjacent to the toe region, stress and strain have a direct relationship such that a change in stress results in a proportional change in strain. This is called the linear region, and its slope depends on the specific tissues response to loading. A tissue that responds to loading with a rapid rise in strain, such as bone, will have a steep slope and higher stiffness than a tissue that responds with a smaller rise in strain. With respect to stretching, tissue stress beyond the toe region aligns collagen fibers in the direction of applied force. As strain increases, some microfailure between the collagen bonds begins and water may be displaced from the ground substance. If strain does not increase beyond the linear region or is not maintained, the tissue returns to its original size and shape when the load is released. (See the following discussion on creep and stress-relaxation for prolonged stretch.)

**Elastic limit** The elastic limit is the end of the linear region and the point beyond which the tissue does not return to its original shape and size.

**Plastic range.** Strain beyond the elastic limit begins to cause permanent tissue deformation. The plastic range extends from the elastic limit to the point of rupture and tissue strained into this range will have permanent deformation after the external load is released. Plastic deformation results from sequential failure (microfailure) of the bonds between collagen fibrils and eventually of collagen fibers. Because collagen is crystalline, individual fibers rupture rather than stretch, a process that may result in increased length from stretching.

**Ultimate strength.** The maximum strain the tissue can sustain is its ultimate strength. Once this point is reached, further increase in strain does not result in increased stress due to tissue macrofailure. The region of necking is reached in which there is considerable weakening of the tissue, and it rapidly fails. Experimentally, maximum tensile deformation (strain) of isolated collagen fibers prior to failure is 7% to 8%, while whole ligaments may withstand strains of 20% to 40% before failing.<sup>113</sup>

**Failure.** Failure is reached when the tissue ruptures and loses its integrity.

**Structural stiffness.** The slope of the linear portion of the curve (elastic range) is known as Young's modulus or the modulus of elasticity and represents the stiffness of the tissue.<sup>34</sup> Tissues with greater stiffness have a steeper slope in the elastic region, with less elastic deformation as stress increases. Contractures and scar tissue have greater stiffness, probably because of a greater degree of bonding between collagen fibers and their surrounding matrix. Tissues with less stiffness will demonstrate greater elongation than those with greater stiffness under similar external loads.<sup>34</sup>

## CLINICAL TIP

The grades of ligament injuries (strains) are related to the stress-strain curve.

**Grade I**—Microfailure: rupture of some fibers after deformation into the early part of the plastic range.

**Grade II**—Macrofailure: rupture of an increased number of fibers and partial failure after deformation into the later part of the plastic range.

**Grade III**—Complete rupture or tissue failure after deformation beyond the plastic range.

## Time and Rate Influences on Tissue Deformation

Because connective tissue has viscoelastic properties, the amount of time and the rate at which an external load is applied to tissue will affect its response.

**Rate dependence.** When a load is rapidly applied to a viscoelastic tissue, the slope of the stress-strain curve will be steeper than if the load is applied slowly. In essence, the tissue becomes stiffer when the load is applied at a high rate. This increased stress response protects the tissue by keeping deformation below the plastic range and minimizing the potential for failure. Viscoelasticity is an extremely valuable tissue property because it allows the body to tolerate high loads applied over short durations—a combination often encountered during high velocity events or activities. A tissue load that is applied gradually during a stretch will minimize this rate-dependent response.

**Creep.** When a gradually increasing external load is applied to a viscoelastic tissue and then sustained, the tissue will continue to slowly elongate during the maintained stretch (Fig. 4.4A). This slow adaptation to sustained loading is a time-dependent property of a viscoelastic tissue. The amount of tissue deformation depends on the amount of force and the rate at which the force is applied. Low-magnitude loads reaching the elastic range and applied for long periods of time increase connective tissue deformation and allow gradual rearrangement of collagen fiber bonds (remodeling) and redistribution of water to surrounding tissues.<sup>33,91,143</sup> Increasing the temperature of the tissue enhances creep and the extensibility of the tissue.<sup>150,154</sup> Complete recovery from creep may occur over time, but not as rapidly as recovery from a short duration load. Long-duration stretches applied to chronic contractures take advantage of this tissue property.

**Stress-relaxation.** When a sub-failure load is applied to a viscoelastic tissue and kept constant, there is a gradual decrease in the force required to maintain the amount of deformation<sup>33</sup> (Fig. 4.4B). This response is also a function of the viscoelastic qualities of the connective tissue and redistribution of water content. Stress-relaxation is the underlying principle used in prolonged stretching procedures in which the stretch position is maintained for several hours or days. Recovery versus permanent changes in length is dependent on both the amount of deformation and the length of time the deformation is maintained.<sup>33</sup>

**FIGURE 4.4** Tissue responses to prolonged stretch forces as a result of viscoelastic properties. **(A)** Effects of creep. A constant load, applied over time, results in increased tissue length until equilibrium is reached. **(B)** Effects of stress-relaxation. A load applied with the tissue kept at a constant length results in decreased internal tension in the tissue until equilibrium is reached.

**Cyclic loading and connective tissue fatigue.** Repetitive loading of tissue within a short time duration increases heat production and may cause failure at strain levels lower than what is needed for a single load. Similarly, the greater these repetitive loads, the fewer number of cycles needed to reach failure. This phenomenon is referred to as connective tissue fatigue. Examples of connective tissue fatigue from cyclic loading are stress fractures and overuse syndromes. These represent situations where the load intensity and number of repetitions exceed the endurance limit, below which an apparently infinite number of cycles of low loading will not cause failure. Animal studies confirm that cyclic loading will result in decreased ligament stiffness, indicative of tissue damage, sooner than will static loading.<sup>142</sup>

### Summary of Mechanical Principles for Stretching Connective Tissue

- Connective tissue deformation (stretch) varies depending on the magnitude of loading and the rate of load application. Permanent changes in tissue length or flexibility requires breaking of collagen bonds and realignment of the fibers. Tissue failure begins as microfailure of fibrils and fibers before complete failure occurs. Complete tissue failure can occur as a single maximal event or from repetitive submaximal stress. Microfailure that induces permanent lengthening can occur through creep, stress-relaxation, and controlled cyclic loading.
- Healing and adaptive remodeling capabilities allow the tissue to respond to repetitive and sustained loads if time is allowed between bouts. This is important for increasing

both flexibility and tensile strength of the tissue. If healing and remodeling time is not allowed, a breakdown of tissue (failure) occurs as in overuse syndromes and stress fractures. Intensive stretching is usually not done every day in order to allow time for healing. If the inflammation from the microruptures is excessive, additional scar tissue, which could become more restrictive, is laid down.<sup>33</sup>

- It is imperative that the individual use any newly gained range to allow the remodeling of tissue and to train the muscle to control the new range. Without functional use of the newly gained range, the tissue may gradually return to its shortened length.

### Changes in Collagen Affecting the Stress-Strain Response

#### Effects of Immobilization

Immobilization causes collagen turnover and weak bonding between the new, nonstressed fibers, resulting in decreased stiffness. There is also greater cross-linking between disorganized collagen fibers and decreased effectiveness of the ground substance in maintaining space and lubrication between the fibers, resulting in adhesion formation.<sup>44,143</sup> The rate of return to normal tensile strength for immobilized tissue is slow. For example, after 8 weeks of immobilization, the anterior cruciate ligament in monkeys failed at 61% of maximum load; after 5 months of reconditioning, it failed at 79%; and after 12 months of reconditioning, it failed at 91%.<sup>112,114</sup> There was also a reduction in energy absorbed and a decrease in stiffness prior to failure following immobilization.<sup>112</sup>

#### Effects of Inactivity (Decrease of Normal Activity)

Inactivity decreases the size and amount of collagen fibers, resulting in weakening of the tissue.<sup>34</sup> With collagen decrease there is a proportional increase in the predominance of elastin fibers, resulting in increased tissue compliance. Recovery from these changes takes about 5 months of regular cyclic loading. Physical activity has a beneficial effect on the strength of connective tissue.

#### Effects of Age

Aging decreases maximum tensile strength and stiffness of tissue, and the rate of adaptation to loading is slower. There is an increased tendency for overuse syndromes, fatigue failures, and tears with stretching.<sup>113</sup>

#### Effects of Corticosteroids

Corticosteroid use has a long-lasting deleterious effect on the mechanical properties of collagen with a subsequent decrease in tensile strength.<sup>34</sup> Adverse effects from corticosteroid injections include decreased collagen synthesis and organization, necrosis, and an increased ratio of type III to type I collagen.<sup>37</sup> There is fibrocyte death next to the injection site with delay in reappearance up to 15 weeks.<sup>113</sup>

#### Effects of Injury

Damaged tissue follows a predictable healing pattern (see Chapter 10), with newly synthesized type III collagen bridging the injury site. This collagen is structurally weaker than mature

type I collagen. As remodeling progresses, the collagen eventually matures to type I. Remodeling usually begins about 3 weeks post-injury and continues for several months to a year, depending on the size of the connective tissue structure and the magnitude of the rupture.

### Other Conditions Affecting Collagen

Nutritional deficiencies, hormonal imbalances, and dialysis may predispose connective tissue to injury at lower levels of loading than normal.<sup>34</sup>

## Mechanical and Physiological Properties of Muscle Tissue

Muscle is composed of both contractile and noncontractile connective tissues. The contractile elements of muscle (Fig. 4.5) give it the characteristics of contractility and irritability.

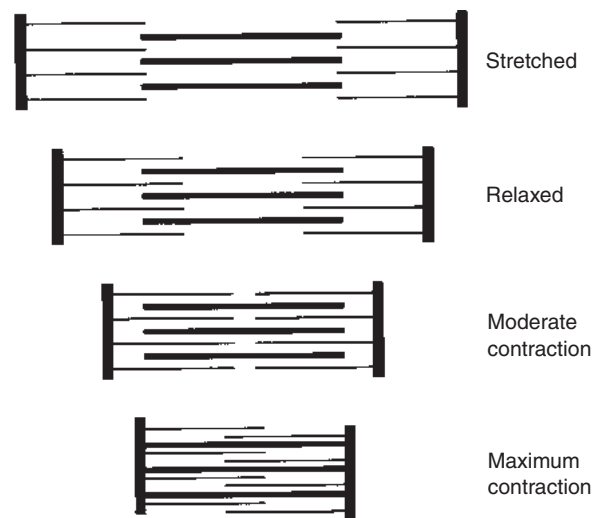

**FIGURE 4.5** Structure of skeletal muscle.

The noncontractile connective tissues in and around muscle (see Fig. 4.1) have the same properties as all connective tissue, including the ability to resist deforming forces.<sup>24,97,98</sup> The noncontractile connective tissue structures of muscle are the *endomysium*, which is the innermost layer that separates individual muscle fibers and myofibrils; the *perimysium*, which encases fiber bundles; and the *epimysium*, which is the fascial sheath enveloping the entire muscle. It is this connective

tissue framework of muscle that is the primary source of a muscle's resistance to passive elongation.<sup>24,33,111</sup> Tissue adhesions within and between the collagen fibers of these structural tissues can resist and restrict movement and result in joint contracture.<sup>33</sup>

### Contractile Elements of Muscle

Individual muscles are composed of many muscle fibers that lie in parallel with one another. A single muscle fiber is made up of many myofibrils. Each myofibril is composed of even smaller structures called sarcomeres, which lie in series (end-to-end) within a myofibril. The sarcomere is the contractile unit of the myofibril and is composed of overlapping myofilaments of actin and myosin proteins. The sarcomeres give muscle the ability to contract and relax. When a motor unit stimulates a muscle to contract, the actin-myosin filaments form connections called cross-bridges, slide relative to each other, and actively shorten the muscle. When a muscle relaxes, the myofilaments slide apart slightly, and the muscle returns to its resting length (Fig. 4.6).

**FIGURE 4.6** A model of myofilament sliding. Elongation and shortening of the sarcomere, the contractile unit of muscle.

### Mechanical Response of the Contractile Unit to Stretch and Immobilization

There are a number of changes in the anatomical structure and physiological function of the sarcomeres that can occur over time. These changes can result from a stretch during an exercise or from extended periods of immobilization followed by remobilization. The noncontractile structures in and around muscle also affect a muscle's response to stretch and immobilization.<sup>31,90</sup>

#### Response to Stretch

When a muscle is stretched and elongates, the stretch force is transmitted to the muscle fibers through the endomysium and perimysium. It is hypothesized that molecular interactions

link these noncontractile elements to the sarcomere and enable this force transduction.<sup>39</sup>

During a passive stretch, both longitudinal (in series) and lateral (in parallel) force transduction occurs in muscle.<sup>39</sup> During initial lengthening, tension rises sharply in the series elastic component. With continued lengthening there is mechanical disruption of the cross-bridges as the myofilaments slide apart, leading to abrupt lengthening of the sarcomeres,<sup>39,55,90,91</sup> sometimes referred to as *sarcomere give*.<sup>55</sup> When the stretch force is released, the individual sarcomeres return to their resting length<sup>39,90,91</sup> (see Fig. 4.6). As noted previously, the property of muscle promoting return to its resting length after short-term stretch is called elasticity. For longer lasting or more permanent (viscoelastic or plastic) length increases to occur the stretch force must be maintained over an extended period of time.<sup>39,90,152</sup>

### Response to Immobilization and Remobilization

**Morphological changes.** If a muscle is subjected to prolonged immobilization, it is not used during functional activities and the physical stresses placed on it are substantially diminished. This results in decay of contractile protein in the immobilized muscle, as well as decreases in muscle fiber diameter, the number of myofibrils, and intramuscular capillary density. The outcome of this process is muscle *atrophy* and *weakness*.<sup>13,17,60,77,80,90,106,141</sup> As the immobilized muscle atrophies, an increase in fibrous and fatty tissue in muscle also occurs.<sup>106</sup>

The composition of muscle affects its response to immobilization, with atrophy occurring more quickly and more extensively in tonic (slow-twitch) postural muscle fibers than in phasic (fast-twitch) fibers.<sup>90,91</sup> The duration and position of immobilization also affect the extent of atrophy and weakness, with longer duration leading to greater atrophy and loss of functional strength. Atrophy can begin within as little as a few days to a week.<sup>79,80,141</sup> Accompanying the decrease in cross-sectional size of muscle fibers with atrophy, an even more significant deterioration in motor unit recruitment occurs as reflected by electromyographic (EMG) activity.<sup>90,91</sup> Both of these factors compromise the force-producing capabilities of the muscle.

**Immobilization in a shortened position.** In studies using animals, when a muscle is immobilized in a shortened position for several weeks there is a reduction in muscle length, the number of muscle fibers, and the number of sarcomeres in series within myofibrils as the result of *sarcomere absorption*.<sup>77,90,137</sup> This absorption occurs at a faster rate than the muscle's ability to regenerate sarcomeres in an attempt to restore itself. This decrease in the overall muscle length and the number of sarcomeres results in muscle atrophy and weakness. It has also been suggested that a muscle immobilized in a shortened position atrophies and weakens at a faster rate than a muscle immobilized in a lengthened state.<sup>17</sup>

With muscle shortening due to immobilization, there is a shift to the left in its length-tension curve, decreasing its capacity to produce maximum tension as it contracts at its normal resting length.<sup>24</sup> The decrease in muscle length also results in an earlier onset of passive tension as the muscle is

stretched. This mechanical alteration is related to the new muscle length and to the increased proportion of connective tissue to muscle tissue that results from immobilization. Importantly, the increase in connective tissue and early onset of passive tension also serves to protect the shorter and weaker muscle when it is elongated.<sup>33,60</sup>

**Immobilization in a lengthened position.** Sometimes a muscle is immobilized in a lengthened position for a prolonged period of time. This occurs with some surgical procedures, such as a limb lengthening,<sup>14</sup> the application of a series of positional casts (serial casts),<sup>72</sup> or the use of a dynamic orthosis to stretch a long-standing contracture and increase ROM.<sup>12,101</sup> There is some evidence from animal studies,<sup>137</sup> but very limited evidence from studies involving human skeletal muscle,<sup>14</sup> to suggest that a muscle held in a lengthened position for an extended time adapts by increasing the number of sarcomeres in series, sometimes referred to as *myofibrillogenesis*.<sup>39</sup> It is theorized that sarcomere addition maintains the optimal functional overlap of actin and myosin filaments in the muscle<sup>90</sup> and may be relatively permanent if the newly gained length is used on a regular basis in functional activities.

The minimum time necessary for an elongated muscle (fiber) to become a longer muscle (fiber) by adding sarcomeres in series is not known. In animal studies, increased muscle length as the result of sarcomere number addition required continuous immobilization in a lengthened position for several weeks.<sup>90</sup> It is speculated that this same process contributes to gains in muscle length (indirectly quantified by increases in joint ROM) following the use of serial casts,<sup>72</sup> dynamic orthoses,<sup>101</sup> and perhaps as the result of stretching exercises.<sup>39</sup> Interestingly, direct evidence of sarcomere adaptation in human skeletal muscle was recently reported following long-term, continuous limb distraction used to lengthen a patient's femur.<sup>14</sup>

**Adaptation.** The adaptation of the contractile units of muscle (an increase or decrease in the number of sarcomeres) to prolonged positioning in either lengthened or shortened positions is transient, lasting only 3 to 5 weeks if the muscle resumes its pre-immobilization use and degree of lengthening for functional activities.<sup>80,90</sup> In clinical practice, this underscores the need for patients to use full-range motions during a variety of functional activities to maintain the stretch-induced gains in muscle extensibility and joint ROM.

## Neurophysiological Properties of Skeletal Muscle

The neurophysiological properties of the muscle-tendon unit will also influence a muscle's response to stretch and the effectiveness of stretching interventions. In particular, two sensory organs of muscle-tendon units, the *muscle spindle* and the *Golgi tendon organ* (GTO), are mechanoreceptors that convey information to the central nervous system about the physical environment within the muscle-tendon unit. This information often results in muscle responses that may impact the effectiveness of a stretch.

## Muscle Spindle

The muscle spindle is the major sensory organ of muscle and is sensitive to quick and sustained (tonic) stretch (Fig. 4.7). The main function of muscle spindles is to detect and convey information about muscle length changes and the velocity of those changes.

Muscle spindles are small, encapsulated receptors composed of afferent sensory fiber endings, efferent motor fiber endings, and specialized muscle fibers called *intrafusal fibers*. Intrafusal muscle fibers are bundled together and lie between and parallel to the extrafusal muscle fibers that make up the main body of a skeletal muscle.<sup>60,73,94,119</sup> Intrafusal muscle fibers connect at their ends to extrafusal muscle fibers, so when a muscle is stretched, intrafusal fibers are also stretched. Intrafusal muscle fibers can also contract, but only their ends (polar regions), not their central portion (equatorial region), are contractile. Consequently, when an intrafusal muscle fiber is stimulated and contracts, it lengthens the central portion and activates the sensory receptors in the nuclear bag and chain. Small-diameter motor neurons, known as *gamma* motor neurons, innervate the contractile polar regions of intrafusal muscle fibers and adjust the sensitivity of muscle spindles to detect length changes. Large-diameter *alpha* motor neurons innervate extrafusal fibers.

There are two general types of intrafusal muscle fibers: *nuclear bag fibers* and *nuclear chain fibers*, named based on the arrangement of their nuclei in the equatorial region. Primary (type Ia) afferent endings, which arise from nuclear bag fibers, sense and cause muscle to respond to both quick and sustained stretch. However, secondary (type II) afferents from the nuclear chain fibers are sensitive only to sustained stretch.

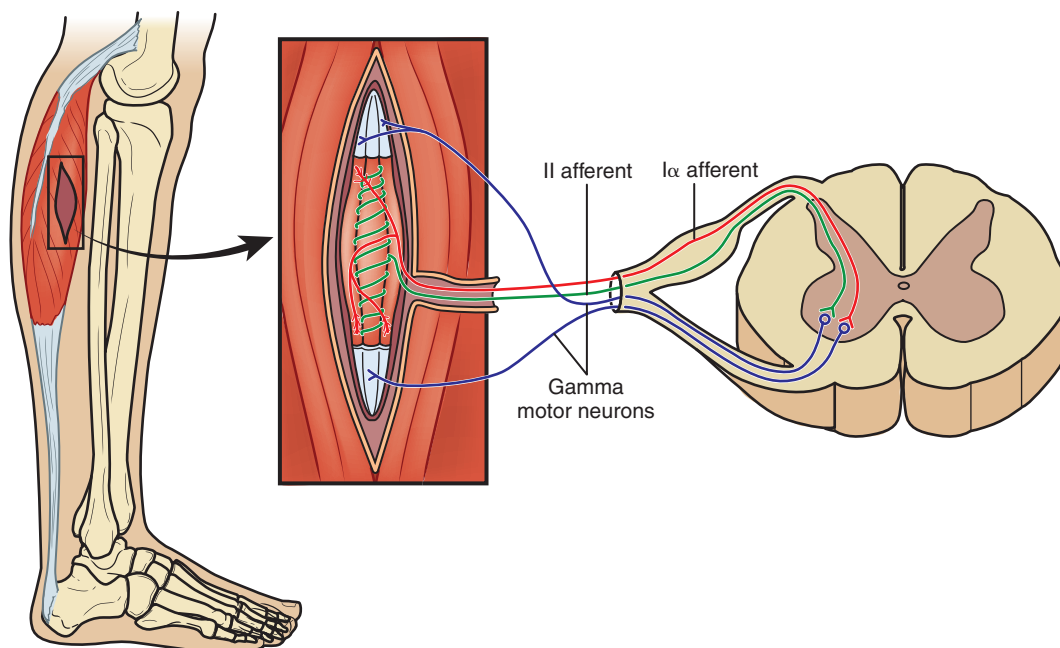

The primary and secondary afferents synapse on alpha or gamma motoneurons, which, when stimulated, cause excitation of their own extrafusal or intrafusal muscle fibers, respectively. There are essentially two ways to stimulate these sensory afferents by means of stretch—one is by overall lengthening of the muscle and the other is by contraction of the intrafusal muscle fibers via the gamma efferent neural pathways.

## Golgi Tendon Organ

The GTO is a sensory organ located near the musculotendinous junctions of extrafusal muscle fibers. The function of a GTO is to monitor changes in tension of muscle-tendon units. These encapsulated nerve endings are woven among collagen strands of a tendon and transmit sensory information via Ib fibers. These sensory organs are sensitive to even slight changes of tension on a muscle-tendon unit brought on by passive stretch or active muscle contractions during normal movement.

When muscle tension develops, GTO activation signals to the spinal cord inhibit alpha motoneuron activity and decrease tension in the muscle-tendon unit.<sup>22,60,73,119</sup> With respect to the neuromuscular system, *inhibition* is a state of decreased neuronal activity and altered synaptic potential, which diminishes the capacity of a muscle to contract.<sup>71,73,94</sup>

Originally, the GTO was thought to respond only to high levels of muscle tension as a protective mechanism for muscle. However, the GTO has since been shown to have a low threshold for firing, functioning to continuously monitor and adjust the force of active muscle contractions during movement or the tension in muscle during passive stretch.<sup>57,119</sup>

**FIGURE 4.7** Muscle spindle showing intrafusal and extrafusal muscle fibers, stretch receptors, afferent and efferent nerve fibers, and spinal cord processes.

## Neurophysiological Response of Muscle to Stretch

**Stretch reflex.** When a quick or sustained stretch force is applied to a muscle-tendon unit, the primary and secondary afferents of intrafusal muscle fibers sense these length changes. These afferent signals synapse with alpha motor neurons in the spinal cord to activate extrafusal muscle fibers. This motor response is known as the stretch reflex, defined as an increase or facilitation of active tension in the muscle being stretched. This increased tension resists lengthening and is thought to compromise the effectiveness of the stretching procedure.<sup>8,43</sup> When the stretch reflex is activated in a muscle being lengthened, decreased activity (inhibition) in the muscle(s) on the opposite side of the joint also may occur.<sup>94,148</sup> This is referred to as *reciprocal inhibition* but to date has only been documented in studies using animal models.<sup>22,131,152</sup> To minimize activation of the stretch reflex and the subsequent increase in muscle tension, a slowly applied, low-intensity, prolonged stretch is considered preferable to a quickly applied, short-duration stretch.

**Autogenic inhibition.** In contrast, the GTO has an inhibitory effect on the level of muscle tension in the muscle-tendon unit in which it lies, particularly if the stretch force is prolonged. This effect is called *autogenic inhibition*.<sup>60,94,119</sup> Inhibition of the contractile components of muscle by the GTO is thought to contribute to reflexive muscle relaxation during a stretching maneuver, enabling a muscle to be elongated against less muscle tension. Consequently, if a low-intensity, slow stretch force is applied to muscle, the stretch reflex is less likely to be activated as the GTO fires and inhibits tension in the muscle, allowing the parallel elastic component (the sarcomeres) of the muscle to remain relaxed and to lengthen.

In summary, current evidence suggests that improvement in muscle extensibility attributed to stretching procedures is more likely due to tensile stresses placed on the viscoelastic, noncontractile connective tissue in and around muscle than to inhibition (reflexive relaxation) of the contractile elements of muscle.<sup>22,97,98,99,131</sup>

## Determinants and Types of Stretching Exercises

There are a number of essential elements that determine the effectiveness and outcomes of stretching interventions. The determinants (parameters) of stretching, all of which are interrelated, include *alignment* and *stabilization* of the body or body segment during stretching; the *intensity*, *duration*, *speed*, *frequency*, and *mode* of stretch; and the integration of neuromuscular factors and functional activities into stretching programs. By manipulating the determinants of stretching interventions, which are defined in Box 4.3, a therapist has many options from which to choose when designing stretching programs that are safe and effective and meet the needs,

### BOX 4.3 Determinants of Stretching Interventions

- **Alignment:** Positioning a limb or the body such that the stretch force is directed to the appropriate muscle group.
- **Stabilization:** Fixation of a bony segment that has an attachment of the muscle to be stretched.
- **Intensity of stretch:** Magnitude of the stretch force applied.
- **Duration of stretch:** Length of time the stretch force is applied during a stretch cycle.
- **Speed of stretch:** Rate of initial application of the stretch force.
- **Frequency of stretch:** Number of stretching sessions per day or per week.
- **Mode of stretch:** Form or manner in which the stretch force is applied (static, ballistic, or cyclic), degree of patient participation (passive, assisted, or active), or the source of the stretch force (manual, mechanical, or self).

functional goals, and capabilities of many patients. Each of these determinants is discussed in this section of the chapter.

Most investigations comparing the type, intensity, duration, and frequency of effective stretching have been carried out with healthy, young adults as subjects. The findings and recommendations of these studies are difficult to generalize and apply to patients with long-standing contractures or other forms of tissue restriction. Therefore, many decisions, particularly those related to the type, intensity, duration, and frequency of stretching, must continue to be based on a balance of scientific evidence and sound clinical judgments by the therapist.

There are four broad categories of stretching exercises: static stretching, cyclic (intermittent) stretching, ballistic stretching, and stretching techniques based on the principles of PNF.<sup>38,47,69,163</sup> Each of these forms of stretching are effective in elongating tissue and increasing ROM. Each can be accomplished in various ways—manually or mechanically, passively or actively, and by a therapist or independently by a patient—giving rise to many terms that are used in the literature to describe stretching interventions. The stretching interventions listed in Box 4.4 are defined and discussed in this section.

### Alignment and Stabilization

Just as appropriate alignment and effective stabilization are fundamental components of muscle testing, goniometry, and all therapeutic exercises, they are also essential elements of effective stretching.

#### Alignment

Proper alignment or positioning of the patient and the specific muscles and joints to be stretched is necessary for patient comfort and stability during stretching. Alignment influences the baseline amount of tension present in soft tissue and

### BOX 4.4 Types of Stretching

- Static stretching
- Cyclic/intermittent stretching
- Ballistic stretching

- Manual stretching
- Mechanical stretching
- Self-stretching
- Passive stretching
- Active stretching

consequently affects the available joint ROM. In addition to the alignment of the muscles and joint to be stretched, the alignment of the trunk and adjacent joints must also be considered. For example, to effectively stretch the rectus femoris, a muscle that crosses two joints, the lumbar spine and pelvis, should be maintained in a neutral position as the knee is flexed and the hip extended. Because effective stretching requires maximizing the distance between origin and insertion, alignment that compromises this requirement—such as pelvis anterior tilt or hip flexion or abduction in our example—must be avoided (Fig. 4.8 A and B). Similarly, when a patient is self-stretching to increase shoulder flexion, the trunk should be erect, not slumped (Fig. 4.9 A and B).

**NOTE:** Throughout this and later chapters, recommendations for appropriate alignment and positioning during stretching procedures are identified. If it is not possible for a patient to attain

**FIGURE 4.8 (A)** Correct alignment when stretching the rectus femoris: The lumbar spine, pelvis, and hip are held in a neutral position as the knee is flexed. **(B)** Incorrect position of the hip in flexion. In addition, avoid anterior pelvic tilt, hyperextension of the lumbar spine, and abduction of the hip.

**FIGURE 4.9 (A)** Correct alignment when stretching to increase shoulder flexion: Note that the cervical and thoracic spine is erect. **(B)** Incorrect alignment: Note the forward head and rounded spine.

the recommended postures because of discomfort, restrictions of motion of adjacent joints, inadequate neuromuscular control, or insufficient cardiopulmonary capacity, the therapist must critically analyze the situation to determine an alternative position.

### Stabilization

To achieve an effective stretch of a specific muscle or muscle group and associated periarticular structures, it is imperative to stabilize (fixate) either the proximal or distal attachment site of the muscle-tendon unit being elongated. Without stabilization, the attachment sites are free to move with the tissue, reducing the ability to effectively maximize the origin-insertion distance. Either site may be stabilized, but for manual stretching, it is common for a therapist to stabilize the proximal attachment and move the distal segment, as shown in Figure 4.10 A.

For self-stretching procedures, a stationary object, such as a chair or a doorframe, or active muscle contractions by the patient may provide stabilization of one segment as the other segment moves. During self-stretching, it is often the distal attachment that is stabilized as the proximal segment moves (Fig. 4.10 B).

Stabilization of multiple body segments also helps maintain the proper alignment necessary for an effective stretch. For example, when stretching the iliopsoas, the pelvis and lumbar spine must maintain a neutral position as the hip is extended to avoid stress to the low back region (see Fig. 4.26). Sources of stabilization include manual contacts; straps or belts; body weight; or a firm surface, such as a table, wall, or floor.

### Intensity of Stretch

The intensity of a stretch is determined by the tensile load placed on soft tissue to elongate it. There is general agreement among clinicians and researchers that stretching should be

**FIGURE 4.10** (A) The proximal attachment (femur and pelvis) of the muscle being stretched (the quadriceps) is stabilized as the distal segment is moved to increase knee flexion. (B) During this self-stretch of the quadriceps, the distal segment (tibia) is stabilized through the foot as the patient moves the proximal segment (femur) by lunging forward.

applied at a *low intensity* by means of a *low load*.<sup>2,12,14,28,47,69,92</sup> Low-intensity stretching in comparison to high-intensity stretching is more comfortable for the patient and minimizes voluntary or involuntary muscle guarding, enabling the patient to remain relaxed or assist with the stretching maneuver.

Low-intensity stretching results in optimal rates of improvement in ROM without exposing tissues, possibly weakened by immobilization, to excessive loads and potential injury.<sup>92</sup> Low-intensity stretching has also been shown to elongate dense connective tissue, a significant component of chronic contractures, more effectively and with less soft tissue damage and post-exercise soreness than a high-intensity stretch.<sup>4</sup>

## Duration of Stretch

One of the most important decisions a therapist makes when selecting and implementing a stretching intervention is the duration of stretch that is expected to be safe, effective, practical, and efficient for each situation. The duration of stretch refers to the period of time a stretch force is applied and tissues are held in a lengthened position. Duration most often refers to how long a *single cycle* of stretch is applied. If more than one repetition of stretch (*stretch cycle*) is carried out during a treatment session, the cumulative time of all the stretch cycles reflects the total duration of stretch, also referred to as the *total elongation time*. In general, the shorter the duration of a single stretch cycle, the greater the number of repetitions needed during a stretching session. Many combinations of duration and cycle have been studied to determine optimal effectiveness.

### FOCUS ON EVIDENCE

In a study by Cipriani and associates,<sup>25</sup> two repetitions of 30-second hamstring stretches were found to be equally effective as six repetitions of 10-second stretches. Similarly, Johnson et al reported that three 30-second stretches were equally effective as nine 10-second stretches for increasing hamstring length,<sup>76</sup> while Sainz de Baranda and associates showed that 180 seconds of daily stretch was also effective to increase hamstring length regardless of whether the individual stretch repetitions were of 15, 30, or 45 seconds.<sup>127</sup> In contrast, Roberts and Wilson<sup>122</sup> found that over the course of a 5-week period and equal total duration times, three 15-second hamstring stretches each day yielded significantly greater stretch-induced gains in ROM than nine daily 5-second stretches.

Despite many studies over several decades, there is lack of agreement on the ideal combination of single stretch duration and number of stretch repetitions that leads to the greatest and most sustained stretch-induced gains in ROM or reduction of muscle stiffness. Ultimately, the duration of stretch must be applied in context with the other stretching parameters of intensity, frequency, and mode. Key findings from a number of studies are summarized in Box 4.5.

Several descriptors are used to differentiate between a long-duration versus a short-duration stretch. Terms such as *static*, *sustained*, *maintained*, and *prolonged* are used to describe a long-duration stretch, whereas terms such as *cyclic*, *intermittent*, or *ballistic* are used to characterize a short-duration stretch. There is no specific time period assigned to any of these descriptors, nor is there a time frame that distinguishes a long-duration from a short-duration stretch.

### Static Stretching

Static stretching\* is a commonly used method of stretching in which soft tissues are elongated just beyond the point of

\*2,7,8,25,38,42,43,52,87,107,110,122,151,161

### BOX 4.5 Intensity, Duration, Frequency, and Mode of Stretch—Evidence-Based Interrelationships and Impact on Stretching Outcomes

- There is an inverse relationship between intensity and duration as well as between intensity and frequency of stretch.
- The lower the intensity of stretch, the longer the time the patient will tolerate stretching and the soft tissues can be held in a lengthened position.
- The higher the intensity, the less frequently the stretching intervention can be applied to allow time for tissue healing and resolution of residual muscle soreness.
- A low-load, long-duration stretch is considered the safest form of stretch and yields the most significant, elastic deformation and long-term, plastic changes in soft tissues.
- Manual stretching and self-stretching in hypomobile but healthy subjects<sup>7-9,25,52</sup> and prolonged mechanical stretching in patients with chronic contractures<sup>72,75,92,102</sup> yield significant stretch-induced gains in ROM.
- In the well elderly, stretch cycles of 15, 30, and 60 seconds applied to the hamstrings for four repetitions have all been shown to produce significant gains in ROM with the greatest and longest-lasting improvements occurring with the use of repeated 60-second stretch cycles.<sup>52</sup>
- In healthy young and/or middle-age adults:
  - Stretch durations of 15, 30, 45, 60, or 120 seconds to lower extremity musculature produced significant gains in ROM.<sup>7,25,43,156</sup>
  - Stretch cycles of 30- and 60-second durations applied to the hamstrings for one repetition daily are both more effective for increasing ROM than one repetition daily of a 15-second stretch cycle but are equally effective when compared with each other.<sup>7,9</sup>
  - Two repetitions daily of a 30-second static stretch of the hamstrings yield significant gains in hamstring flexibility similar to those seen with six repetitions of 10-second static stretches daily.<sup>25</sup>
- There seems to be no additional benefit to holding each stretch cycle beyond 60 seconds.<sup>7,83</sup>
- Three cycles of 30-second and 1-minute stretches are no more effective for improving ROM than one cycle of each duration of stretch.<sup>7</sup>
- Longer total durations of passive stretch yield longer-lasting decreases in muscle-tendon stiffness than short-duration stretches.<sup>56,97,125</sup>
- A 2-minute passive stretch yields only a transient decrease in stiffness of the gastrocnemius muscle of healthy, young adults, whereas 4-minute and 8-minute stretches reduce stiffness for up to 20 minutes after stretching.<sup>125</sup>
- When the total duration of stretch (total elongation time) is equal, cyclic stretching is equally effective and possibly more comfortable than static stretching.<sup>135</sup>
- For patients with chronic, fibrotic contractures:
  - Common durations of manual stretching or self-stretching (several repetitions of 15-second or 30-second stretches) may not be effective.<sup>92,107</sup>
  - Use of prolonged static stretch with orthotics or casts is more effective.<sup>75,92,102</sup>
- Frequency of stretching needs to occur a minimum of two times per week for healthy hypomobile individuals, but more frequent stretching is necessary for patients with soft tissue pathology to achieve gains in ROM.<sup>9</sup>
- Although stretch-induced gains in ROM often persist for several weeks to a month in healthy adults after cessation of a stretching program, permanent improvement in mobility can be achieved only by use of the newly gained ROM in functional activities and/or with a maintenance stretching program.<sup>156</sup>

tissue resistance and then held in the lengthened position with a sustained stretch force over a period of time. The duration of static stretch can be predetermined prior to stretching or be based on the patient's tolerance and response during the stretch.

There is considerable variability in defining the duration of a static stretch. The term has been used to describe a single stretch cycle ranging from as short as 5 seconds to as long as 5 minutes per repetition when either a manual stretch or self-stretch is employed.<sup>†</sup> If a mechanical device provides the static stretch, the time frame can range from almost an hour to several days or weeks.<sup>15,72,75,92,101</sup> (See additional information on mechanical stretching later in this section.)

#### FOCUS ON EVIDENCE

In a systematic review of the effectiveness of hamstring stretching,<sup>38</sup> a 30-second manual or self-stretch performed

for one or more repetitions was the most frequently used duration per repetition of static stretch. A median duration of 30-seconds per repetition has also been reported in a review on calf muscle stretching effectiveness.<sup>161</sup>

Static stretching is well accepted as an effective method to increase flexibility and ROM<sup>2,38,69,70,87,110,125,152</sup> and is considered safer than ballistic stretching.<sup>42</sup> Early research established that tension created in muscle during static stretching is approximately half that created during ballistic stretching.<sup>149</sup> This is consistent with our current understanding of the viscoelastic properties of connective tissue, which lies in and around muscles, and of the neurophysiological properties of the contractile elements of muscle.

As described earlier in this chapter, noncontractile soft tissues are known to yield to a low-intensity, continuously applied stretch force, as used in static stretching. Furthermore, a low-intensity, slowly applied, continuous, end-range static stretch does not appear to cause significant neuromuscular activation of the stretched muscle.<sup>22,99</sup> However, the assertion

<sup>†</sup>7,8,14,25,52,87,92,110,122,151,161

that static stretching contributes to neuromuscular relaxation (inhibition) of the stretched muscle through activation of the GTO is not supported by experimental evidence in human research studies.<sup>22,131</sup>

### Static Progressive Stretching

Static progressive stretching is a term that characterizes how static stretching is applied for maximum effectiveness. The shortened soft tissues are held in a comfortably lengthened position until a degree of relaxation is felt by the patient or therapist. Then the shortened tissues are incrementally lengthened even further and again held in the new end-range position for an additional duration of time.<sup>15,75</sup> This approach involves periodically adjusting joint or segment alignment to increase the stretch force and capitalize on the stress-relaxation properties of soft tissue<sup>102</sup> (see Fig. 4.4B).

Most studies that have explored the merits of static *progressive* stretching have examined the effectiveness of a dynamic orthosis (see Fig. 4.13), which allows the patient to control the degree of joint angular displacement.<sup>15,75</sup> Manual stretching and self-stretching are also routinely applied in this manner.

### Cyclic (Intermittent) Stretching

A relatively short-duration stretch force that is repeatedly but gradually applied, released, and then reapplied multiple times during a single treatment session is described as a cyclic (intermittent) stretch.<sup>50,103,135</sup> With cyclic stretching, the end-range stretch force is applied at a slow velocity, in a controlled manner, and at relatively low intensity. For these reasons, cyclic stretching is not synonymous with ballistic stretching, which is characterized by high-velocity movements.

There is no clear differentiation between cyclic stretching and static stretching that is repeated several times during a treatment session. According to some authors, in cyclic stretching, each cycle of stretch is held between 5 and 10 seconds.<sup>50,135</sup> However, others refer to stretches of 5- and 10-second duration as static.<sup>25,122</sup> There is also no consensus on the minimum number of repetitions during a treatment session needed to differentiate cyclic stretching from static stretching. In practice, this determination is often based on the patient's response to stretching.

Although the evidence is limited, cyclic loading has been shown to increase flexibility as effectively or more effectively than static stretching.<sup>103,135</sup>

## FOCUS ON EVIDENCE

In a study of nonimpaired young adults, 60 seconds of cyclic stretching of calf muscles caused tissues to yield at slightly lower loads than one 60-second, two 30-second, or four 15-second static stretches, possibly due to decreased muscle stiffness.<sup>103</sup> In another study that compared cyclic to static stretching,<sup>135</sup> the authors speculated that heat production might occur because of the movement inherent in cyclic stretching and cause soft tissues to yield more readily to stretch. The authors of the latter study also concluded that cyclic stretching was more comfortable than a prolonged static stretch.

## Speed of Stretch

### Importance of a Slowly Applied Stretch

To minimize muscle activation during stretching and reduce the risk of injury to tissues and poststretch muscle soreness, a stretch force should be applied and released at a slow rate. A slowly applied stretch is less likely to increase tensile stresses on connective tissues<sup>97,98</sup> or to activate the stretch reflex. A slowly applied stretch also moderates the viscoelastic effects of connective tissue, making them more compliant. In addition, a stretch force applied at a low velocity is easier for the therapist or patient to control making it safer than a high-velocity stretch.

### Ballistic Stretching

A rapid, forceful intermittent stretch—that is, a high-velocity and high-intensity stretch—is commonly called ballistic stretching.<sup>2,7,8,47,163</sup> It is characterized by fast joint movement that quickly elongates the targeted soft tissues. For example, a rapidly produced straight leg raise can be used to ballistically stretch the hamstrings. Although both static and ballistic stretching have been shown to improve flexibility equally, ballistic stretching is thought to cause greater trauma to stretched tissues and greater residual muscle soreness than static stretching.<sup>153</sup>

Dynamic stretching, noted earlier as a stretch shown to enhance performance, uses controlled movement to stretch muscle groups.<sup>54</sup> Dynamic stretching is similar to ballistic stretching in that it moves the joint through its ROM, yet differs by doing so at low velocities and intensities. As dynamic stretching is emerging as a viable replacement for static stretching prior to athletic activities,<sup>9</sup> it may also have the potential to be appropriate for general fitness or rehabilitation programs.

Although ballistic stretching safely increases ROM in young, healthy subjects participating in a conditioning program,<sup>65</sup> it is, for the most part, not recommended for elderly or sedentary individuals or patients with musculoskeletal pathology or chronic contractures. The rationale for this recommendation is based on the following:<sup>33</sup>

- Tissues weakened by immobilization or disuse are easily injured.
- Dense connective tissue found in chronic contractures does not yield easily with high-intensity, short-duration stretch; rather, it becomes more brittle and tears more readily.

### High-Velocity Stretching in Conditioning Programs and Advanced-Phase Rehabilitation

Although controversial, there are situations in which high-velocity stretching is appropriate for certain individuals. For example, a highly trained athlete involved in a sport, such as gymnastics, that requires significant dynamic flexibility may need to incorporate high-velocity stretching in a conditioning program. Also, a young, active patient in the final phase of rehabilitation who wishes to return to high-demand recreational or sport activities after a musculoskeletal injury may

need to perform carefully progressed, high-velocity stretching activities prior to beginning plyometric training or simulated, sport-specific exercises or drills.

When high-velocity stretching is deemed appropriate, low-intensity stretches are recommended while paying close attention to effective stabilization. The following self-stretching progression is designed to improve dynamic flexibility using a transition from static stretching to dynamic stretching and then to ballistic stretching.<sup>163</sup>

- Static stretching → Slow, short end-range stretching → Slow, full-range stretching → Fast, short end-range stretching → Fast, full-range stretching.
- The stretch force is initiated by having the individual actively contract the muscle group opposite the muscle and connective tissues to be stretched.

## Frequency of Stretch

Frequency of stretching refers to the number of individual sessions per day or per week that a patient carries out the planned intervention. The optimal frequency of stretching is based on factors such as the underlying cause of impaired mobility, the quality and level of tissue healing, and the chronicity and severity of a contracture, as well as a patient's age, use of corticosteroids, and previous response to stretching. Because few studies have attempted to determine the optimal frequency of stretching within a day or a week, decisions on treatment frequency often depend on experience and best judgment. Frequency typically ranges from two to five sessions per week with time between sessions as needed for tissue healing and to minimize post-exercise soreness. Ultimately, the decision is based on the clinical discretion of the therapist and the response and needs of the patient.

A therapist must be aware of signs of tissue damage that may result from repetitive stretching. The correct balance between collagen tissue microfailure and subsequent repair is needed to allow an increase in soft tissue lengthening. With excessive loading frequency, tissue breakdown may exceed repair and tissue macrofailure becomes possible. In addition, if there is progressive loss of ROM over time rather than a gain in range, continued low-grade inflammation from repetitive stress may be causing excessive collagen formation and hypertrophic scarring.

## Mode of Stretch

Stretching exercises can be executed in a variety of ways. The mode of stretch refers to how the stretch force is applied and who is actively participating in the process. Categories include, but are not limited to, *manual* and *mechanical stretching* or *self-stretching*, as well as *passive*, *assisted*, or *active stretching*. Regardless of the mode of stretching selected and implemented, it is imperative that the shortened muscle remains relaxed and that the restricted connective tissues yield as easily as possible to the stretch. To facilitate this, stretching should

be preceded by either low-intensity active exercise or therapeutic heat to warm the tissues that are to be lengthened.

There is no best form or type of stretching. What is important is that the therapist and patient have many modes of stretching from which to choose. Box 4.6 lists some questions a therapist needs to answer to determine which forms of stretching are most appropriate and likely to be most effective for each patient at different stages of a rehabilitation program.

## Manual Stretching

**Characteristics.** During manual stretching, the clinician or caregiver applies an external force that lengthens the targeted tissue beyond the point of tissue resistance. The therapist manually controls the site of stabilization and the direction, rate of application, intensity, and duration of stretch. Manual stretching can be performed passively, with assistance from the patient, or even independently by the patient.

Manual stretching typically employs a controlled, static stretch applied at an intensity consistent with the patient's comfort level. It is held for 15 to 60 seconds and repeated for at least several repetitions. The intensity is often increased as tolerated for subsequent repetitions in an effort to achieve progressive lengthening.

### CLINICAL TIP

Remember—stretching and ROM exercises are not synonymous terms. Stretching takes soft tissue structures *beyond* their available length to *increase* ROM. ROM exercises stay within the limits of available tissue length to *maintain* mobility.

### BOX 4.6 Considerations for Selecting Methods of Stretching

- Based on the results of your examination, what tissues are involved and impairing mobility?
- Is there evidence of pain or inflammation?
- How long has the hypomobility existed?
- What is the stage of healing of restricted tissues?
- What form(s) of stretching have been implemented previously? How did the patient respond?
- Are there any underlying diseases, disorders, or deformities that might affect the choice of stretching procedures?
- Does the patient have the ability to actively participate in, assist with, or independently perform the exercises? Consider the patient's physical capabilities, age, ability to cooperate, or ability to follow and remember instructions.
- Is assistance from a therapist or caregiver necessary to execute the stretching procedures and appropriate stabilization? If so, what is the size and strength of the therapist or the caregiver who is assisting the patient with a stretching program?

**Effectiveness.** Despite widespread use of manual stretching by clinicians, its effectiveness for increasing tissue extensibility is debatable. Although some investigators<sup>43</sup> report that manual stretching increases muscle length and ROM in nonimpaired subjects, other investigators have reported a negligible effect from manual stretching,<sup>61</sup> especially in the presence of long-standing contractures associated with tissue pathology.<sup>92</sup> The short duration of typical manual stretching may be responsible for these disparate outcomes.

**Application.** The following are points to consider about the use of manual stretching:

- Manual stretching may be most appropriate in the early stages of a stretching program when a therapist wants to determine how a patient responds to varying intensities or durations of stretch and when optimal stabilization is most critical.
- Passive manual stretching by the therapist or caregiver is appropriate if a patient lacks neuromuscular control of the body segment to be stretched and cannot perform a self-stretch.
- When the patient has adequate neuromuscular control of the body segment to be stretched, it is often helpful to ask them to assist the therapist with the stretch, particularly if the patient is apprehensive about moving or having difficulty relaxing. When the patient concentrically contracts the muscle opposite the target muscle to assist with joint movement, the target muscle tends to relax reflexively and allow elongation. This is one of several stretching procedures based on PNF techniques that are discussed later in this chapter.
- Using procedures and hand placements similar to those described for self-ROM exercises (see Chapter 3), the patient can also independently lengthen target muscles and periarticular tissues with manual stretching. This is usually described as *self-stretching* and is discussed in more detail as the next topic in this section.

**NOTE:** Specific guidelines for the application of manual stretching, as well as descriptions and illustrations of manual stretching techniques for the extremities (Figs. 4.16 through 4.34), are presented in later sections of this chapter.

## Self-Stretching

**Characteristics.** Self-stretching (also referred to as flexibility exercises or active stretching) is a type of stretching procedure done independently by the patient after careful instruction and supervised practice. Self-stretching enables the patient to maintain or increase the extensibility gained as the result of direct intervention by a therapist. This form of stretching is often an integral component of a home exercise program and is necessary for long-term self-management of many musculoskeletal and neuromuscular disorders.

**Effectiveness.** To facilitate effectiveness, the patient must be taught to perform self-stretching procedures *correctly* and

*safely*. Factors identified earlier in the chapter such as alignment, stabilization, intensity, dose, and mode must all be addressed with the patient to prevent re-injury and maintain function.

**Application.** The guidelines for the intensity, speed, duration, and frequency that apply to manual stretching are also appropriate for self-stretching. Static stretching for a 30- to 60-second duration per repetition is considered the safest type of self-stretching.

Self-stretching can be carried out in several ways:

- Using positions for self-ROM exercises described in Chapter 3, a patient can passively move the distal segment of a restricted joint with one or both hands to elongate a shortened muscle while stabilizing the proximal segment (Fig. 4.11 A).

**FIGURE 4.11 (A)** When manually self-stretching the adductors and internal rotators of the hip, the patient moves the distal segment (femur) while stabilizing the proximal segment (pelvis) with body weight.

- If the distal attachment of a shortened muscle is stabilized on a support surface, body weight can be used as the source of the stretch force to elongate the shortened muscle-tendon unit (Fig. 4.11 B).
- Neuromuscular inhibition, using PNF stretching techniques, can be integrated into self-stretching procedures to promote relaxation in the muscle that is being elongated.
- Low-intensity active stretching (referred to by some as *dynamic ROM*<sup>8</sup>), using repeated, short-duration, end-range active muscle contractions of the muscle opposite the target muscle is another form of self-stretching exercise.<sup>8,151,158</sup>

**FIGURE 4.11—cont'd (B)** When self-stretching the hamstrings, the distal segment (tibia) is stabilized through the foot on the surface of a chair as the patient bends forward and moves the proximal segment. The weight of the upper body is the source of the stretch force.

## Mechanical Stretching

**Characteristics.** Mechanical stretching devices apply a very low-intensity stretch force over a prolonged period of time to create relatively permanent lengthening of soft tissues, presumably due to plastic deformation.

There are many ways to use equipment to stretch shortened tissues and increase ROM. The equipment can be as simple as a cuff weight or weight-pulley system or as sophisticated as some adjustable orthotic devices or automated stretching machines.<sup>12,15,75,89,92,101,135</sup> These mechanical stretching devices provide either a constant load with variable displacement or constant displacement with variable loads.

**Effectiveness.** Studies<sup>15,75</sup> about the efficacy of the two categories of mechanical loading devices base their effectiveness on the short-term soft tissue properties of either creep or stress-relaxation and on the long-term effects of plastic deformation.

Be cautious when interpreting studies or product information reporting “permanent” lengthening through the use of mechanical stretching devices. The term permanent may mean that length increases were maintained for as little as a few days or a week after discontinuing use of a stretching device, while long-term follow-up may indicate that tissues have returned to their shortened state.

**Application.** It is often the responsibility of a therapist to recommend the type of stretching device that is most suitable to the patient and to teach them how to safely use and monitor the equipment in the home setting. A therapist may also be involved in the fabrication of serial casts or orthoses used for mechanical stretching.

Each form of mechanical stretching listed below has been shown to be effective, particularly in reducing long-standing contractures:

- Stretch force applied with a cuff weight (Fig. 4.12) as low as a few pounds.<sup>92</sup>

**FIGURE 4.12** Low-load mechanical stretch with a cuff weight and self-stabilization of the proximal humerus to stretch the elbow flexors and increase end-range elbow extension.

- Devices such as the Joint Active Systems™ adjustable orthosis (Fig. 4.13) allow a patient to control and adjust the stretch force during a session.<sup>15,75</sup>

**FIGURE 4.13** JAS orthosis is a patient-directed device that applies a static progressive stretch. (Courtesy of Joint Active Systems, Effingham, IL.)

- Orthotics with a preset load that remains constant while the orthotic is in place.

### Duration of Mechanical Stretch

Mechanical stretching involves a substantially longer overall duration of stretch than is practical with manual stretching or self-stretching exercises. Mechanical stretch durations reported in the literature range from 15 to 30 minutes to as long as 8 to 10 hours per session<sup>15,56,75</sup> or continuous throughout the day except for time out of the device for hygiene and exercise.<sup>12</sup>

Serial casts are worn for days or weeks before being removed and then reapplied.<sup>72</sup> The duration is dependent on the type of device; patient tolerance; and the cause, severity, and chronicity of impairment. Longer duration stretches are typically required for patients with chronic contractures stemming from neurological or musculoskeletal disorders rather than healthy subjects with mild hypomobility.<sup>15,72,75,92,102,107</sup>

### FOCUS ON EVIDENCE

Light and colleagues<sup>92</sup> compared the effects of mechanical and manual stretching on nonambulatory elderly nursing home residents with long-standing bilateral knee flexion contractures. Both types of stretches were applied twice a day, 5 days per week, for a 4-week period. Low-intensity, prolonged mechanical stretching (a 5- to 12-lb stretch force applied by a weight-pulley system for 1 hour) was applied to one knee, and manual passive stretching was applied to the other knee by a therapist (three repetitions of 1-minute static stretches). At the conclusion of the study, the mechanical stretching procedure was found to be considerably more effective than the manual stretching procedure for reducing knee flexion contractures. The subjects also reported that the prolonged mechanical stretch was more comfortable than the manual stretching procedure. The investigators recognized that the total duration of mechanical stretch (40 hours) was substantially longer over the course of the study than the total duration of manual stretch (2 hours) but believed that the manual stretching procedures were practical and typical of the clinical setting.

## Proprioceptive Neuromuscular Facilitation Stretching Techniques

PNF stretching techniques,<sup>22,69,99,115,131</sup> sometimes referred to as *active stretching*<sup>158</sup> or *facilitative stretching*,<sup>117</sup> integrate active muscle contractions into stretching. These techniques are used to inhibit or facilitate muscle activation and to increase the likelihood that the muscle to be lengthened remains as relaxed as possible as it is stretched.

The traditional explanation of the underlying mechanisms of PNF stretching is that reflexive muscle relaxation occurs during the stretch as the result of autogenic or reciprocal inhibition. This inhibition leads to decreased tension in muscle fibers and decreased resistance to elongation by the contractile elements of the target muscle. However, this explanation has come into question in recent years.

Current thinking suggests that gains in ROM during or following PNF stretching techniques cannot be attributed solely to autogenic or reciprocal inhibition, which involves the spinal processing of proprioceptive information. Rather, increased ROM is the result of more complex mechanisms of sensorimotor processing, most likely combined with viscoelastic adaptation of the muscle-tendon unit and increases in the patient's tolerance to stretching.<sup>22,99,131</sup> Regardless of these

competing explanations, numerous studies have demonstrated that the various PNF stretching techniques can increase flexibility and ROM.<sup>8,36,50,115,158</sup> However, the degree of neuromuscular relaxation associated with the PNF stretching maneuvers investigated was not determined in these studies. There is also some evidence<sup>99</sup> that PNF stretching yields greater gains in ROM than static stretching, but there is no consensus on whether one PNF technique is significantly superior to another.

### Types of PNF Stretching VIDEO 4.1

There are several types of PNF stretching procedures, all of which have been shown to improve ROM. They include:

- Hold-relax (HR) or contract-relax (CR)
- Agonist contraction (AC)
- Hold-relax with agonist contraction (HR-AC)

With classic PNF, these techniques are always performed with combined muscle groups acting in diagonal patterns.<sup>117,118,148</sup> Over time the techniques have been modified by clinicians and others to include stretching in a single plane or opposite the line of pull of a specific muscle group.<sup>8,27,63,71,99,115,158</sup> (For a description of the PNF diagonal patterns, refer to Chapter 6.)

### CLINICAL TIP

PNF stretching techniques require that a patient has normal innervation and voluntary control of either the range-limiting target muscle or the muscle on the opposite side of the joint. As such, these techniques cannot be used effectively for patients with paralysis or spasticity resulting from neuromuscular diseases or injury. Furthermore, because PNF stretching procedures are designed to affect the contractile elements of muscle, as opposed to noncontractile connective tissues, they are more appropriate to use when muscle spasm limits motion and less appropriate for long-standing fibrotic contractures.

### Hold-Relax and Contract-Relax

With the HR and CR procedures,<sup>27,71,99,115,117,118</sup> the range-limiting target muscle is first lengthened to the point of tissue resistance or to the extent that is comfortable for the patient. The patient then actively performs a *prestretch*, *end-range, isometric contraction* of the range-limiting target muscle against manual resistance applied by the clinician. This contraction is held for about 5 seconds and followed by *voluntary* relaxation of the target muscle. The limb is then passively moved by the clinician into the new range as the range-limiting muscle is elongated. Clinicians with experience using PNF report that the HR and CR techniques appear to make passive elongation of muscles more comfortable for a patient than manual passive stretching.<sup>71</sup> A sequence for using the HR and CR technique to stretch shortened pectoralis major muscles bilaterally and increase horizontal abduction of the shoulders is illustrated in Figure 4.14.

**FIGURE 4.14** Hold-relax (HR) procedure to stretch the pectoralis major muscles bilaterally. **(A)** The therapist horizontally abducts the shoulders bilaterally to a comfortable position. The patient isometrically contracts the pectoralis major muscles against the therapist's resistance for about 5 to 10 seconds. **(B)** The patient relaxes voluntarily, and the therapist passively lengthens the pectoralis major muscles by horizontally abducting the shoulders into the newly gained range. After a 10-second rest with the muscles maintained in a comfortably lengthened position, the entire sequence is repeated several times.

**NOTE:** Although the terms *CR* and *HR* often are used interchangeably, in classic PNF the technique descriptions are not identical. Both techniques are performed in diagonal patterns, but in the *CR* technique, the axial rotators of the limb are allowed to contract concentrically in the prestretch phase, while all other muscle groups of the diagonal pattern contract isometrically. In contrast, the prestretch isometric contraction occurs in all muscles of the diagonal pattern during the *HR* technique.<sup>118,148</sup>

As noted earlier, the traditional explanation for PNF effectiveness is that neuromuscular relaxation results from autogenic inhibition following the prestretch isometric contraction of the target muscle.<sup>95,117,118</sup> Some investigators<sup>99</sup> have challenged this assumption, attributing the gains in flexibility to the viscoelastic properties of the muscle-tendon unit. These studies report a postcontraction sensory discharge (increased EMG activity) in the range-limiting muscle after the prestretch contraction, suggesting that the muscle was not reflexively relaxed prior to stretch. However, the results of another study<sup>28</sup> indicated no evidence of a postcontraction elevation in EMG activity with the *HR* or *CR* techniques.

In light of the mixed evidence about the extent of neuromuscular relaxation achieved after the prestretch contraction, practitioners must determine the effectiveness of the *HR* or *CR* techniques based on the responses of their patients.

**PRECAUTION:** Multiple repetitions of maximal prestretch isometric contractions have been shown to result in an acute

increase in arterial blood pressure, most notably after the third repetition.<sup>29</sup>

### CLINICAL TIP

It is not necessary for the patient to perform a maximal isometric contraction of the range-limiting target muscle prior to stretch. To minimize the adverse effects of the Valsalva maneuver (elevation in blood pressure associated with a high-intensity effort), have the patient breathe regularly while performing *submaximal* (low-intensity) isometric contractions held for about 5 seconds with each repetition of the *HR* or *CR* procedure. From a practical perspective, a submaximal contraction is also easier for the therapist to control if the patient is strong.

### Agonist Contraction

Another PNF stretching technique is the *agonist contraction* (*AC*), a term that may be misleading.<sup>28,71,115</sup> The “agonist” in this case refers to the muscle *opposite* the range-limiting target muscle, while the “antagonist” refers to the range-limiting muscle. It may help to frame this paradigm as the short muscle (the antagonist) preventing the prime mover (the agonist) from actively achieving full movement. *Dynamic ROM* (*DROM*)<sup>8</sup> and *active stretching*<sup>158</sup> are other terms that have been used to describe the *AC* procedure.

With the AC procedure, the patient *concentrically contracts (shortens) the muscle opposite the range-limiting muscle* and then holds the end-range position for at least several seconds.<sup>22,28,71,115</sup> The movement of the limb is controlled independently by the patient and is deliberate and slow, not ballistic. In most instances, the shortening contraction is performed without the addition of resistance. For example, if the hip flexors are the range-limiting target muscle group, the patient performs end-range prone leg lifts by contracting the hip extensors concentrically and holding at the end range for several seconds. After a brief rest period, the patient repeats the procedure.

Increased muscle length and joint ROM using the AC procedure have been reported. However, when the effectiveness of the AC technique has been compared with that of static stretching, the evidence is mixed.

### FOCUS ON EVIDENCE

Two studies have compared the effect of the AC procedure, referred to as DROM, to static stretching of the hamstrings of healthy subjects over a 6-week period. One study<sup>151</sup> demonstrated that DROM is as effective as static stretching, but the other study<sup>8</sup> showed that one daily session of a 30-second static stretch was almost three times as effective in increasing hamstring flexibility as was six repetitions of a 5-second end-range DROM hold performed daily.

In a study of young adults with hypomobile hip flexors and periodic lumbar or lower-quarter pain, investigators compared active stretching with the AC procedure to static passive stretching.<sup>158</sup> Both techniques resulted in increased hip extension with no significant difference between the AC and passive stretching groups.

In addition to the evidence related to the AC stretching procedure, clinicians have observed the following:

- The AC technique seems to be especially effective when significant antagonist muscle guarding restricts muscle lengthening and joint movement but is less effective in reducing chronic contractures.
- AC is also useful when the patient cannot generate a strong, pain-free contraction of the range-limiting muscle, which is needed for the HR and CR procedures.
- AC is also useful for initiating neuromuscular control in newly gained joint ROM to re-establish dynamic flexibility.
- The AC technique is least effective if a patient has close to normal flexibility.

**PRECAUTION:** Avoid full-range, ballistic movements when performing concentric contractions of the agonist muscle group.

### CLINICAL TIP

If, while performing an AC technique, the agonist is contracting in a very shortened position, have the patient rest after each repetition to avoid muscle cramping.

Classic PNF theory suggests that when the agonist is activated and contracts concentrically, the antagonist (the range-limiting muscle) is reciprocally inhibited, allowing it to relax and lengthen more readily.<sup>117,122</sup> However, the theoretical mechanism of reciprocal inhibition has been substantiated only in animal studies.<sup>119</sup> Evidence of reciprocal inhibition during the AC procedure has not been demonstrated in human subjects.<sup>22,119,131</sup> In fact, increased EMG activity, not reciprocal inhibition, has been identified in the range-limiting muscle during the AC stretching procedure.<sup>28,115</sup>

### Hold-Relax With Agonist Contraction

The HR-AC stretching technique combines the HR and AC procedures. The HR-AC technique is also referred to as the CR-AC procedure<sup>22</sup> or the slow reversal hold-relax technique.<sup>148</sup> To perform the HR-AC procedure, move the limb to the point that tissue resistance is felt in the range-limiting target muscle; then have the patient perform a resisted, prestretch isometric contraction of the range-limiting muscle, *followed* by voluntary relaxation of that muscle and an immediate concentric contraction of the muscle *opposite* the range-limiting muscle.<sup>28,117,148</sup>

For example, to stretch knee flexors, extend the patient's knee to a comfortable end-range position and then have the patient perform an isometric contraction of the knee flexors against resistance for about 5 seconds. Tell the patient to voluntarily relax and then actively extend the knee as far as possible, holding any newly gained range for several seconds.

### FOCUS ON EVIDENCE

Studies comparing two PNF stretching procedures have produced differing results. In one study,<sup>50</sup> the HR-AC technique produced a greater increase in ankle dorsiflexion range than the HR technique alone, while both HR-AC and HR alone produced a greater increase than manual passive stretching. However, another study<sup>71</sup> reported no significant difference in ROM between the use of the HR and HR-AC techniques.

**PRECAUTIONS:** Recognize the same precautions as described for both the HR and AC procedures and follow the CLINICAL TIPS to minimize complications and discomfort.

## Integration of Function Into Stretching

### Importance of Strength and Muscle Endurance

As previously discussed, the strength of soft tissue is altered when it is immobilized for a period of time.<sup>23,106</sup> The magnitude of peak tension produced by muscle decreases, and the tensile strength of noncontractile tissues decreases. A muscle group that has been elongated while its opposing muscle

group has been in a shortened state for an extended period of time also becomes weak.<sup>82,90,91</sup> Therefore, it is critical to include low-load resistance exercises to improve muscle performance (strength and endurance) as early as possible in a stretching program.

Initially, emphasis should be on developing neuromuscular control and strength of the agonist, the muscle group opposite the range-limiting target muscle. For example, if the elbow flexors are the range-limiting muscle group, emphasize contraction of the elbow extensors in the newly gained range. Early use of the agonist enables the patient to elongate the hypomobile structures actively and use the recently gained ROM.

As ROM approaches a “normal” or functional level, the muscles that were range limiting and then stretched must also be strengthened to maintain an appropriate balance of strength between agonists and antagonists throughout the ROM. Manual and mechanical resistance exercises are effective ways to load and strengthen muscles, but functional weight-bearing activities, such as those mentioned below, will specifically strengthen antigravity muscle groups.

### Use of Increased Mobility for Functional Activities

As mentioned previously, gains in flexibility and ROM achieved as the result of a stretching program are transient, lasting only about 4 weeks after the cessation of stretching.<sup>156</sup> The most effective means of achieving permanent increases in ROM and reducing functional limitations is to integrate functional activities that use the newly gained range on a regular basis into the stretching program. Use of functional activities to maintain mobility also lends diversity and interest to a stretching program, which may benefit patient compliance.

Active movements should be performed within the pain-free ROM. As soon as even small increases in tissue extensibility and ROM have been achieved, have the patient use the gained range by performing motions that *simulate* functional activities. Have the patient transition to using all of the available ROM while doing specific functional tasks when they are ready.

Functional movements that are practiced should complement the stretching program. For example, if a patient has been performing stretching exercises to increase shoulder mobility, have the patient fully use the available ROM by reaching as far as possible behind the back and overhead when grooming or dressing or by reaching for or placing objects on a high shelf (Fig. 4.15). Gradually increase the weight of objects placed on or removed from a shelf to strengthen shoulder musculature simultaneously.

If the focus of a stretching program has been to increase knee flexion after removal of a long-leg cast, emphasize flexing both knees before standing up from a chair or when stooping to pick up an object from the floor. These weight-bearing activities also strengthen the quadriceps that were held in a shortened position and likely became weak while the leg was immobilized.

**FIGURE 4.15 (A, B)** Stretching-induced gains in ROM are used during daily activities.

## Procedural Guidelines for Application of Stretching Interventions

The following guidelines are central to the development and implementation of stretching interventions. The results of an examination and evaluation of a patient’s status determine the need for and types of stretching procedures that will be most effective in the patient’s plan of care. This section identifies general guidelines to be addressed before, during, and after stretching procedures, as well as specific guidelines for the application of manual stretching. Special considerations for teaching self-stretching exercises to the patient and the use of mechanical stretching devices are listed in Boxes 4.7 and 4.8.

### BOX 4.7 Special Considerations for Teaching Self-Stretching Exercises

- Be sure to carefully teach the patient all elements of self-stretching procedures, including appropriate alignment and stabilization, intensity, duration, and frequency. Because many self-stretching exercises are performed using a portion of the body weight as the stretch force (by moving the body over a fixed distal segment), emphasize the importance of performing a slow, sustained stretch, not a ballistic stretch that creates momentum and may lengthen but can potentially injure hypomobile soft tissues.
- Make sure the patient is taught to carry out stretching exercises on a firm, stable, comfortable surface to maintain proper alignment.
- Supervise the patient and make suggestions or corrections to be certain the patient performs each exercise using safe biomechanics that protect joints and ligaments, especially at the end of the ROM. Pay particular attention to maintaining postural alignment and effective stabilization.
- Emphasize the importance of warming up the tissues prior to stretching with low-intensity, rhythmic activities such as cycling. Stretching should not be the first activity in an exercise routine because cold tissue may be easier to injure.
- If appropriate and possible, teach the patient how to independently incorporate neuromuscular inhibition techniques, such as the hold-relax procedure, into selected stretching exercises.
- Provide written instructions with illustrations to which the patient can refer when independently performing the self-stretching exercises.
- Demonstrate how items commonly found around the house, such as a towel, belt, broomstick, or homemade weight, can be used to assist with stretching activities.
- Emphasize the importance of using the gained ROM during appropriately progressed functional activities.

## Examination and Evaluation of the Patient

- Carefully review the patient's history and perform a comprehensive systems review.
- Select and perform appropriate tests and measurements. Determine the ROM available in involved and adjacent joints and assess if active and/or passive mobility is impaired.
- Determine if hypomobility is related to other impairments of body structure or function and if it is causing activity limitations or participation restrictions.
- Determine if soft tissues are the source of the impaired mobility. If so, differentiate between joint capsule, periarticular structures, noncontractile tissue, and muscle length restrictions as the cause of limited ROM. Be sure to assess joint play and fascial mobility.
- Evaluate the irritability of the involved tissues and estimate their stage of healing. When moving the patient's extremities

### BOX 4.8 Special Considerations for Use of Mechanical Stretching Devices

- Become thoroughly familiar with the manufacturer's product information.
- Become familiar with stretching protocols recommended by the manufacturer; seek out research studies that provide evidence of the efficacy of the equipment or protocols.
- Determine if modifying a suggested protocol is warranted to meet your patient's needs. For example, should the suggested intensity of stretch or recommended wearing time (duration and frequency) be modified?
- Check the fit of a device before sending it home with a patient. Teach the patient how to apply and safely adjust the device and how to maintain it in good working order. Be sure that the patient knows who to contact if the equipment appears to be defective.
- Teach the patient where and how to inspect the skin to detect areas of excessive pressure from the stretching device and potential skin irritation.
- If the mechanical stretching device is "homemade," such as a cuff weight, check to see if the equipment is safe and effective.
- Have the patient keep a daily record of using the stretching device.
- Re-examine and re-evaluate the patient and equipment periodically to determine the effectiveness of the mechanical stretching program and to modify and progress the program as necessary.
- Be sure the patient complements the use of mechanical stretching with active exercises.

or spine, pay close attention to the patient's reaction to movements. This not only helps identify the stage of healing of involved tissues; it also helps determine the probable dosage (such as intensity and duration) of stretch that stays within the patient's comfort range.

- Assess the strength of muscles in which there is motion limitation and realistically consider the value of stretching the range-limiting structures. Ideally, an individual should have the capability of developing adequate strength to control and use any newly gained ROM safely.
- Consider the outcome goals (i.e., functional improvements) that the patient hopes to achieve as the result of the intervention program and determine if those goals are realistic.
- Analyze the impact of any factors that could adversely affect the projected outcomes of the stretching program.

## Preparation for Stretching

- Review the goals and desired outcomes of the stretching program with the patient. Obtain the patient's consent to initiate treatment.
- Select the stretching techniques that will be most effective and efficient.

- Warm up the soft tissues to be stretched by the application of local heat or by active, low-intensity exercises. Warming up tight structures may increase their extensibility and decrease the risk of injury from stretching.
- Have the patient assume a comfortable, stable position that allows the correct plane of motion for the stretching procedure. *The direction of stretch is exactly opposite the direction of the joint or muscle restriction.*
- Explain the procedure to the patient and be certain he or she understands.
- Free the area to be stretched of any restrictive clothing, bandages, or orthotics.
- Explain to the patient that it is important to be as relaxed as possible and that the stretching procedures are meant to remain within his or her tolerance level.

## Application of Manual Stretching Procedures

- Move the extremity slowly through the free range to the point of tissue restriction.
- Grasp the areas proximal and distal to the joint in which motion is to occur. The grasp should be firm but not uncomfortable for the patient. Use padding, if necessary, in areas with minimal subcutaneous tissue, reduced sensation, or over a bony surface. Use the broad surfaces of your hands to spread forces over a larger surface area.
- Firmly stabilize the proximal segment (manually or with equipment) and move the distal segment.
- To stretch a multijoint muscle, stabilize either the proximal or distal segment to which the range-limiting muscle attaches. Stretch the muscle over one joint at a time and then over all joints simultaneously until the optimal length of soft tissues is achieved. To minimize compressive forces in small joints, stretch the distal joints first and proceed proximally.
- Consider incorporating a prestretch, isometric contraction of the range-limiting muscle (the HR procedure).
- To minimize joint compression during the stretch, a gentle (grade I) distraction to the moving joint can be applied.
- Apply the stretch using a slow, sustained rate. Remember, the direction of the stretching movement is directly *opposite* the line of pull of the range-limiting muscle. Ask the patient to assist you with the stretch or apply a passive stretch to lengthen the tissues. Take the hypomobile soft tissues to the point of firm tissue resistance and then move just beyond that point. The force must be enough to place tension on soft tissue structures but not so great as to cause pain or injure the structures. The patient should experience a *pulling sensation*, but not pain, *in the structures being stretched*. When stretching adhesions of a tendon within its sheath, the patient may describe a “stinging” sensation as adhesions are mobilized.
- Maintain the stretch position for 30 seconds or longer. During this time, the tension in the tissues should slowly decrease. When tension decreases, move the extremity or joint a little farther to progressively lengthen the hypomobile tissues.

- Gradually release the stretch force and allow the patient and therapist to rest momentarily while maintaining the range-limiting tissues in a comfortably elongated position. Then repeat the sequence several times.
- If the patient does not seem to tolerate a sustained stretch, use several very slow, gentle, intermittent stretches with the muscle in a lengthened position.
- If deemed appropriate, apply selected soft tissue mobilization procedures, such as fascial massage or cross-fiber friction massage, at or near the sites of adhesion during the stretching maneuver.

### CLINICAL TIP

Do not attempt to gain the full range in one or two treatment sessions. Resolving mobility impairment is a slow, gradual process. It may take several weeks of stretching to see significant results. Between stretching sessions, it is important to use the newly increased range to maintain what has been gained.

## After Stretching

- Apply cold to the soft tissues that have been stretched and allow these structures to cool in a lengthened position. Cold may minimize poststretch muscle soreness that can occur as the result of microtrauma during stretching. When soft tissues are cooled in a lengthened position, increases in ROM are more readily maintained.<sup>73,102</sup>
- Have the patient perform active ROM and strengthening exercises through the gained range immediately after stretching. With your supervision and feedback, have the patient use the gained range by performing simulated functional movement patterns that are part of daily living, occupational, or recreational tasks.
- Strengthen the antagonistic muscles in the newly gained range to ensure adequate neuromuscular control and stability as flexibility increases.

## Precautions for Stretching

There are a number of general precautions that apply to all forms of stretching interventions. In addition, some special precautions must be taken when advising patients about stretching exercises that are part of community-based fitness programs or commercially available exercise products marketed to the general public.

### General Precautions

- Do not passively force a joint beyond its normal ROM. Remember, normal (typical) ROM varies among individuals. In adults, flexibility is greater in women than in men.<sup>162</sup> When treating older adults, be aware of age-related changes in flexibility.

## FOCUS ON EVIDENCE

Some studies suggest that flexibility decreases with age, particularly when coupled with decreased activity levels.<sup>4,5</sup> However, a study of more than 200 adults ages 20 to 79 who regularly exercised demonstrated that hamstring length did not significantly decrease with age.<sup>162</sup>

- Use extra caution in patients with known or suspected osteoporosis due to disease, prolonged bed rest, age, or prolonged use of steroids.
- Protect newly united fractures; be certain there is appropriate stabilization between the fracture site and the joint in which the motion takes place.
- Remember that a longer lever arm creates greater torque at a joint. Always be aware that the point of force application on each of the segments will influence the tensile load on the target tissue.
- Avoid vigorous stretching of muscles and connective tissues that have been immobilized for an extended period of time. Connective tissues, such as tendons and ligaments, lose their tensile strength after prolonged immobilization.<sup>90</sup> High-intensity, short-duration stretching procedures tend to cause more trauma and resulting weakness of soft tissues than low-intensity, long-duration stretch.
- Progress the dosage (intensity, duration, and frequency) gradually to minimize soft tissue trauma and postexercise muscle soreness. If a patient experiences joint pain or muscle soreness lasting more than 24 hours after stretching, it is likely that too much stretch force caused an inflammatory response. This, in turn, can result in increased scar tissue formation. Patients should experience no more residual discomfort than a transitory feeling of tenderness.
- Avoid stretching edematous tissue, as it is more susceptible to injury than normal tissue and continued irritation usually causes increased pain and edema.
- Avoid overstretching weak muscles, particularly those that support body structures in relation to gravity.

## Special Precautions for Mass-Market Flexibility Programs

To develop and maintain a desired level of fitness, many people participate in physical conditioning programs at home or in the community. Self-stretching exercises are often an integral component of these programs. As a result, individuals frequently learn self-stretching procedures in fitness classes or from popular videos or television programs. Although much of the information in these resources is usually safe and accurate, there may also be errors or potential problems in flexibility programs designed for the mass market. These problems are possible any time the assessment of an individual's specific limitations is not obtained

by a trained professional and a “one-size-fits-all” approach is used.

## Common Errors and Potential Problems

***Nonselective or poorly balanced stretching activities.*** General flexibility programs may advise stretching body regions that are already mobile or even hypermobile, while neglecting regions that are tight from faulty posture or inactivity. For example, in the sedentary population, some degree of hypomobility tends to develop in the hip flexors, trunk flexors, shoulder extensors and internal rotators, and scapular protractors from sitting in a slumped posture. Yet, if the commercially available flexibility routines overemphasize exercises that stretch posterior muscle groups and fail to include exercises to stretch the tight anterior structures, faulty postures may worsen rather than improve.

***Insufficient warm-up.*** Individuals involved in flexibility programs may fail to warm up prior to stretching.

***Ineffective stabilization.*** Programs often lack effective methods of self-stabilization. Therefore, an exercise may fail to stretch the intended tight structures and may transfer the stretch force to structures that are already mobile or even hypermobile.

***Use of ballistic stretching.*** Although a less common problem than in the past, some exercise routines still recommend ballistic stretching. Because this form of stretching is not well controlled, it increases the likelihood of post-exercise muscle soreness and significant injury to soft tissues.

***Excessive intensity.*** The phrase “no pain, no gain” is often used inappropriately as the guideline for intensity of stretch. An effective flexibility routine should be progressed gradually by remaining within each individual's pain tolerance levels.

***Abnormal biomechanics.*** Some popular stretching exercises do not respect the biomechanics of the region. For example, the “hurdler's” stretch is designed to simultaneously stretch the hamstrings of one lower extremity and the quadriceps of the opposite extremity but may impose detrimental strain on the medial capsule and ligaments of the flexed knee.

***Insufficient information about age-related differences.*** A single flexibility program does not fit all age groups. As a result of the normal aging process, mobility of connective tissues diminishes.<sup>4,5,77</sup> Consequently, elderly individuals typically exhibit less flexibility than young adults. Even an adolescent after a growth spurt temporarily exhibits restricted flexibility, particularly in two-joint muscle groups. Flexibility programs marketed to the general public may not be sensitive to these normal, age-related differences in flexibility.

## Strategies for Risk Reduction

- When possible, assess the appropriateness and safety of exercises in a “prepackaged” flexibility program.
- If a patient you are treating is participating in a community-based fitness class, review the exercises in the program

and determine their appropriateness and safety for your patient.

- Stay up to date on current exercise programs, products, and trends by reviewing the content and safety of your patient's home exercise videos.
- Determine whether a class or video is intended for individuals of the same age or with similar physical conditions.
- Eliminate or modify those exercises that are inconsistent with the intervention plan you have developed for your patient.
- See that the flexibility program maintains a balance of mobility between antagonistic muscle groups and emphasizes stretching those muscle groups that often become shortened with age, faulty posture, or a sedentary lifestyle.
- Teach your patient the basic principles of self-stretching and to evaluate fitness materials that they are using. Encourage them to select only safe and appropriate stretching exercises while avoiding those that perpetuate impairments or have no value.
- Make sure your patient understands the importance of warming up prior to stretching. Give suggestions on how to warm up before stretching.
- Be certain that the patient knows how to provide effective self-stabilization and isolate a stretch to specific muscle groups.
- Teach your patient how to determine the appropriate intensity of stretch; be sure your patient knows that, at most, postexercise muscle soreness should be mild and last no more than 24 hours.

## Adjuncts to Stretching Interventions

Practitioners managing patients with structural or functional impairments, including chronic pain, muscle guarding or imbalances, and restricted mobility, may find it useful to integrate complementary therapies that address the body, mind, and spirit, such as relaxation training, Pilates, yoga, or tai chi into a patient's plan of care to improve function and quality of life. Other interventions that are useful adjuncts to a stretching program include superficial or deep heat, cold, massage, biofeedback, and joint traction.

### Complementary Approaches

#### Relaxation Training

*Relaxation training* has been used for many years by a variety of practitioners<sup>49,53,74,129,146</sup> to help patients learn to relieve or reduce pain; muscle tension; anxiety or stress; and associated physical impairments or medical conditions, including tension headaches, high blood pressure, and respiratory distress. Some of the many approaches used to achieve beneficial

relaxation include progressive relaxation, biofeedback, stress and anxiety management, and imagery. A brief overview of techniques is presented in this section.

There are a number of physiological, behavioral, cognitive, and emotional responses that occur during total body relaxation.<sup>146</sup> These key indicators are decreased muscle tension, lowered blood pressure, lowered heart and respiratory rates, increased skin temperature in the extremities, constricted pupils, little to no body movement, eyes closed and flat facial expression, jaw and hands relaxed, and decreased distractibility.

#### Common Elements of Relaxation Training

The purpose of relaxation training is to reduce muscle tension in the entire body or the painful or restricted region by using conscious effort and thought. Training typically occurs in a quiet environment with low lighting and soothing music or an auditory cue on which the patient may focus. The patient performs deep breathing exercises or visualizes a peaceful scene. When giving instructions, the therapist uses a calm and soft tone of voice.

#### Examples of Approaches to Relaxation Training

**Autogenic training.** This approach, advocated by Schultz and Luthe<sup>129</sup> and Engle,<sup>49</sup> involves conscious relaxation through autosuggestion and a progression of exercises as well as meditation.

**Progressive relaxation.** This technique, pioneered by Jacobson,<sup>74</sup> uses systematic, distal-to-proximal progression of voluntary contraction and relaxation of muscles. It is sometimes incorporated into childbirth education.

**Awareness through movement.** The system of therapy developed by Feldenkrais<sup>53</sup> combines sensory awareness, movements of the limbs and trunk, deep breathing, conscious relaxation procedures, and self-massage to remediate muscle tension and pain by altering muscle imbalances and abnormal postural alignment.

#### Sequence for Progressive Relaxation Techniques

- Place the patient in a quiet area and in a comfortable position and be sure that restrictive clothing is loosened.
- Have the patient breathe in a deep, relaxed manner.
- Ask the patient to contract the distal musculature in the hands or feet voluntarily for several (5 to 7) seconds and then consciously relax those muscles for 20 to 30 seconds.
- Suggest that the patient try to feel a sense of heaviness in the hands or feet and a sense of warmth in the muscles just relaxed.
- Progress to a more proximal area of the body and have the patient actively contract and actively relax the more proximal musculature. Eventually have the patient isometrically contract and consciously relax the entire extremity.
- Suggest to the patient that he or she should feel a sense of relaxation and warmth throughout the entire limb and eventually throughout the whole body.

## Pilates

Pilates is an approach to exercise that combines Western theories of biomechanics, core stability, and motor control with Eastern theories of the interaction of body, mind, and spirit.<sup>6</sup> Components of a Pilates exercise session typically include deep breathing and core stabilization exercises, focus on activation and relaxation of specific muscle groups, posture control and awareness training, strength training (primarily using body weight as resistance), balance exercises, and flexibility exercises.<sup>134</sup>

Although Pilates training may be part of community-based fitness programs for healthy adults, therapists may also incorporate elements of Pilates into individualized intervention programs for patients with a variety of diagnoses. Despite limited research, Pilates exercises appear to have a positive benefit on function (including improved flexibility, strength, and pain control) and quality of life in healthy individuals<sup>130</sup> and those with impairments.<sup>81,126</sup>

## Heat

Warming up prior to stretching is an important element of rehabilitation and fitness programs. It is well documented in human and animal studies that as intramuscular temperature increases, the extensibility of contractile and noncontractile soft tissues likewise increases. In addition, as the temperature of muscle increases, the amount of force required and the time the stretch force must be applied decrease.<sup>88,89,123,154</sup> There is also a decrease in the rate of firing of the type II efferents from the muscle spindles and an increase in the sensitivity of the GTO, which makes it more likely to fire.<sup>57</sup> It is also believed that when tissues relax and more easily lengthen, stretching is associated with less muscle guarding and is more comfortable for the patient.<sup>88,89</sup>

### CLINICAL TIP

Although stretching is often thought of as a warm-up activity performed prior to vigorous exercise,<sup>132</sup> an appropriate warm-up, typically through low-intensity active exercise, must be carried out *in preparation* for stretching.

## Methods of Warm-Up

Superficial heat (hot packs or paraffin) or deep-heating modalities (ultrasound or shortwave diathermy) provide different mechanisms to heat tissues.<sup>104,121</sup> These thermal agents are used primarily to heat small areas such as individual joints, muscle groups, or tendons and may be applied prior to or during the stretching procedure.<sup>46,83,123</sup> There is no consensus as to whether heating modalities should be applied prior to or during the stretching procedure.

Low-intensity, active exercises, which generally increase circulation and core body temperature, also can be used as a

mechanism to warm up large muscle groups prior to stretching.<sup>43,83</sup> Some common warm-up exercises are a brief walk, nonfatiguing cycling on a stationary bicycle, use of a stair-stepping machine, active heel raises, or a few minutes of active arm exercises.

## Effectiveness of Warm-Up Methods

Thermal agents or warm-up exercises used alone without stretching have either little or no effect on improving muscle flexibility.<sup>16,43,65,135</sup> While some evidence indicates that heat combined with stretching produces greater long-term gains in tissue length than stretching alone,<sup>45,46</sup> other studies have not shown differences in ROM gain between these two methods.<sup>43,65,83,139</sup>

## Cold

The application of cold prior to stretching (cryostretching) compared with heat has been studied,<sup>139</sup> and advocates suggest it decreases muscle tone and makes the muscle less sensitive during stretch in healthy subjects<sup>62</sup> and in patients with spasticity or rigidity secondary to upper motor neuron lesions.<sup>148</sup> While the use of cold immediately after soft tissue injury effectively decreases pain and muscle spasm, once healing and scar formation begin, cold makes healing tissues less extensible and more susceptible to microtrauma during stretching.<sup>33,88</sup> Cooling soft tissues in a lengthened position *after* stretching has been shown to promote more lasting increases in soft tissue length and to minimize poststretch muscle soreness.<sup>89</sup>

### CLINICAL TIP

The authors of this text recommend that cold be applied to injured soft tissues during the first 24 to 48 hours after injury to minimize swelling, muscle spasm, and pain. Remember, stretching is contraindicated in the presence of inflammation that occurs during the acute phase of tissue healing (see Chapter 10). When inflammation subsides and stretching is indicated, the authors advocate warming soft tissues prior to or during a stretching maneuver. After stretching, cold should be applied to soft tissues held in a lengthened position to minimize poststretch muscle soreness and to promote longer-lasting gains in ROM.

## Massage

### Massage for Relaxation

Local muscle relaxation can be enhanced by massage, particularly with light or deep stroking techniques.<sup>40,138</sup> Self-massage with light stroking techniques is used to enhance relaxation in some approaches to pain or stress and anxiety management.<sup>53</sup> In sports and conditioning programs,<sup>11,138</sup> massage is used for general relaxation purposes or to

enhance recovery after strenuous physical activity, although the efficacy of the latter is not well founded.<sup>144</sup> Because massage has been shown to increase circulation to muscles and decrease muscle spasm, it can be a useful adjunct to stretching exercises.

### Soft Tissue Mobilization/Manipulation Techniques

Another broad category of massage is soft tissue mobilization/manipulation. Although these techniques involve various forms of deep massage, the primary purpose is not relaxation but to increase the mobility of adherent or shortened connective tissues including fascia, tendons, and ligaments.<sup>20</sup>

There are several soft tissue mobilization/manipulation techniques that are used clinically to improve soft tissue mobility. These techniques are often specific to a tissue or specific adhesion, and the rationale for their use is based primarily on the mechanical effects of stress and strain. Stresses during the technique are applied for a long enough duration for creep and stress-relaxation of tissues to occur. With *myofascial massage*,<sup>20,93</sup> stretch forces are applied across fascial planes or between muscle and septae. With *friction massage*,<sup>35,70,138</sup> deep circular or cross-fiber (perpendicular to tissue fiber orientation) massage is applied to break up adhesions or minimize rough surfaces between tendons and their synovial sheaths. *Instrument-assisted soft tissue mobilization* uses specially crafted tools to release fascial restrictions and scar tissue. Friction massage is also used to increase the mobility of scar tissue in muscle as it heals. Theoretically, stresses applied to maturing scar tissue align the collagen fibers along the lines of stress to encourage normal mobility. These forms of connective tissue massage, as well as many other approaches and techniques of soft tissue mobilization, are useful interventions for patients with restricted mobility.

### Biofeedback

Biofeedback is another tool that can help a patient learn and practice the process of relaxation. A patient, with proper instruction, can monitor and learn to reduce the amount of muscle tension through biofeedback instrumentation.<sup>49,146</sup> Through the visual or auditory feedback provided by the instrumentation, the patient can begin to sense or feel the relaxed muscle. By voluntarily reducing muscle tension, pain can be decreased and flexibility increased. Biofeedback can also be used to help a patient increase voluntary muscle activation, such as when learning how to perform quadriceps setting exercises after knee surgery.

### Joint Traction or Oscillation

Slight manual distraction of joint surfaces prior to stretching a muscle-tendon unit can be used to inhibit joint pain and muscle spasm around a joint (see Chapter 5).<sup>35,70,78</sup> Pendular motions of a joint use the weight of the limb to

distract the joint surfaces and simultaneously oscillate and relax the limb. The joint may be further distracted by adding a 1- or 2-lb weight to the extremity, which causes a stretch force on joint tissues.

## Manual Stretching Techniques in Anatomical Planes of Motion

As with the ROM exercises described in Chapter 3, the manual stretching techniques in this section are described with the patient in a *supine* position. Alternative patient positions, such as prone or sitting, are indicated for some motions and are noted when necessary. Manual stretching procedures in an aquatic environment are described in Chapter 9.

Effective manual stretching techniques require adequate stabilization of the patient and sufficient strength and good body mechanics of the therapist. Depending on the size (height and weight) of the therapist and the patient, modifications in the patient's position and suggested hand placements for stretching or stabilization may have to be made by the therapist.

Each description of a stretching technique is identified by the anatomical plane of motion that is to be increased followed by a notation of the muscle group being stretched. Limitations in functional ROM usually are caused by shortening of multiple muscle groups and periarticular structures, and they affect movement in combined (as well as anatomical) planes of motion. In this situation, however, stretching multiple muscle groups simultaneously using diagonal patterns (i.e., D<sub>1</sub> and D<sub>2</sub> flexion and extension of the upper or lower extremities as described in Chapter 6) is *not* recommended and therefore is not described in this chapter. The authors believe that combined, diagonal patterns are appropriate for maintaining available ROM with passive and active exercises and increasing strength in multiple muscle groups but are ineffective for *isolating* a stretch force to specific muscles or muscle groups of the extremities that are shortened and restricting ROM. Special considerations for each region being stretched are also noted in this section.

Prolonged passive stretching techniques using mechanical equipment are applied using the same points of stabilization as manual stretching. The forces used in mechanical stretching are applied at a lower intensity and over a much longer period than with manual stretching. The stretch force is provided by weights or orthotics rather than the strength or endurance of a therapist. The patient is stabilized with belts, straps, or counterweights.

**NOTE:** Manual stretching procedures for the musculature of the cervical, thoracic, and lumbar spine may be found in Chapter 16.

Selected self-stretching techniques of the spine and extremities that a patient can do without assistance from a therapist can be found in Chapters 16 through 22.

## Upper Extremity Stretching

### The Shoulder: Special Considerations

Many muscles that move the arm attach to the scapula rather than the thorax. Therefore, when muscles of the shoulder girdle are stretched, it is imperative to stabilize the scapula. Without scapular stabilization some of the stretch force will be transmitted to the scapulothoracic muscles. This subjects these muscles to possible overstretching, limits the effectiveness of the applied stretch, and disguises the actual ROM of the glenohumeral (GH) joint. Remember:

- When the scapula is stabilized and not allowed to abduct or upwardly rotate, only 120° of shoulder flexion and abduction can occur at the GH joint.
- The humerus must be externally rotated to gain full ROM of abduction.
- Muscles most apt to become shortened are those that *prevent* full shoulder flexion, abduction, and external rotation. It is rare to find restrictions in structures that prevent shoulder adduction and extension to neutral.

### Shoulder Flexion VIDEO 4.2

To increase flexion of the shoulder, stretch the shoulder extensors (Fig. 4.16).

**FIGURE 4.16 (A)** Hand placement and stabilization of the scapula to stretch the teres major and increase shoulder flexion.

**FIGURE 4.16 (B)** Hand placement and stabilization of the pelvis to stretch the latissimus dorsi and increase shoulder flexion.

### Hand Placement and Procedure

- Grasp the posterior aspect of the distal humerus just above the elbow.
- Stabilize the axillary border of the scapula to stretch the teres major or stabilize the lateral aspect of the thorax and superior aspect of the pelvis to stretch the latissimus dorsi.
- Move the patient's arm into full shoulder flexion to elongate the shoulder extensors.

### Shoulder Hyperextension VIDEO 4.3

To increase hyperextension of the shoulder, stretch the shoulder flexors (Fig. 4.17).

**FIGURE 4.17** Hand placement and stabilization of the scapula to increase extension of the shoulder beyond neutral.

### Patient Position

Place the patient in a prone position.

### Hand Placement and Procedure

- Support the forearm and grasp the distal humerus.
- Stabilize the posterior aspect of the scapula to prevent substitute movements.
- Move the patient's arm into full hyperextension of the shoulder to elongate the shoulder flexors.

### Shoulder Abduction

To increase abduction of the shoulder, stretch the adductors (Fig. 4.18).

**FIGURE 4.18** Hand placement and stabilization of the scapula for the stretching procedure to increase shoulder abduction.

### Hand Placement and Procedure

- With the elbow flexed to 90°, grasp the distal humerus.
- Stabilize the axillary border of the scapula.
- Move the patient into full shoulder abduction to lengthen the adductors of the shoulder.

### Shoulder Adduction

To increase adduction of the shoulder, stretch the abductors. It is rare when a patient is unable to adduct the shoulder fully to 0° (so the upper arm is at the patient's side). Even if a patient has worn an abduction orthotic after a soft tissue or joint injury of the shoulder, when he or she is upright the constant pull of gravity elongates the shoulder abductors so the patient can adduct to a neutral position.

### Shoulder External Rotation VIDEO 4.4

To increase external rotation of the shoulder, stretch the internal rotators (Fig. 4.19).

**FIGURE 4.19** Shoulder position (slightly abducted and flexed) and hand placement at the mid to proximal forearm to increase external rotation of the shoulder. A folded towel is placed under the distal humerus to maintain the shoulder in slight flexion. The table stabilizes the scapula.

### Hand Placement and Procedure

- Abduct the shoulder to a comfortable position—initially 30° or 45° and later to 90° if the GH joint is stable—or place the arm at the patient's side.
- Flex the elbow to 90° so the forearm can be used as a lever.
- Grasp the volar surface of the mid-forearm with one hand.
- Stabilization of the scapula is provided by the table on which the patient is lying.
- Externally rotate the patient's shoulder by moving the patient's forearm closer to the table. This fully lengthens the internal rotators.

**PRECAUTION:** Because it is necessary to apply the stretch forces across the intermediate elbow joint when elongating the internal and external rotators of the shoulder, be sure the elbow joint is stable and pain-free. In addition, keep the intensity of the stretch force very low, particularly in patients with osteoporosis.

### Shoulder Internal Rotation

To increase internal rotation of the shoulder, stretch the external rotators (Fig. 4.20).

### Hand Placement and Procedure

- Abduct the shoulder to a comfortable position that allows internal rotation to occur without the thorax blocking the motion (initially to 45° and eventually to 90°).
- Flex the elbow to 90° so the forearm can be used as a lever.
- Grasp the dorsal surface of the midforearm with one hand, stabilize the anterior aspect of the shoulder, and support the elbow with your other forearm and hand.
- Move the patient's arm into an internal rotation to lengthen the external rotators of the shoulder.

**FIGURE 4.20** Hand placement and stabilization of the shoulder to increase internal rotation of the shoulder.

### Shoulder Horizontal Abduction

To increase horizontal abduction of the shoulder, stretch the pectoralis muscles (Fig. 4.21).

**FIGURE 4.21** Hand placement and stabilization of the anterior aspect of the shoulder and chest to increase horizontal abduction of the shoulder past neutral (to stretch the pectoralis major).

#### Patient Position

To reach full horizontal abduction in the supine position, the patient's shoulder must be at the edge of the table. Begin with the shoulder in 60° to 90° of abduction. The patient's elbow may also be flexed.

#### Hand Placement and Procedure

- Grasp the anterior aspect of the distal humerus.
- Stabilize the anterior aspect of the shoulder.
- Move the patient's arm below the edge of the table into full horizontal abduction to stretch the horizontal adductors.

**NOTE:** The horizontal adductors are usually tight bilaterally. Stretching techniques can be applied bilaterally by the therapist, or a bilateral self-stretch can be done by the patient by using a corner or wand (see Figs. 17.30 through 17.32).

### Scapular Mobility

To have full shoulder motion, a patient must have normal scapular mobility. (See the scapular mobilization/manipulation techniques in Chapter 5.)

### The Elbow and Forearm: Special Considerations

Several muscles that cross the elbow, such as the biceps brachii and brachioradialis, also influence supination and pronation of the forearm. Therefore, when stretching the elbow flexors and extensors, the techniques should be performed with the forearm pronated as well as supinated.

### Elbow Flexion

To increase elbow flexion, stretch the one-joint elbow extensors.

#### Hand Placement and Procedure

- Grasp the distal forearm just proximal to the wrist.
- With the arm at the patient's side supported on the table, stabilize the proximal humerus.
- Flex the patient's elbow just past the point of tissue resistance to lengthen the elbow extensors.

To increase elbow flexion with the shoulder flexed, stretch the long head of the triceps (Fig. 4.22).

**FIGURE 4.22** Hand placement and stabilization to increase elbow flexion with shoulder flexion (to stretch the long head of the triceps brachii).

#### Patient Position, Hand Placement, and Procedure

- With the patient sitting or lying supine with the arm at the edge of the table, flex the patient's shoulder as far as possible.

- While maintaining shoulder flexion, grasp the distal forearm and flex the elbow just past the point of resistance to lengthen the long head of the triceps.

### Elbow Extension VIDEO 4.5

To increase elbow extension, stretch the elbow flexors (Fig. 4.23).

**FIGURE 4.23** Hand placement and stabilization of the scapula and proximal humerus for stretching procedures to increase elbow extension.

### Hand Placement and Procedure

- Grasp the distal forearm.
- With the upper arm at the patient's side supported on the table, stabilize the scapula and anterior aspect of the proximal humerus.
- Extend the elbow just past the point of tissue resistance to lengthen the elbow flexors.

**NOTE:** Be sure to do this with the forearm in supination, pronation, and neutral position to stretch each of the elbow flexors.

To increase elbow extension with the shoulder extended, stretch the long head of the biceps.

### Patient Position, Hand Placement, and Procedure

- With the patient lying supine close to the side of the table, stabilize the anterior aspect of the shoulder, or with the patient lying prone, stabilize the scapula.
- Pronate the forearm, extend the elbow, and then extend the shoulder.

**PRECAUTION:** It has been reported that heterotopic ossification (the appearance of ectopic bone in the soft tissues around a joint) can develop around the elbow after traumatic or burn injuries.<sup>48</sup> It is believed that *vigorous, forcible* passive stretching of the elbow flexors may increase the risk of this condition developing. Passive or assisted stretching should therefore be applied very gently and gradually in the elbow region. Use of active stretching techniques, such as agonist contraction, might also be considered.

### Forearm Supination or Pronation

To increase supination or pronation of the forearm.

### Hand Placement and Procedure

- With the patient's humerus supported on the table and the elbow flexed to 90°, grasp the distal forearm.
- Stabilize the humerus.
- Supinate or pronate the forearm just beyond the point of tissue resistance.
- Be sure the stretch force is applied to the radius rotating around the ulna. Do not twist the hand, thereby avoiding stress to the wrist articulations.
- Repeat the procedure with the elbow extended. Be sure to stabilize the humerus to prevent internal or external rotation of the shoulder.

### The Wrist and Hand: Special Considerations

#### VIDEO 4.6

The extrinsic muscles of the fingers cross the wrist joint and therefore may influence the ROM of the wrist. Wrist motion may also be influenced by the position of the elbow and forearm because the wrist flexors and extensors attach proximally on the epicondyles of the humerus.

When stretching the musculature of the wrist, the stretch force should be applied proximal to the metacarpophalangeal (MCP) joints, and the fingers should be relaxed.

### Patient Position

When stretching the muscles of the wrist and hand, have the patient sit in a chair adjacent to you with the forearm supported on a table to stabilize the forearm effectively.

### Wrist Flexion

To increase wrist flexion.

### Hand Placement and Procedure

- The forearm may be supinated, in midposition, or pronated.
- Stabilize the forearm against the table and grasp the dorsal aspect of the patient's hand.
- To elongate the wrist extensors, flex the patient's wrist and allow the fingers to extend passively.
- To further elongate the wrist extensors, extend the patient's elbow.

### Wrist Extension

To increase wrist extension (Fig. 4.24).

### Hand Placement and Procedure

- Pronate the forearm or place it in midposition and grasp the patient at the palmar aspect of the hand. If there is a severe wrist flexion contracture, it may be necessary to place the patient's hand over the edge of the treatment table.
- Stabilize the forearm against the table.
- To lengthen the wrist flexors, extend the patient's wrist, allowing the fingers to flex passively.

**FIGURE 4.24** Hand placement and stabilization of the forearm for stretching procedure to increase extension of the wrist.

### Radial Deviation

*To increase radial deviation.*

#### Hand Placement and Procedure

- Grasp the ulnar aspect of the hand along the fifth metacarpal.
- Hold the wrist in midposition.
- Stabilize the forearm.
- Radially deviate the wrist to lengthen the ulnar deviators of the wrist.

### Ulnar Deviation

*To increase ulnar deviation.*

#### Hand Placement and Procedure

- Grasp the radial aspect of the hand along the second metacarpal, not the thumb.
- Stabilize the forearm.
- Ulnarly deviate the wrist to lengthen the radial deviators.

### The Digits: Special Considerations VIDEO 4.7

The complexity of the relationships among the joint structures and the intrinsic and multijoint extrinsic muscles of the digits requires careful examination and evaluation of the factors that contribute to loss of function in the hand because of motion limitations. The therapist must determine if a limitation is from joint restrictions, decreased muscle-tendon unit extensibility, or adhesions of tendons or ligaments. The digits should always be stretched individually, not simultaneously. If an extrinsic muscle limits motion, lengthen it over one joint while stabilizing the other joints. Then, hold the lengthened position and stretch it over the second joint, and so forth, until normal length is obtained. Begin the motion with the most distal joint to minimize shearing and compressive stresses to the surfaces of the small joints of the digits. Specific interventions to manage adhesions of tendons are described in Chapter 19.

### CMC Joint of the Thumb

*To increase flexion, extension, abduction, or adduction of the carpometacarpal (CMC) joint of the thumb.*

### Hand Placement and Procedure

- Stabilize the trapezium with your thumb and index finger.
- Grasp the first metacarpal (not the first phalanx) with your other thumb and index finger.
- Move the first metacarpal in the desired direction to increase CMC flexion, extension, abduction, and adduction.

### MCP Joints of the Digits

*To increase flexion, extension, abduction, or adduction of the MCP joints of the digits.*

#### Hand Placement and Procedure

- Stabilize the metacarpal with your thumb and index finger.
- Grasp the proximal phalanx with your other thumb and index finger.
- Keep the wrist in midposition.
- Move the MCP joint in the desired direction for stretch.
- Allow the interphalangeal (IP) joints to flex or extend passively.

### PIP and DIP Joints

*To increase flexion or extension of the proximal and distal interphalangeal (PIP and DIP) joints.*

#### Hand Placement and Procedure

- Grasp the middle or distal phalanx with your thumb and finger.
- Stabilize the proximal or middle phalanx with your other thumb and finger.
- Move the PIP or DIP joint in the desired direction for stretch.

### Stretching Specific Extrinsic and Intrinsic Muscles of the Fingers

Elongation of extrinsic and intrinsic muscles of the hand is described in Chapter 3. To stretch these muscles beyond their available range, the same hand placement and stabilization are used as with passive ROM. The only difference in technique is that the therapist moves each segment into the stretch range.

## Lower Extremity Stretching

### The Hip: Special Considerations VIDEO 4.8

Because muscles of the hip attach to the pelvis or lumbar spine, the pelvis must always be stabilized when lengthening muscles about the hip. If the pelvis is not stabilized, the stretch force is transferred to the lumbar spine and unwanted compensatory motion results.

### Hip Flexion

*To increase flexion of the hip with the knee flexed,* stretch the gluteus maximus.

#### Hand Placement and Procedure

- Flex the hip and knee simultaneously.
- Stabilize the opposite femur in extension to prevent posterior tilt of the pelvis.

- Move the patient's hip and knee into full flexion to lengthen the one-joint hip extensor.

### Hip Flexion With Knee Extension

To increase flexion of the hip with the knee extended, stretch the hamstrings (Fig. 4.25 A and B).

#### Hand Placement and Procedure

- With the patient's knee fully extended, support the patient's lower leg with your arm or shoulder.
- Stabilize the opposite extremity along the anterior aspect of the thigh with your other hand or a belt or with the assistance of another person.

**FIGURE 4.25** Hand placement and stabilization of the opposite femur to stabilize the pelvis and low back for stretching procedures to increase hip flexion with knee extension (stretch the hamstrings) with the therapist (A) standing by the side of the table or (B) kneeling on the table.

- With the knee at 0° extension and the hip in neutral rotation, flex the hip as far as possible.

**NOTE:** Externally rotate the hip prior to hip flexion to isolate the stretch force to the medial hamstrings and internally rotate the hip to isolate the stretch force to the lateral hamstrings.

#### Alternative Therapist Position

Kneel on the mat and place the patient's heel or distal tibia against your shoulder (see Fig. 4.25 B). Place both of your hands along the anterior aspect of the distal thigh to keep the knee extended. The opposite extremity is stabilized in extension by a belt or towel around the distal thigh and held in place by the therapist's knee.

### Hip Extension VIDEO 4.9

To increase hip extension, stretch the iliopsoas (Fig. 4.26).

**FIGURE 4.26** Hand placement and stabilization of the pelvis to increase extension of the hip (stretch the iliopsoas) with the patient lying supine. Flexing the knee when in this position also elongates the rectus femoris.

#### Patient Position

Have the patient positioned close to the edge of the treatment table so the hip being stretched can be extended beyond neutral. The opposite hip and knee are flexed toward the patient's chest to stabilize the pelvis and spine.

#### Hand Placement and Procedure

- Stabilize the opposite leg against the patient's chest with one hand or, if possible, have the patient assist by grasping around the thigh and holding it to the chest to prevent an anterior tilt of the pelvis during stretching.
- Move the hip to be stretched into extension or hyperextension by placing downward pressure on the anterior aspect of the distal thigh with your other hand. Allow the knee to extend so the two-joint rectus femoris does not restrict the range.

#### Alternate Position

Have the patient assume the prone-lying position (Fig. 4.27).

**FIGURE 4.27** Hand placement and stabilization to increase hyperextension of the hip with the patient lying prone.

#### Hand Placement and Procedure

- Support and grasp the anterior aspect of the patient's distal femur.
- Stabilize the patient's pelvis with a downward force on their buttocks.
- Extend the patient's hip by lifting the femur off the table.

#### Hip Extension With Knee Flexion

To increase hip extension and knee flexion simultaneously, stretch the rectus femoris.

#### Patient Position

Use either of the positions previously described for increasing hip extension in the supine or prone positions (see Figs. 4.26 and 4.27).

#### Hand Placement and Procedure

- With the hip held in full extension on the side to be stretched, move your hand to the distal tibia and gently flex the knee of that extremity as far as possible.
- Do not allow the hip to abduct or rotate.

#### Hip Abduction VIDEO 4.10

To increase abduction of the hip, stretch the adductors (Fig. 4.28).

#### Hand Placement and Procedure

- Support the distal thigh with your arm and forearm.
- Stabilize the pelvis by placing pressure on the opposite anterior iliac crest or by maintaining the opposite lower extremity in slight abduction.
- Abduct the hip as far as possible to stretch the adductors.

**NOTE:** You may apply your stretch force cautiously at the medial malleolus only if the knee is stable and pain-free. An abduction force applied at this location creates a great deal of stress to the medial supporting structures of the knee and is generally not recommended by the authors.

**FIGURE 4.28** Hand placement and stabilization of the opposite extremity (or pelvis) for the stretching procedure to increase abduction of the hip.

#### Hip Adduction VIDEO 4.11

To increase adduction of the hip, stretch the tensor fasciae latae and iliotibial (IT) band (Fig. 4.29).

**FIGURE 4.29** Patient positioned side-lying. Hand placement and procedure to stretch the tensor fasciae latae and IT band.

#### Patient Position

Place the patient in a side-lying position with the hip to be stretched uppermost. Flex the bottom hip and knee to stabilize the patient.

#### Hand Placement and Procedure

- Stabilize the pelvis at the iliac crest with your proximal hand.
- With the knee flexed, extend the patient's hip to neutral or into slight hyperextension, if possible. Moving the hip into a small amount of flexion and abduction prior to extending it may help orient the IT band for the stretch.
- Let the patient's hip adduct with gravity and apply an additional stretch force with your other hand to the lateral aspect of the distal femur to further adduct the hip.

**NOTE:** If the patient's hip cannot be extended to neutral, the hip flexors must be stretched before the tensor fasciae latae can be stretched.

### Hip External Rotation

To increase external rotation of the hip, stretch the internal rotators (Fig. 4.30 A).

**FIGURE 4.30 (A)** Hand placement and stabilization of the pelvis to increase external rotation of the hip.

#### Patient Position

Place the patient in a prone position with the hips extended and knee flexed to 90°.

#### Hand Placement and Procedure

- Grasp the distal tibia of the extremity to be stretched.
- Stabilize the pelvis by applying pressure with your other hand across the buttocks.
- Apply pressure to the lateral malleolus or lateral aspect of the tibia and externally rotate the hip as far as possible.

#### Alternate Position and Procedure

Sitting at the edge of a table with hips and knees flexed to 90°:

- Stabilize the pelvis by applying pressure to the iliac crest with one hand.
- Apply the stretch force to the lateral malleolus or lateral aspect of the lower leg and externally rotate the hip.

**NOTE:** When you apply the stretch force against the lower leg in this manner, thus crossing the knee joint, the knee must be stable and pain-free. If the knee is not stable, it is possible to

apply the stretch force by grasping the distal thigh, but the leverage is poor and there is a tendency to twist the skin.

### Hip Internal Rotation

To increase internal rotation of the hip, stretch the external rotators (Fig. 4.30 B).

**FIGURE 4.30 (B)** Hand placement and stabilization of the pelvis to increase internal rotation of the hip with the patient prone.

#### Patient Position and Stabilization

Position the patient the same as when increasing external rotation, described previously.

#### Hand Placement and Procedure

Apply pressure to the medial malleolus or medial aspect of the tibia and internally rotate the hip as far as possible.

### The Knee: Special Considerations

#### VIDEO 4.12

The position of the hip during stretching influences the flexibility of the flexors and extensors of the knee. The flexibility of the hamstrings and the rectus femoris must be examined and evaluated separately from the one-joint muscles that affect knee motion.

### Knee Flexion

To increase knee flexion, stretch the knee extensors (Fig. 4.31).

#### Patient Position

Have the patient assume a prone position.

**FIGURE 4.31** Hand placement and stabilization to increase knee flexion (stretch the rectus femoris and quadriceps) with the patient lying prone.

### Hand Placement and Procedure

- Stabilize the pelvis by applying downward pressure across the buttocks.
- Grasp the anterior aspect of the distal tibia and flex the patient's knee.

**PRECAUTION:** Place a rolled towel under the thigh just above the knee to prevent compression of the patella against the table during the stretch. Stretching the knee extensors too vigorously in the prone position can traumatize the knee joint and cause swelling.

### Alternate Position and Procedure

- Have the patient sit with the thigh supported on the treatment table and leg flexed over the edge as far as possible.
- Stabilize the anterior aspect of the proximal femur with one hand.
- Apply the stretch force to the anterior aspect of the distal tibia and flex the patient's knee just past the point of tissue resistance.

**NOTE:** This position is useful when working in the 0° to 100° range of knee flexion. The prone position is best for increasing knee flexion from 90° to 135°.

### Knee Extension

To increase knee extension in the midrange, stretch the knee flexors (Fig. 4.32).

### Patient Position

Place the patient in a prone position and put a small, rolled towel under the patient's distal femur, just above the patella.

### Hand Placement and Procedure

- Grasp the distal tibia with one hand and stabilize the buttocks to prevent hip flexion with the other hand.
- Slowly extend the knee to stretch the knee flexors.

**FIGURE 4.32** Hand placement and stabilization to increase midrange knee extension with the patient lying prone.

### End-Range Knee Extension VIDEO 4.13

To increase end-range knee extension (Fig. 4.33).

**FIGURE 4.33** Hand placement and stabilization to increase terminal knee extension.

### Patient Position

Patient assumes a supine position.

### Hand Placement and Procedure

- Grasp the distal tibia of the knee to be stretched.
- Stabilize the hip by placing your hand or forearm across the anterior thigh. This prevents hip flexion during stretching.
- Apply the stretch force to the posterior aspect of the distal tibia and extend the patient's knee.

### The Ankle and Foot: Special Considerations

#### VIDEO 4.14

The ankle and foot are composed of multiple joints. Consider the mobility of these joints (see Chapter 5) as well as the multijoint muscles that cross these joints when increasing ankle and foot ROM.

## Ankle Dorsiflexion

To increase dorsiflexion of the ankle with the knee extended, stretch the gastrocnemius muscle (Fig. 4.34).

**FIGURE 4.34** Hand placement and procedure to increase dorsiflexion of the ankle with the knee extended (stretching the gastrocnemius).

### Hand Placement and Procedure

- Grasp the patient's heel (calcaneus) with one hand, maintain the subtalar joint in a neutral position, and place your forearm along the plantar surface of the foot.
- Stabilize the anterior aspect of the tibia with your other hand.
- Dorsiflex the talocrural joint of the ankle by pulling the calcaneus in an inferior direction with your thumb and fingers while gently applying pressure in a superior direction just proximal to the heads of the metatarsals with your forearm.

To increase dorsiflexion of the ankle with the knee flexed, stretch the soleus muscle. The knee must be flexed to eliminate the effect of the two-joint gastrocnemius muscle. Hand placement, stabilization, and stretch force are the same as when stretching the gastrocnemius.

**PRECAUTION:** When stretching the gastrocnemius or soleus muscles, avoid placing too much pressure against the heads of the metatarsals and stretching the long arch of the foot. Overstretching the long arch of the foot can cause a flat foot or a rocker-bottom foot.

## Ankle Plantarflexion

To increase plantarflexion of the ankle.

### Hand Placement and Procedure

- Support the posterior aspect of the distal tibia with one hand.
- Grasp the foot along the tarsal and metatarsal areas.
- Apply the stretch force to the anterior aspect of the foot and plantarflex the foot.

## Ankle Inversion and Eversion

To increase inversion and eversion of the ankle. Inversion and eversion of the ankle occur at the subtalar joint as a component of pronation and supination. Mobility of the subtalar joint (with appropriate strength) is particularly important for walking on uneven surfaces.

### Hand Placement and Procedure

- Stabilize the talus by grasping just distal to the malleoli with one hand.
- Grasp the calcaneus with your other hand and move it medially and laterally at the subtalar joint.

## Stretching Specific Muscles of the Ankle and Foot

### Hand Placement and Procedure

- Stabilize the distal tibia with your proximal hand.
- Grasp around the foot with your other hand and align the motion and force opposite the line of pull of the tendons. Apply the stretch force against the bone to which the muscle attaches distally.
  - To stretch the *tibialis anterior* (which inverts and dorsiflexes the ankle), grasp the dorsal aspect of the foot across the tarsals and metatarsals and plantarflex and abduct the foot.
  - To stretch the *tibialis posterior* (which plantarflexes and inverts the foot), grasp the plantar surface of the foot around the tarsals and metatarsals and dorsiflex and abduct the foot.
  - To stretch the *peroneals* (which evert the foot), grasp the lateral aspect of the foot at the tarsals and metatarsals and invert the foot.

## Toe Flexion and Extension

To increase flexion and extension of the toes. It is best to stretch any musculature that limits motion in the toes individually. With one hand, stabilize the bone proximal to the restricted joint, and with the other hand, move the phalanx in the desired direction.

## Neck and Trunk

Stretching techniques to increase mobility in the cervical, thoracic, and lumbar spine may be found in Chapter 16.

## Self-Stretching Techniques

Examples of self-stretching techniques, performed independently by the patient after appropriate instruction, may be found in Chapters 17 through 22 (upper and lower extremities) and Chapter 16 (neck and trunk).

## Independent Learning Activities

### Critical Thinking and Discussion

1. What physical findings from the patient examination would lead you to decide that stretching exercises were an appropriate intervention?
2. Discuss the advantages and disadvantages of various stretching exercises, specifically manual stretching, self-stretching, and mechanical stretching. Under what circumstances would one form be a more appropriate choice than another?
3. Discuss how the effectiveness of a stretching program is influenced by the responses of contractile and noncontractile soft tissues to stretch.
4. Explain how factors such as intensity, rate, duration, and frequency of stretch can be used to maximize stretching effectiveness.
5. Discuss how your approach to and application of stretching would differ when developing stretching exercises for a healthy young adult with limited mobility in the (a) shoulder, (b) knee, or (c) ankle in contrast to an elderly individual with osteoporosis and limited motion in the same regions.
6. Explain the procedures for and rationale behind each of the following types of neuromuscular inhibition: HR, HR-AC, CR, and AC. Under what circumstances would you choose one technique over another?
7. Select a popular exercise video. Review and critique the flexibility exercises on the video. Were the flexibility exercises appropriately distributed across body regions and joints? Were the exercises executed safely and correctly? Were the exercises appropriate for the target population?
8. Your patient has been attending a Pilates class over the past few months but is now receiving your therapy services for management of a chronic hamstring strain. How could you integrate your patient's participation in these classes with your plan of care?

### Laboratory Practice

1. Manually stretch as many major muscle groups of the upper and lower extremities as is *safe* and *practical* with the patient in supine, prone, side-lying, and/or seated.
2. While considering individual muscle actions and lines of pull, demonstrate how to specifically and fully elongate the following muscles: pectoralis major, biceps brachii, brachioradialis, brachialis, triceps, extensor or flexor carpi ulnaris or radialis, flexor digitorum superficialis or profundus, rectus femoris versus the iliopsoas, gastrocnemius versus soleus, and the tibialis anterior and posterior.
3. Teach your partner how to stretch major muscle groups of the upper and lower extremities using either body weight or a cuff weight as the stretch force. Be sure to include effective stabilization procedures for these stretching techniques whenever possible.
4. Using either the hold-relax or contract-relax and the hold-relax agonist contraction PNF stretching techniques, stretch at least two muscle groups at the shoulder, elbow, wrist, hip, knee, and ankle. Be sure to position, align, and stabilize your partner properly.
5. Design an effective and efficient series of self-stretches that a person who works at a desk most of the day could incorporate into a daily home exercise routine. Demonstrate and teach each self-stretching exercise to your laboratory partner.
6. Identify a recreational/sport activity that your partner enjoys and design and demonstrate a program of self-stretching exercises to prepare your partner for the activity.
7. Design a program of progressive relaxation exercises for total body relaxation. Then, implement the relaxation training sequence with your partner.

- Intermetatarsal, Metatarsophalangeal, and Interphalangeal Joints 164

#### Independent Learning Activities 164

*Joint mobilization*, also known as manipulation, refers to manual therapy techniques that are used to modulate pain and treat joint impairments that limit range of motion (ROM) by specifically addressing the altered mechanics of the joint. The altered joint mechanics may be due to pain and muscle guarding, joint effusion, contractures or adhesions in the joint capsules or supporting ligaments, or aberrant joint motion. Joint mobilization stretching techniques differ from other forms of

passive or self-stretching (described in Chapter 4) in that they specifically address restricted capsular tissue by replicating normal joint mechanics while minimizing abnormal compressive stresses on the articular cartilage in the joint.<sup>17</sup>

Historically, mobilization has been the preferred term to use as therapists began using the passive, skilled joint techniques because mobilization had a less aggressive connotation than manipulation. High-velocity thrust (HVT) techniques,

typically called manipulation, were not universally taught or used by most practitioners. However, with the increased level of education<sup>3,5</sup> and current practice of physical therapy,<sup>2</sup> both non-thrust and thrust manipulation techniques are skills that therapists are learning and safely using in many practice settings. The *Manipulation Education Manual for Physical Therapist Professional Degree Programs*<sup>2</sup> as well as the *Guide to Physical Therapist Practice*<sup>8</sup> couple the terms “mobilization” and “manipulation” in order to demonstrate their common usage.

An editorial<sup>25</sup> described problems with using the terms interchangeably without clear definitions. The authors cited confusion in interpreting research and describing outcomes when the techniques used are not specifically described. They also indicated possible confusion in communicating with patients and with referral sources. It is therefore critical that the practitioner clearly understands and defines the characteristics of the techniques used when referring to manipulative techniques.

In this text, the terms “mobilization” and “manipulation” will be used interchangeably, with the distinction made between non-thrust and thrust techniques. The procedures section in this chapter describes documentation and the importance of identifying rate, range, and direction of force application, as well as target, relative structural movement, and patient position whenever referring to mobilization/manipulation intervention techniques.<sup>24</sup> This information should be used in all documentation and communication in order to minimize discrepancies in interpretation of outcomes.

To use joint mobilization/manipulation techniques for effective treatment, the practitioner must know and be able to examine the anatomy, arthrokinematics, and pathology of the neuromusculoskeletal system and to recognize when the techniques are indicated or when other techniques would be more effective for regaining lost motion. Indiscriminate use of joint techniques, when not indicated, could lead to potential harm to the patient’s joints. We assume that, prior to learning the techniques presented in this text, the student or therapist has had (or will be concurrently learning) orthopedic examination and evaluation and therefore will be able to choose appropriate, safe techniques for treating the patient’s impairments. The reader is referred to several resources for additional study of examination and evaluation procedures.<sup>6,12,17,20</sup> When indicated, joint manipulative techniques are safe, effective means of restoring or maintaining joint play and can also be used for treating pain.<sup>12,17</sup>

## Principles of Joint Mobilization/Manipulation

### Definitions of Terms

#### Mobilization/Manipulation

As noted in the introductory paragraphs, mobilization and manipulation are two terms that have come to have the same meaning<sup>3,21</sup> and are therefore interchangeable. In general, they are passive, skilled manual therapy techniques applied

to joints and related soft tissues at varying speeds and amplitudes using physiological or accessory motions for therapeutic purposes. The varying speeds and amplitudes can range from a small-amplitude force applied at fast velocity to a large-amplitude force applied at slow velocity—that is, there is a continuum of intensities and speeds at which the technique could be applied.<sup>12,17</sup>

**Thrust manipulation/HVT.** Thrust refers to high-velocity, short-amplitude techniques.<sup>12,30</sup> The thrust is performed at the end of the pathological limit of the joint and is intended to alter positional relationships, snap adhesions, or stimulate joint receptors.<sup>30</sup> Pathological limit means the end of the available ROM when there is restriction.

**NOTE:** The terms thrust and manipulation are often used interchangeably,<sup>4</sup> but with the trend to use manipulation to include all manipulative techniques, including non-thrust techniques, this text will not use these two terms interchangeably.

#### Self-Mobilization (Auto-Mobilization)

Self-mobilization refers to self-stretching techniques that specifically use joint traction or glides that direct the stretch force to the joint capsule. When indicated, these techniques are described in the chapters on specific regions of the body.

#### Mobilization With Movement

Mobilization with movement (MWM) is the concurrent application of sustained accessory mobilization applied by a therapist and an active physiological movement to end-range applied by the patient. Passive end-of-range overpressure, or stretching, is then delivered without pain as a barrier. The techniques are always applied in a pain-free direction and are described as correcting joint tracking from a positional fault.<sup>23,26</sup> Brian Mulligan of New Zealand originally described these techniques.<sup>26</sup> MWM techniques related to specific peripheral joint regions are described in Chapters 17 through 22.

#### Physiological Movements

Physiological movements are movements the patient can do voluntarily (e.g., the classic or traditional movements, such as flexion, abduction, and rotation). The term *osteokinematics* is used when these motions of the bones are described.<sup>13</sup>

#### Accessory Movements

Accessory movements are movements in the joint and surrounding tissues that are necessary for normal ROM but that cannot be actively performed by the patient.<sup>30</sup> Terms that relate to accessory movements are *component motions* and *joint play*.

**Component motions.** These are motions that accompany active motion but are not under voluntary control. The term is often used synonymously with accessory movement. For example, motions such as upward rotation of the scapula and rotation of the clavicle, which occur with shoulder flexion,

and rotation of the fibula, which occurs with ankle motions, are component motions.

**Joint play.** Joint play describes the motions that occur between the joint surfaces and also the distensibility or “give” in the joint capsule, which allows the bones to move. The movements are necessary for normal joint functioning through the ROM and can be demonstrated passively, but they cannot be performed actively by the patient.<sup>30</sup> The movements include distraction, sliding, compression, rolling, and spinning of the joint surfaces. The term *arthrokinematics* is used when these motions of the bone surfaces within the joint are described.<sup>13</sup>

**NOTE:** Procedures to distract or slide the joint surfaces to decrease pain or restore joint play are the fundamental joint mobilization techniques described in this text.

## Resting Position

The *resting position*, *open-pack position*, and *loose-pack position* are terms that describe the position of the joint where the greatest mobility is possible; that is, where the least amount of tension is placed on the joint capsule and supporting ligaments. This position is typically used for testing joint play and for applying the initial mobilization treatment.

## Manipulation Under Anesthesia

Manipulation under anesthesia is a procedure used to restore full ROM by breaking adhesions around a joint while the patient is anesthetized. The technique may be a rapid thrust or a passive stretch using physiological or accessory movements. Therapists may assist surgeons in the application of these skilled techniques in the operating room and continue with follow-up care.

## Muscle Energy

Muscle energy techniques use active contraction of deep muscles that attach near the joint and whose line of pull can cause the desired accessory motion. The technique requires the therapist to provide stabilization to the segment on which the distal aspect of the muscle attaches. A command for an isometric contraction of the muscle is given that causes accessory movement of the joint. Several specific muscle energy techniques are described for the sacroiliac joint in Chapter 15 and for the subcranial region of the cervical spine in Chapter 16.

## Basic Concepts of Joint Motion: Arthrokinematics

### Joint Shapes

The type of motion occurring between bony partners in a synovial joint is influenced by the shape of the joint surfaces. The shape may be described as *ovoid* or *sellar*.<sup>13,17,19,33</sup>

- In ovoid joints, one surface is convex and the other is concave (Fig. 5.1 A).

- In sellar (saddle) joints, one surface is concave in one direction and convex in the other, with the opposing surface convex and concave, respectively—similar to a horseback rider being in complementary opposition to the shape of a saddle (Fig. 5.1 B).

**FIGURE 5.1** (A) With ovoid joints, one surface is convex and the other is concave. (B) With saddle (sellar) joints, one surface is concave in one direction and convex in the other, with the opposing surface convex and concave, respectively.

## Types of Motion

As a bony lever moves about an axis of motion, there is also movement of the bone surface on the opposing bone surface in the joint.

- The movement of the bony lever is called *swing* and is classically described as flexion, extension, abduction, adduction, and rotation. The amount of movement can be measured in degrees with a goniometer and is called ROM.
- Motion of the bone surfaces in the joint is a variable combination of *rolling* and *sliding*, or *spinning*.<sup>13,17,19,33</sup> These accessory motions allow greater angulation of the bone as it swings. For the rolling, sliding, or spinning to occur, there must be adequate capsule laxity or joint play.

### Roll

Characteristics of one bone rolling on another (Fig. 5.2) are as follows:

- The surfaces are incongruent.
- New points on one surface meet new points on the opposing surface.
- Rolling results in angular motion of the bone (swing).
- Rolling is always in the same direction as the swinging bone motion whether the surface is convex (Fig. 5.3 A) or concave (Fig. 5.3 B).
- Rolling, if it occurs alone, causes compression of the surfaces on the side to which the bone is swinging and separation on the other side. Passive stretching using bone angulation alone may cause stressful compressive forces to portions of the joint surface, potentially leading to joint damage.

**FIGURE 5.2** Representation of one surface rolling on another. New points on one surface meet new points on the opposing surface.

**FIGURE 5.3** Rolling is always in the same direction as bone motion, whether the moving bone is (A) convex or (B) concave.

- In normally functioning joints, pure rolling does not occur alone but in combination with joint sliding and spinning.

### Slide/Translation

Characteristics of one bone sliding (translating) across another include the following:

- For a pure slide, the surfaces must be congruent, either flat (Fig. 5.4 A) or curved (Fig. 5.4 B).
- The same point on one surface comes into contact with the new points on the opposing surface.

**FIGURE 5.4** Representation of one surface sliding on another, whether (A) flat or (B) curved. The same point on one surface comes into contact with new points on the opposing surface.

- Pure sliding does not occur in joints because the surfaces are not completely congruent.
- The direction in which sliding occurs depends on whether the moving surface is concave or convex. Sliding is in the opposite direction of the angular movement of the bone if the moving joint surface is convex (Fig. 5.5 A). Sliding is in the same direction as the angular movement of the bone if the moving surface is concave (Fig. 5.5 B).

**FIGURE 5.5** Representation of the concave-convex rule. (A) If the surface of the moving bone is convex, sliding is in the direction opposite to that of the angular movement of the bone. (B) If the surface of the moving bone is concave, sliding is in the same direction as the angular movement of the bone.

**NOTE:** This mechanical relationship is known as the *convex-concave rule* and is the theoretical basis for determining the direction of the mobilizing force when joint gliding techniques are used.<sup>15</sup>

### FOCUS ON EVIDENCE

Several studies<sup>11,14,16</sup> have examined the translational movement of the humeral head with shoulder motions and have documented translations opposite to what is predicted by the convex-concave rule. Hsu and associates<sup>15</sup> proposed that this apparent contradiction to the convex-concave rule is the result of asymmetrical tightening of the shoulder joint capsule during movement resulting in translation of the moving bone opposite to the direction of capsular tightening. They documented that stretching the tight capsule with translations that affect the restricting tissues leads to greater ROM in cadaver shoulder joints. This apparent contradiction is further discussed in an editorial that points out the potential misinterpretation of the results of studies that appear to negate the convex-concave arthrokinematic descriptors; that it is important to recognize the size of the joint surfaces, starting position/

relationship of the joint surface, not just the end position, as well as effect of capsule tightness.<sup>28</sup>

### Combined Roll-Sliding in a Joint

- The more congruent the joint surfaces are, the more sliding there is of one bony partner on the other with movement.
- The more incongruent the joint surfaces are, the more rolling there is of one bony partner on the other with movement.
- When muscles actively contract to move a bone, some of the muscles may cause or control the sliding movement of the joint surfaces. For example, the caudal sliding motion of the humeral head during shoulder abduction is caused by the rotator cuff muscles, and the posterior sliding of the tibia during knee flexion is caused by the hamstring muscles. If this function is lost, the resulting abnormal joint mechanics may cause microtrauma and joint dysfunction.
- The joint mobilization techniques described in this chapter use the sliding component of joint motion to restore joint play and reverse joint hypomobility. Rolling (passive angular stretching) is not used to stretch tight joint capsules because it causes joint compression.

#### CLINICAL TIP

When the therapist applies a passive accessory motion to the articulating surface using the slide component of joint motion, the technique is called translatory glide, translation, or simply glide.<sup>17</sup> It is used to control pain when applied gently or to stretch the capsule when applied with a stretch force.

### Spin

Characteristics of one bone spinning on another include the following:

- There is rotation of a segment about a stationary mechanical axis (Fig. 5.6).

**FIGURE 5.6** Representation of spinning. There is rotation of a segment about a stationary mechanical axis.

- The same point on the moving surface creates an arc of a circle as the bone spins.
- Spinning rarely occurs alone in joints but in combination with rolling and sliding.
- Three examples of spin occurring in joints of the body are the shoulder with flexion/extension, the hip with flexion/extension, and the radiohumeral joint with pronation/supination (Fig. 5.7).

**FIGURE 5.7** Examples of joint spin locations in the body. (A) Humerus with flexion/extension; (B) Femur with flexion/extension; (C) Head of the radius with pronation/supination.

### Passive-Angular Stretching Versus Joint-Glide Stretching

- Passive-angular stretching procedures, as when the bony lever is used to stretch a tight joint capsule, may cause increased pain or joint trauma because:
  - The use of a lever magnifies the force at the joint.
  - The force causes compression of the joint surfaces in the direction of the rolling bone (see Fig. 5.3).
  - The roll without a slide does not replicate normal joint mechanics.
- Joint glide stretching procedures, as when the translatory slide component of the joint function is used to stretch a tight capsule, are safer and more selective because:
  - The force is applied close to the joint surface and controlled at an intensity compatible with the pathology.
  - The direction of the force replicates the sliding component of the joint mechanics and does not compress the cartilage.
  - The amplitude of the motion is small yet specific to the restricted or adherent portion of the capsule or ligaments. Thus, the forces are selectively applied to the desired tissue.

### Other Accessory Motions That Affect the Joint

#### Compression

Compression is the decrease in the joint space between bony partners.

- Compression normally occurs in the extremity and spinal joints when weight bearing.

- Some compression occurs as muscles contract, which provides stability to the joints.
- As one bone rolls on the other (see Fig. 5.3), some compression also occurs on the side to which the bone is angulating.
- Normal intermittent compressive loads help move synovial fluid and thus help maintain cartilage health.
- Abnormally high compression loads may lead to articular cartilage changes and deterioration.<sup>19</sup>

### Traction/Distraction VIDEO 5.1

Traction and distraction are not synonymous. Traction is a longitudinal pull. Distraction is a separation, or pulling apart.

- Separation of the joint surfaces (distraction) does not always occur when a traction force is applied to the long axis of a bone. For example, if traction is applied to the shaft of the humerus when the arm is at the side, it results in a glide of the joint surface (Fig. 5.8 A). Distraction of the glenohumeral joint requires a force to be applied at right angles to the glenoid fossa (Fig. 5.8 B).

**FIGURE 5.8 (A)** Traction applied to the shaft of the humerus results in caudal gliding of the joint surface; **(B)** Distraction of the glenohumeral joint requires separation at right angles to the glenoid fossa.

- For clarity in this textbook, whenever there is to be a pulling force applied to the long axis of a bone, the term *long-axis traction* is used. Whenever the surfaces are to be separated, the term *distraction*, *joint traction*, or *joint separation* is used.

### CLINICAL TIP

For joint mobilization/manipulation techniques, distraction is used to control or relieve pain when applied gently or to stretch the capsule when applied with a stretch force. For patient comfort a slight distraction force is used when applying stretch gliding techniques.

## Effects of Joint Motion

Joint motion stimulates biological activity by moving synovial fluid, which brings nutrients to the avascular articular cartilage of the joint surfaces and intra-articular fibrocartilage of the menisci.<sup>19</sup> Atrophy of the articular cartilage begins soon after immobilization is imposed on joints.<sup>1,8,9</sup>

Extensibility and tensile strength of the articular and peri-articular tissues are maintained with joint motion. With immobilization there is fibrofatty proliferation, which causes intra-articular adhesions as well as biochemical changes in tendon, ligament, and joint capsule tissue, which in turn causes joint contractures and ligamentous weakening.<sup>1</sup>

Afferent nerve impulses from joint receptors transmit information to the central nervous system and therefore provide awareness of position and motion. With injury, swelling within the joint, or joint degeneration, there is a potential decrease in an important source of proprioceptive feedback that may affect an individual's balance response.<sup>13,34</sup> Joint motion provides sensory input relative to:<sup>36,37</sup>

- Static position and sense of speed of movement (type I receptors found in the superficial joint capsule)
- Change of speed of movement (type II receptors found in deep layers of the joint capsule and articular fat pads)
- Sense of direction of movement (type I and III receptors; type III found in joint ligaments).
- Regulation of muscle tone (type I, II, and III receptors)
- Nociceptive stimuli (type IV receptors found in the fibrous capsule, ligaments, articular fat pads, periosteum, and walls of blood vessels)

## Indications and Limitations for Use of Joint Mobilization/Manipulation

Gentle mobilizations may be used to treat pain and muscle guarding, whereas stretching techniques are used to treat restricted movement in order to improve the functional mobility.

### Pain, Muscle Guarding, and Spasm

Painful joints, reflex muscle guarding, and muscle spasm can be treated with *gentle joint-play* techniques to stimulate neurophysiological and mechanical effects.<sup>12</sup>

### Neurophysiological Effects

Small-amplitude oscillatory and distraction movements are used to stimulate the mechanoreceptors that may inhibit the transmission of nociceptive stimuli at the spinal cord or brain stem levels.<sup>30,33</sup>

### Mechanical Effects

Small-amplitude distraction or gliding movements of the joint are used to cause synovial fluid motion, which is the

vehicle for bringing nutrients to the avascular portions of the articular cartilage (and intra-articular fibrocartilage when present). Gentle joint-play techniques help maintain nutrient exchange and thus prevent the painful and degenerating effects of stasis when a joint is swollen or painful and cannot move through the ROM. When applied to treat pain, muscle guarding, or muscle spasm, these techniques should not place stretch on the reactive tissues (see section on Contraindications and Precautions).

## Reversible Joint Hypomobility

Reversible joint hypomobility can be treated with *progressively vigorous joint-play stretching* techniques to elongate hypomobile capsular and ligamentous connective tissue. Sustained or oscillatory stretch forces are used to distend the shortened tissue mechanically.<sup>12,17</sup>

## Positional Faults/Subluxations

A faulty position of one bony partner with respect to its opposing surface may result in limited motion or pain. This can occur with a traumatic injury, after periods of immobility, or with muscle imbalances. The faulty positioning may be perpetuated with maladapted neuromuscular control across the joint, so whenever attempting active ROM, there is faulty tracking of the joint surfaces resulting in pain or limited motion. MWM techniques attempt to realign the bony partners while the person actively moves the joint through its ROM.<sup>26</sup> Thrust techniques are used to reposition an obvious subluxation, such as a pulled elbow or capitate-lunate subluxation.

## Progressive Limitation

Diseases that progressively limit movement can be treated with joint-play techniques to maintain available motion or retard progressive mechanical restrictions. The dosage of distraction or glide is dictated by the patient's response to treatment and the state of the disease.

## Functional Immobility

When a patient cannot functionally move a joint for a period of time, the joint can be treated with nonstretch gliding or distraction techniques to maintain available joint play and prevent the degenerating and restricting effects of immobility.

### FOCUS ON EVIDENCE

DiFabio<sup>7</sup> summarized evidence on the effectiveness of manual therapy (primarily mobilization/manipulation) for patients with somatic pain syndromes in the low back region and concluded that there was significantly greater improvement in patients receiving manual therapy than in controls. Boissonnault and associates<sup>5</sup> cited several studies that demonstrated the effectiveness of manual therapy interventions (defined as

“a continuum of skilled passive movements to the joints and/or related soft tissues that are applied at varying speeds and amplitudes”) in patients with low back pain as well as shoulder impingement, knee osteoarthritis, and cervical pain. However, there is a lack of randomized, controlled studies on the effects of mobilization for all the peripheral joints. Case studies that describe patient selection and/or interventions using joint mobilization/manipulation techniques are identified in various chapters in this text (see Chapters 15 and 17 to 22).

## Limitations of Joint Mobilization/Manipulation Techniques

Joint techniques cannot change the disease process of disorders such as rheumatoid arthritis or the inflammatory process of injury. In these cases, treatment is directed toward minimizing pain, maintaining available joint play, and reducing the effects of any mechanical limitations (see Chapter 11).

The skill of the therapist affects the outcome. The techniques described in this text are relatively safe if directions are followed and precautions are heeded. However, if these techniques are used indiscriminately on patients not properly examined and screened for such maneuvers or if they are applied too vigorously for the condition, joint trauma or hypermobility may result.

## Contraindications and Precautions

The only true contraindications to mobilization/manipulation stretching techniques are hypermobility, joint effusion, and inflammation.

## Hypermobility

- The joints of patients with potential necrosis of the ligaments or capsule should not be mobilized with stretching techniques.
- Patients with painful hypermobile joints may benefit from gentle joint-play techniques if kept within the limits of motion. Stretching is not done.

## Joint Effusion

There may be joint swelling (effusion) due to trauma or disease. Rapid swelling of a joint usually indicates bleeding in the joint and may occur with trauma or diseases such as hemophilia. Medical intervention is required for aspiration of the blood to minimize its necrotizing effect on the articular cartilage. Slow swelling (more than 4 hours) usually indicates serous effusion (a build-up of excess synovial fluid) or edema in the joint due to mild trauma, irritation, or a disease such as arthritis.

- Do not stretch a swollen joint with mobilization or passive stretching techniques. The capsule is already on a stretch by being distended to accommodate the extra fluid. The limited motion is from the extra fluid and muscle response to pain, not from shortened fibers.
- Gentle oscillating motions that do not stress or stretch the capsule may help block the transmission of a pain stimulus so it is not perceived and also may help improve fluid flow while maintaining available joint play.
- If the patient's response to gentle techniques results in increased pain or joint irritability, the techniques were applied too vigorously or should not have been done with the current state of pathology.

## Inflammation

Whenever inflammation is present, stretching increases pain and muscle guarding and results in greater tissue damage. Gentle oscillating or distraction motions may temporarily inhibit the pain response. See Chapter 10 for an appropriate approach to treatment when inflammation is present.

## Conditions Requiring Special Precautions for Stretching

In most cases, joint mobilization/manipulation techniques are safer than passive angular stretching, in which the bony lever is used to stretch tight tissue and joint compression results. Mobilization may be used with *extreme care* in the following conditions if the signs and the patient's response are favorable.

- Malignancy
- Bone disease detectable on radiographs
- Unhealed fracture (The site of the fracture and the stabilization provided will dictate whether or not manipulative techniques can be safely applied.)
- Excessive pain (Determine the cause of pain and modify treatment accordingly.)
- Hypermobility in associated joints (Associated joints must be properly stabilized so the mobilization force is not transmitted to them.)
- Total joint replacements (The mechanism of the replacement is self-limiting, and therefore the mobilization techniques may be inappropriate.)
- Newly formed or weakened connective tissue such as immediately after injury, surgery, or disuse or when the patient is taking certain medications such as corticosteroids (Gentle progressive techniques within the tolerance of the tissue help align the developing fibrils, but forceful techniques are destructive.)
- Systemic connective tissue diseases such as rheumatoid arthritis, in which the disease weakens the connective tissue (Gentle techniques may benefit restricted tissue, but forceful techniques may rupture tissue and result in instabilities.)
- Elderly individuals with weakened connective tissue and diminished circulation (Gentle techniques within the tolerance of the tissue may be beneficial to increase mobility.)

## Procedures for Applying Passive Joint Techniques

### Examination and Evaluation

If the patient has limited or painful motion, examine and decide which tissues are limiting function and the state of pathology. Determine whether treatment should be directed primarily toward relieving pain or stretching a joint or soft tissue limitation.<sup>5,12</sup>

### Quality of Pain

The quality of pain when testing the ROM helps determine the stage of recovery and the dosage of techniques used for treatment (see Fig. 10.2).

- If pain is experienced *before* tissue limitation—such as the pain that occurs with muscle guarding after an acute injury or during the active stage of a disease—gentle pain-inhibiting joint techniques may be used. The same techniques also can help maintain joint play (see the next section on Grades or Dosages of Movement). Stretching under these circumstances is contraindicated.
- If pain is experienced *concurrently* with tissue limitation—such as the pain and limitation that occur when damaged tissue begins to heal—the limitation is treated cautiously. Gentle stretching techniques specific to the tight structure are used to improve movement gradually yet not exacerbate the pain by reinjuring the tissue.
- If pain is experienced *after* tissue limitation is met because of stretching of tight capsular or periarticular tissue, the stiff joint can be aggressively stretched with joint-play techniques and the periarticular tissue with the stretching techniques described in Chapter 4.

### Capsular Restriction

The joint capsule is limiting motion and should respond to mobilization techniques if some or all of the following signs are present.

- The passive ROM for that joint is limited in a capsular pattern. (These patterns are described for each peripheral joint under the respective sections on joint problems in Chapters 17 through 22).
- There is a firm capsular end-feel when overpressure is applied to the tissues limiting the range.
- There is decreased joint-play movement when mobility tests (articulations) are performed.
- An adhered or contracted ligament is limiting motion if there is decreased joint play and pain when the fibers of the ligament are stressed; ligaments often respond to joint mobilization techniques if applied specific to their line of stress.

### Subluxation or Dislocation

Subluxation or dislocation of one bony part on another and loose intra-articular structures that block normal motion

may respond to thrust techniques. Some of the simpler thrust techniques for extremity joints are described in the respective chapters in this text; thrust techniques for the spine are described in Chapter 16.

## Documentation

Use of standardized terminology for communication is recommended in order to facilitate research on effective outcomes using mobilization/manipulation. A task force formed by the American Academy of Orthopaedic Manual Physical Therapists published recommendations regarding the characteristics to use in the description of manipulative techniques.<sup>24</sup> These are listed in Box 5.1.

The principles describing the *rate of application of the force*, *location in range of available movement*, and *direction and target of force* that the therapist applies are described in this section. The actual *target of force*, *structural movement*, and *patient position* are specific to each joint technique; these are described in the section on peripheral joint mobilization techniques in this chapter, for the temporomandibular joint in Chapter 15, and for the spine in Chapter 16.

## Grades or Dosages of Movement for Non-Thrust and Thrust Techniques

Two systems of grading dosages (or rate of application) and their application in the range of available motion have been popularized.<sup>12,17</sup>

### Non-Thrust Oscillation Techniques (Fig. 5.9)

The oscillations may be performed using physiological (osteokinematic) motions or joint-play (arthrokinematic) techniques.

#### Dosage and Rate of Application

**Grade I.** Small-amplitude rhythmic oscillations are performed at the beginning of the range. They are usually rapid oscillations, like manual vibrations.

**FIGURE 5.9** Representation of oscillation techniques. (Adapted from Hengeveld, E, and Banks, K: Maitland's Peripheral Manipulation, ed. 4. Oxford: Butterworth Heinemann, 2005.<sup>12</sup>)

**Grade II.** Large-amplitude rhythmic oscillations are performed within the range, not reaching the limit. They are usually performed at two or three per second for 1 to 2 minutes.

**Grade III.** Large-amplitude rhythmic oscillations are performed up to the limit of the available motion and are stressed into the tissue resistance. They are usually performed at two or three per second for 1 to 2 minutes.

**Grade IV.** Small-amplitude rhythmic oscillations are performed at the limit of the available motion and stressed into the tissue resistance. They are usually rapid oscillations, like manual vibrations.

#### Indications

- Grades I and II are primarily used for treating joints limited by pain or muscle guarding. The oscillations may have an inhibitory effect on the perception of painful stimuli by repetitively stimulating mechanoreceptors that block nociceptive pathways at the spinal cord or brain stem levels.<sup>30,38</sup> These nonstretch motions help move synovial fluid to improve nutrition to the cartilage.
- Grades III and IV are primarily used as stretching maneuvers.
- Vary the speed of oscillations for different effects, such as low amplitude and high speed, to inhibit pain or slow speed to relax muscle guarding.

### Non-Thrust Sustained Joint-Play Techniques (Fig. 5.10)

This grading system describes only joint-play techniques that separate (distract) or glide/translate (slide) the joint surfaces.

#### Dosages and Rate of Application

As indicated by the name, rate of application is slow and sustained for several seconds followed by partial relaxation and then repeated depending on the indications.

### BOX 5.1 Characteristics to Describe Mobilization and Manipulation Techniques for Documentation<sup>24</sup>

1. *Rate of application of the force*
2. *Location in range of available movement*
3. *Direction of force as applied by the therapist*
4. *Target of force* (The specific structure to which the force is applied is described identifying palpable anatomical structures.)
5. *Relative structural movement* (The structure that is to move is identified first, followed by the structure that is kept stable.)
6. *Patient position*

**FIGURE 5.10** Representation of sustained joint-play techniques. (Adapted from Kaltenborn, FM, et al: *Manual Mobilization of the Joints: Joint Examination and Basic Treatment, Vol I: The Extremities, ed. 8. Oslo, Norway: Norli, 2014.*<sup>17</sup>)

**Grade I (loosen).** Small-amplitude distraction is applied when no stress is placed on the capsule. It equalizes cohesive forces, muscle tension, and atmospheric pressure acting on the joint.

**Grade II (tighten).** Enough distraction or glide is applied to tighten the tissues around the joint. Kaltenborn<sup>15</sup> called this “taking up the slack.”

**Grade III (stretch).** A distraction or glide is applied with an amplitude large enough to place stretch on the joint capsule and surrounding periarticular structures.

#### Indications

- Grade I distraction is used with all gliding motions and may be used for relief of pain. Apply intermittent distraction for 7 to 10 seconds with a few seconds of rest in between for several cycles. Note the response and either repeat or discontinue.
- Grade II distraction is used for the initial treatment to determine the sensitivity of the joint. Once the joint reaction is known, the treatment dosage is increased or decreased accordingly.
- Gentle grade II distraction applied intermittently may be used to inhibit pain. Grade II glides may be used to maintain joint play when ROM is not allowed.
- Grade III distractions or glides are used to stretch the joint structures and thus increase joint play. For restricted joints, apply a minimum of a 6-second stretch force followed by partial release (to grade I or II), then repeat with slow, intermittent stretches at 3- to 4-second intervals.

#### Comparison of Oscillation and Sustained Techniques

When using either grading system, dosages I and II are low intensity and so do not cause a stretch force on the joint capsule or surrounding tissue, although by definition, sustained

grade II techniques take up the slack of the tissues, whereas grade II oscillation techniques stay within the slack. Grades III and IV oscillations and grade III sustained stretch techniques are similar in intensity in that they all are applied with a stretch force at the limit of motion. The differences are related to the rhythm or speed of repetition of the stretch force.

- For clarity and consistency, when referring to dosages in this text, the notation *graded oscillations* means to use the dosages as described in the section on oscillation techniques. The notation *sustained grade* means to use the dosages as described in the section on sustained joint-play techniques.
- The choice of using oscillating or sustained techniques depends on the patient’s response.
  - When dealing with managing pain, either grade I or II oscillation techniques or slow intermittent grade I or II sustained joint distraction techniques are recommended; the patient’s response dictates the intensity and frequency of the joint-play technique.
  - When dealing with loss of joint play and thus decreased functional range, sustained techniques applied in a cyclic manner are recommended; the longer the stretch force can be maintained, the greater the creep and plastic deformation of the connective tissue.
  - When attempting to maintain available range by using joint-play techniques, either grade II oscillating or sustained grade II techniques can be used.

#### Thrust Manipulation/High Velocity Thrust

HVT is a small-amplitude, high-velocity technique.

#### Application

- Prior to application, the joint is moved to the limit of the motion so that all slack is taken out of the tissue, then a quick thrust is applied to the restricting tissue. It is important to keep the amplitude of the thrust small so as not to damage unrelated tissues or lose control of the maneuver.
- HVT is applied with one repetition only.

#### Indications

HVT is used to snap adhesions or is applied to a dislocated structure to reposition the joint surfaces.

#### Positioning and Stabilization

- The patient and the extremity to be treated should be positioned so the patient can relax. To relax the muscles crossing the joint, techniques of inhibition (see Chapter 4) may be used prior to or between mobilization techniques.
- Examination of joint play (passive accessory motion) and the first treatment are initially performed in the loose pack or the resting position for that joint so that the greatest capsule laxity is possible. In some cases, the position to use is the one in which the joint is least painful.
- With progression of treatment, the joint is positioned at or near the end of the available range prior to application of the mobilization force. This places the restricting tissue in

its most lengthened position where the stretch force can be more specific and effective.<sup>17</sup>

- Firmly and comfortably stabilize one joint partner, usually the proximal bone. A belt, one of the therapist's hands, or an assistant holding the part may provide stabilization. Appropriate stabilization prevents unwanted stress to surrounding tissues and joints and makes the stretch force more specific and effective.

## Direction and Target of Treatment Force

- The treatment force (either gentle or strong) is applied as close to the opposing joint surface as possible. It is imperative that the therapist be able to identify anatomical landmarks and use these as guides for accurate hand placement and force application. The larger the contact surface, the more comfortable the patient will be with the procedure. For example, instead of forcing with your thumb, use the flat surface of your hand.
- The direction of movement during treatment is either parallel or perpendicular to the treatment plane. *Treatment plane* was described by Kaltenborn<sup>17</sup> as a plane perpendicular to a line running from the axis of rotation to the middle of the concave articular surface. The plane is in the concave partner, so its position is determined by the position of the concave bone (Fig. 5.11).

**FIGURE 5.11** Treatment plane (T.P.) is at right angles to a line drawn from the axis of rotation to the center of the concave articulating surface and lies in the concave surface. Joint traction (distraction) is applied perpendicular to and glides parallel to the T.P.

- Distraction techniques are applied perpendicular to the treatment plane. The entire bone is moved so the joint surfaces are separated.

- *Gliding techniques are applied parallel to the treatment plane.* The direction of gliding may be determined by using the convex-concave rule (described earlier in the chapter). If the surface of the moving bony partner is convex, the treatment glide should be opposite to the direction in which the bone swings. If the surface of the moving bony partner is concave, the treatment glide should be in the same direction (see Fig. 5.5). Or, if a restricted feel is identified during the examination, the glide is performed in the direction that stretches the restriction.
- The entire bone is moved so there is gliding of one joint surface on the other. The bone should not be used as a lever; it should have no arcing motion (swing), which would cause rolling and thus compression of the joint surfaces.

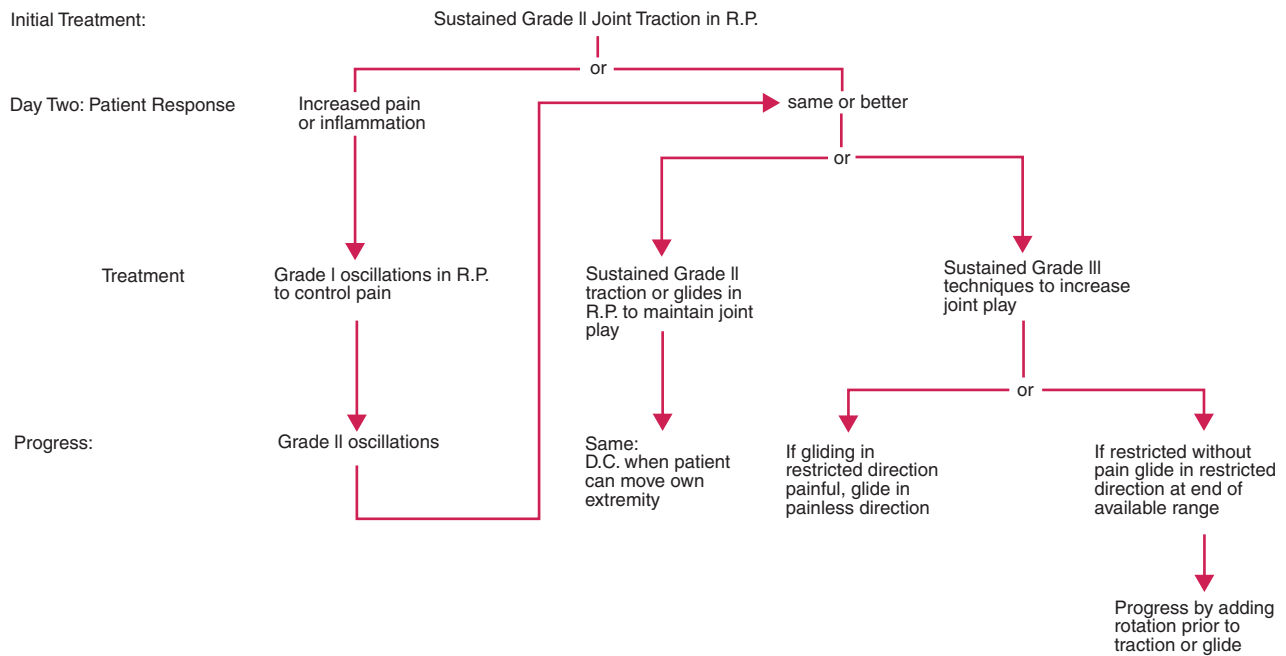

## Initiation and Progression of Treatment (Fig. 5.12)

1. The initial treatment is the same whether treating to decrease pain or increase joint play. The purpose is to determine joint reactivity before proceeding. Use a sustained grade II distraction of the joint surfaces with the joint held in resting position or the position where the greatest mobility is detected.<sup>17</sup> Note the immediate joint response relative to irritability and range.
2. The next day, evaluate the joint response or have the patient report the response at the next visit.
  - If there is increased pain and sensitivity, reduce the amplitude of treatment to grade I oscillations.
  - If the joint is the same or better, perform either of the following: Repeat the same maneuver if the goal of treatment is to maintain joint play, or progress the maneuver to stretching techniques if the goal of treatment is to increase joint play.
3. To maintain joint play by using gliding techniques when ROM techniques are contraindicated or not possible for a period of time, use sustained grade II or grade II oscillation techniques.
4. To progress the stretch technique, move the bone to the end of the available ROM<sup>17</sup> and then apply a sustained grade III distraction or glide technique. Progressions include prepositioning the bone at the end of the available range and rotating it prior to applying grade III distraction or glide techniques. The direction of the glide and rotation is dictated by the joint mechanics. For example, laterally rotate the humerus as shoulder abduction is progressed; medially rotate the tibia as knee flexion is progressed.

### CLINICAL TIP

For effective mobilization:

- Warm the tissue around the joint prior to stretching. Modalities, massage, or gentle muscle contractions increase the circulation and warm the tissues.

**FIGURE 5.12** Initiation and progression of treatment.

- Muscle relaxation techniques and grade I and II oscillation techniques may inhibit muscle guarding and should be alternated with sustained stretching techniques, if necessary.
- When using grade III gliding techniques, a grade I distraction should be used with it. A grade II or III distraction should not be used with a grade III glide to avoid excessive trauma to the joint.
- If gliding in the restricted direction is too painful, begin gliding mobilizations in the painless direction. Progress to gliding in the restricted direction when mobility improves and pain decreases.
- When stretching to increase joint play, move the bony partner through the available range of joint play first—that is, “take up the slack.” When tissue resistance is felt, apply the stretch force against the restriction.
- Incorporate MWM techniques (described in the following section) as part of the total approach to treatment.

## Patient Response

- Stretching maneuvers usually cause soreness. Perform the maneuvers on alternate days to allow the soreness to decrease and tissue healing to occur between stretching sessions. The patient should perform ROM into any newly gained range during this time.
- If there is increased pain lasting longer than 24 hours after stretching, the dosage (amplitude) or duration of treatment was too vigorous. Decrease the dosage or duration until the pain is under control.
- The patient’s joint and ROM should be reassessed after treatment and again before the next treatment. Alterations in treatment are dictated by the joint response.

## Total Program

Mobilization techniques are one part of a total treatment program when there is decreased function. If muscles or connective tissues are also limiting motion, PNF stretching and passive stretching techniques are alternated with joint mobilization during the same treatment session. Interventions should also include appropriate ROM, strengthening, and functional exercises, so the patient learns effective control and use of the gained mobility (Box 5.2).

### BOX 5.2 Suggested Sequence of Treatment to Gain and Reinforce Functional Mobility

1. Warm the tissues
2. Relax the muscles
  - Hold-relax inhibition technique
  - Grade I or II joint oscillation techniques
3. Joint mobilization stretches
  - Position and dosage for level of tissue tolerance
5. Passive stretch periarticular tissues
6. Patient actively uses new range
  - Reciprocal inhibition
  - Active ROM
  - Functional activities
7. Maintain new range; patient instruction
  - Self-stretching
  - Auto-mobilization
  - Active, resistive ROM
  - Functional activities using the new range

## Mobilization With Movement: Principles of Application

Brian Mulligan's concept of MWM is the natural continuance of progression in the development of manual therapy from active self-stretching exercises, to therapist-applied passive physiological movement, to passive accessory mobilization techniques.<sup>23</sup> MWM is the concurrent application of pain-free accessory mobilization with active and/or passive physiological movement.<sup>26</sup> Passive end-range overpressure or stretching is then applied without pain as a barrier. These techniques are applicable when:

- No contraindication for manual therapy exists (described earlier in the chapter).
- A full orthopedic examination has been completed, and evaluation of the results indicates local musculoskeletal pathology.
- A specific biomechanical analysis reveals localized loss of movement and/or pain associated with function.
- No pain is produced during or immediately after application of the technique.<sup>22</sup>

### Principles and Application of MWM in Clinical Practice

**Comparable sign.** One or more comparable signs are identified during the examination.<sup>12</sup> A comparable sign is a positive test sign that can be repeated after a therapeutic maneuver to determine the effectiveness of the maneuver. For example, a comparable sign may include loss of joint play movement, loss of ROM, or pain associated with movement during specific functional activities, such as lateral elbow pain with resisted wrist extension, painful restriction of ankle dorsiflexion, or pain with overhead reaching.

**Passive techniques.** A passive joint mobilization is applied using the principles described in the previous section following the principles of Kaltenborn.<sup>17</sup> Utilizing knowledge of joint anatomy and mechanics, a sense of tissue tension, and sound clinical reasoning, the therapist investigates various combinations of parallel or perpendicular accessory glides to find the pain-free direction and grade of accessory movement. This may be a glide, spin, distraction, or combination of movements. This accessory motion must be pain-free.<sup>26</sup>

**Accessory glide with active comparable sign.** While the therapist sustains the pain-free accessory force, the patient is requested to perform the comparable sign. The comparable sign should now be significantly improved—that is, there should be increased ROM, and the motion should *be free of the original pain*.<sup>26</sup>

**No pain.** The therapist must continuously monitor the patient's reaction to ensure no pain is produced. Failure to improve the comparable sign would indicate that the therapist has not

found the correct direction of accessory movement, the grade of movement, or that the technique is not indicated.

**Repetitions.** The previously restricted and/or painful motion or activity is repeated 6 to 10 times by the patient while the therapist continues to maintain the appropriate accessory mobilization. Further gains are expected with repetition during a treatment session, particularly when *pain-free* passive overpressure is applied to achieve end-range loading.

**Description of techniques.** Techniques applicable to the extremity joints are described throughout this text in the treatment sections for various conditions (see Chapters 17 through 22).

### Patient Response and Progression

**Pain as a guide.** Successful MWM techniques should render the comparable sign painless while significantly improving function during the application of the technique.

**Self-treatment.** Once patient response is determined, self-treatment is often possible using MWM principles with sports-type adhesive tape and/or the patient providing the mobilization component of the MWM concurrent with the active physiological movement.<sup>10</sup>

**Total program.** Having restored articular function with MWMs, the patient is progressed through the ensuing rehabilitation sequences of the recovery of muscular power, endurance, and neural control. Sustained improvements are necessary to justify ongoing intervention.

### Theoretical Framework

Mulligan postulated a positional fault model to explain the results gained through his concept. Alternatively, inappropriate joint tracking mechanisms due to an altered instantaneous axis of rotation and neurophysiological response models have also been considered.<sup>10,22,23,27</sup> For further details of the application of the Mulligan concept as it applies to the spine and extremities, refer to *Manual Therapy*, “NAGS,” “SNAGS,” “MWMS,” *etc.*<sup>26</sup>

#### FOCUS ON EVIDENCE

Early research on the MWM approach confirms its benefits; however, the mechanism by which it affects the musculoskeletal system, whether mechanical or physiological, has yet to be fully determined.<sup>4,18,29,31,32,35</sup> A study by Paungmali and associates<sup>31</sup> measured a significant reduction in pain, increased grip strength, and increased sympathetic nervous system response immediately following MWM for chronic lateral epicondylalgia compared with a placebo intervention, results that were similar to those in studies of spinal manipulation. They interpreted this to imply that there is a multisystem response to manipulation whether the spine or the elbow is manipulated.

## Peripheral Joint Mobilization Techniques

The following are suggested joint distraction and gliding techniques for use by entry-level therapists and those attempting to gain a foundation in joint mobilization of extremity joints. A variety of adaptations can be made from these techniques. Some adaptations are described in the respective chapters in which specific impairments and interventions are discussed (see Chapters 17 through 22). The distraction and glide techniques should be applied with respect to the dosage, frequency, progression, precautions, and procedures as described earlier in this chapter. Manipulation and HVT techniques for the spine are described in Chapter 16.

**NOTE:** Terms, such as proximal hand, distal hand, lateral hand, or other descriptive terms, indicate that the therapist should use the hand that is more proximal, distal, or lateral to the patient or the patient's extremity.

## Shoulder Girdle Complex

Joints of the shoulder girdle consist of three synovial articulations—sternoclavicular, acromioclavicular, and glenohumeral—and the functional articulation of the scapula gliding on the thorax (Fig. 5.13). To gain full elevation of the humerus, the accessory and component motions of clavicular elevation and rotation, scapular rotation, and external rotation of the humerus, as well as adequate joint play, are necessary. The clavicular and scapular techniques are described following the glenohumeral joint techniques. For a review of the mechanics of the shoulder complex, see Chapter 17.

### Glenohumeral Joint

The concave glenoid fossa receives the convex humeral head.

**FIGURE 5.13** Bones and joints of the shoulder girdle complex.

**Resting position.** The shoulder is abducted 55°, horizontally adducted 30°, and rotated so the forearm is in the horizontal plane with respect to the body (called plane of the scapula).

**Treatment plane.** The treatment plane is in the glenoid fossa and moves with the scapula as it rotates.

**Stabilization.** Fixate the scapula with a belt or have an assistant help.

### Glenohumeral Distraction (Fig. 5.14)

#### VIDEO 5.1

#### Indications

Testing; initial treatment (sustained grade II); pain control (grade I or II oscillations); general mobility (sustained grade III).

**FIGURE 5.14** Glenohumeral joint: distraction in resting position. Note that the force is perpendicular to the T.P. in the glenoid fossa.

#### Patient Position

Supine, with arm in the resting position.

#### Therapist Position and Hand Placement

- Stand at the patient's side, facing toward his or her head.
- Use the hand nearer the part being treated (e.g., left hand if treating the patient's left shoulder) and place it in the patient's axilla with your thumb just distal to the joint margin anteriorly and fingers posteriorly. Support the forearm between your trunk and elbow.
- Your other hand supports the humerus from the lateral surface.

#### Mobilizing Force

With the hand in the axilla, move the humerus laterally.

**NOTE:** The entire arm moves in a translatory motion away from the plane of the glenoid fossa. Distractions may be performed with the humerus in any position (see Figs. 5.17, 5.19,

and 17.20). You must be aware of the amount of scapular rotation and adjust the distraction force against the humerus, so it is perpendicular to the plane of the glenoid fossa.

### Glenohumeral Caudal Glide in Resting Position (Fig. 5.15) VIDEO 5.2

#### Indications

To increase abduction (sustained grade III); to reposition the humeral head if superiorly positioned.

**FIGURE 5.15** Glenohumeral joint: caudal glide in the resting position. Note that the distraction force is applied by the hand in the axilla, and the caudal glide force is from the hand superior to the humeral head.

#### Patient Position

Supine, with arm in the resting position.

#### Therapist Position and Hand Placement

- Stand lateral to the patient's arm being treated and support the forearm between your trunk and elbow. Place one hand in the patient's axilla to provide a grade I distraction.
- The web space of your other hand is placed just distal to the acromion process.

#### Mobilizing Force

With the superiorly placed hand, glide the humerus in an inferior direction.

### Glenohumeral Caudal Glide (Long Axis Traction)

#### Patient Position

Supine, with arm in the resting position.

#### Hand Placement and Mobilizing Force

Support the patient's forearm between your trunk and elbow. Grasp around the distal arm with both hands and apply the force in a caudal direction as you shift your body weight toward the patient's feet.

### Glenohumeral Caudal Glide Progression (Fig. 5.16)

#### Indication

To increase abduction.

**FIGURE 5.16** Glenohumeral joint: caudal glide with the shoulder near 90°.

#### Patient Position

- Supine or sitting, with the arm abducted to the end of its available range.
- External rotation of the humerus should be added to the end-range position as the arm approaches and goes beyond 90°.

#### Therapist Position and Hand Placement

- With the patient *supine*, stand facing the patient's feet and stabilize the patient's arm against your trunk with the hand farthest from the patient. Slight lateral motion of your trunk provides grade I distraction via a long-axis traction.
- With the patient *sitting*, stand behind the patient and cradle the distal humerus with the hand farthest from the patient; this hand provides a grade I distraction via a long-axis traction.
- Place the web space of your other hand just distal to the acromion process on the proximal humerus.

#### Mobilizing Force

With the hand on the proximal humerus, glide the humerus in an inferior direction with respect to the glenoid fossa of the scapula.

### Glenohumeral Elevation Progression (Fig. 5.17)

#### Indication

To increase elevation beyond 90° of abduction.

**FIGURE 5.17** Glenohumeral joint: elevation progression in the sitting position. This is used when the range is greater than 90°. Note the externally rotated position of the humerus; pressure against the head of the humerus is toward the axilla.

### Patient Position

Supine or sitting, with the arm abducted and externally rotated to the end of its available range.

### Therapist Position and Hand Placement

- Hand placement is the same as for caudal glide progression.
- Adjust your body position so the hand applying the mobilizing force is aligned with the treatment plane in the glenoid fossa.
- With the hand grasping the elbow, apply a grade I distraction force (this is a long axis traction as pictured in Fig. 5.17).

### Mobilizing Force

- With the hand on the proximal humerus, glide the humerus in a progressively anterior direction against the inferior folds of the capsule in the axilla.
- The direction of force with respect to the patient's body depends on the amount of upward rotation and protraction of the scapula.

## Glenohumeral Posterior Glide, Resting Position (Fig. 5.18) VIDEO 5.3

### Indications

To increase flexion; to increase internal rotation.

### Patient Position

Supine, with the arm in resting position.

### Therapist Position and Hand Placement

- Stand with your back to the patient between the patient's trunk and arm.
- Support the arm against your trunk, grasping the distal humerus with your lateral hand. This position provides grade I distraction to the joint.

**FIGURE 5.18** Glenohumeral joint: posterior glide in the resting position.

- Place the lateral border of your top hand just distal to the anterior margin of the joint, with your fingers pointing superiorly. This hand gives the mobilizing force.

### Mobilizing Force

Glide the humeral head posteriorly by moving the entire arm as you bend your knees.

## Glenohumeral Posterior Glide Progression (Fig. 5.19)

### Indications

To increase posterior gliding when flexion approaches 90°; to increase horizontal adduction.

### Patient Position

Supine, with the arm flexed to 90° and internally rotated and with the elbow flexed. The arm may also be placed in horizontal adduction.

### Hand Placement

- Place padding under the scapula for stabilization.
- Place one hand across the proximal surface of the humerus to apply a grade I distraction.
- Place your other hand over the patient's elbow.
- A belt placed around your pelvis and the proximal aspect of the patient's humerus may be used to apply the distraction force.

### Mobilizing Force

Glide the humerus posteriorly by pushing down at the elbow through the long axis of the humerus.

**FIGURE 5.19** Glenohumeral joint: posterior glide progression. **(A)** One hand or **(B)** a belt is used to exert a grade I distraction force.

### Glenohumeral Anterior Glide, Resting Position (Fig. 5.20) VIDEO 5.4

#### Indications

To increase extension; to increase external rotation.

#### Patient Position

Prone, with the arm in resting position over the edge of the treatment table, supported on your thigh. Stabilize the acromion with padding. The supine position may also be used.

**FIGURE 5.20** Glenohumeral joint: anterior glide in the resting position.

#### Therapist Position and Hand Placement

- Stand facing the top of the table with the leg closer to the table in a forward stride position.
- Support the patient's arm against your thigh with your outside hand; the arm positioned on your thigh provides a grade I distraction.
- Place the ulnar border of your other hand just distal to the posterior angle of the acromion process, with your fingers pointing superiorly; this hand gives the mobilizing force.

#### Mobilizing Force

Glide the humeral head in an anterior and slightly medial direction. Bend both knees so the entire arm moves anteriorly.

**PRECAUTION:** Do not lift the arm at the elbow and thereby cause angulation of the humerus. Such angulation could lead to anterior subluxation or dislocation of the humeral head. Do not use this position to progress external rotation. Placing the shoulder in 90° abduction with external rotation and applying an anterior glide may cause anterior subluxation of the humeral head.

### Glenohumeral External Rotation Progressions (Fig. 5.21) VIDEO 5.5

#### Indication

To increase external rotation.

#### Techniques

Because of the danger of subluxation when applying an anterior glide with the humerus externally rotated, use a distraction progression or elevation progression to gain range.

- *Distraction progression:* Begin with the shoulder in resting position, externally rotate the humerus to end-range, and

**FIGURE 5.21** Glenohumeral joint: distraction for external rotation progression. Note that the humerus is positioned in the resting position with maximum external rotation prior to the application of distraction stretch force.

then apply a grade III distraction perpendicular to the treatment plane in the glenoid fossa.

- **Elevation progression** (see Fig. 5.17): This technique incorporates end-range external rotation.
- Several research studies have documented increased external rotation by using a posterior glide. This is particularly beneficial when the humeral head is anteriorly displaced in the glenoid fossa and the posterior capsule is tight.<sup>11,14,15,16</sup>

## Acromioclavicular Joint

**Indication.** To increase mobility of the joint.

**Stabilization.** Fixate the scapula with your more lateral hand around the acromion process.

### Anterior Glide of Clavicle on Acromion (Fig. 5.22)

#### Patient Position

Sitting or prone.

#### Hand Placement

- With the patient sitting, stand behind the patient and stabilize the acromion process with the fingers of your lateral hand.
- The thumb of your other hand pushes downward through the upper trapezius and is placed posteriorly on the clavicle, just medial to the joint space.
- With the patient prone, stabilize the acromion with a towel roll under the shoulder.

**FIGURE 5.22** Acromioclavicular joint: anterior glide.

#### Mobilizing Force

Push the clavicle anteriorly with your thumb.

## Sternoclavicular Joint

**Joint surfaces.** The proximal articulating surface of the clavicle is convex superiorly/inferiorly and concave anteriorly/posteriorly with an articular disk between it and the manubrium of the sternum.

**Treatment plane.** For protraction/retraction, the treatment plane is in the clavicle. For elevation/depression, the treatment plane is in the manubrium.

**Patient position and stabilization.** Supine; the thorax provides stability to the sternum.

### Sternoclavicular Posterior Glide and Superior Glide (Fig. 5.23)

#### Indications

Posterior glide to increase retraction; superior glide to increase depression of the clavicle.

#### Hand Placement

- Place your thumb on the anterior surface of the proximal end of the clavicle.
- Flex your index finger and place the middle phalanx along the caudal surface of the clavicle to support the thumb.

#### Mobilizing Force

- **Posterior glide:** Push with your thumb in a posterior direction.
- **Superior glide:** Push with your index finger in a superior direction.

**FIGURE 5.23** Sternoclavicular joint: posterior and superior glides. (A) Press down with the thumb for posterior glide; (B) Press upward with the index finger for superior glide.

### Sternoclavicular Anterior Glide and Caudal (Inferior) Glide (Fig. 5.24)

#### Indications

Anterior glide to increase protraction; caudal glide to increase elevation of the clavicle.

**FIGURE 5.24** Sternoclavicular joint: anterior and inferior glides. (A) Pull the clavicle upward for an anterior glide; (B) Press caudalward with the curled fingers for an inferior glide.

#### Hand Placement

Your fingers are placed superiorly and thumb inferiorly around the clavicle.

#### Mobilizing Force

- *Anterior glide:* lift the clavicle anteriorly with your fingers and thumb.
- *Caudal glide:* press the clavicle inferiorly with your fingers.

### Scapulothoracic Soft-Tissue Mobilization (Fig. 5.25) VIDEO 5.6

The scapulothoracic articulation is not a true joint, but the soft tissue and muscles supporting the articulation are mobilized to obtain scapular motions of elevation, depression, protraction, retraction, upward and downward rotation, and winging for normal shoulder girdle mobility.

**FIGURE 5.25** Scapulothoracic articulation: elevation, depression, protraction, retraction, upward and downward rotations, and winging.

**Patient position.** If there is considerable restriction in mobility, begin prone and progress to side-lying, with the patient facing you. Support the weight of the patient's arm by draping it over your inferior arm and allowing it to hang so the scapular muscles are relaxed.

**Hand placement.** Place your superior hand across the acromion process to control the direction of motion. With the fingers of your inferior hand, scoop under the medial border and under the inferior angle of the scapula.

**Mobilizing force.** Move the scapula in the desired direction by lifting from the inferior angle or by pushing on the acromion process.

## Elbow and Forearm Complex

The elbow and forearm complex consists of four joints: humeroulnar, humeroradial, proximal radioulnar, and distal radioulnar (Fig. 5.26). For full elbow flexion and extension,

accessory motions of varus and valgus (with radial and ulnar glides) are necessary. The techniques for each of the joints as well as accessory motions are described in this section. For a review of the joint mechanics, see Chapter 18.

**FIGURE 5.26** Bones and joints of the elbow complex.

### Humero-ulnar Articulation

The convex trochlea articulates with the concave olecranon fossa.

**Resting position.** Elbow is flexed 70°, and forearm is supinated 10°.

**Treatment plane.** The treatment plane is in the olecranon fossa, angled approximately 45° from the long axis of the ulna (Fig. 5.27).

**FIGURE 5.27** Lateral view of the humero-ulnar joint, depicting the treatment plane (T.P.).

**Stabilization.** Fixate the humerus against the treatment table with a belt or use an assistant to hold it. The patient may roll onto his or her side and fixate the humerus with the contralateral hand if muscle relaxation can be maintained around the elbow joint being mobilized.

### Humero-ulnar Distraction and Progression (Fig. 5.28 A) VIDEO 5.7

#### Indications

Testing; initial treatment (sustained grade II); pain control (grade I or II oscillation); to increase flexion or extension (grade III or IV).

**FIGURE 5.28** Humero-ulnar joint: (A) Distraction;

#### Patient Position

Supine, with the elbow over the edge of the treatment table or supported with padding just proximal to the olecranon process. Rest the patient's wrist against your shoulder, allowing the elbow to be in resting position for the initial treatment. To stretch into either flexion or extension, position the joint at the end of its available range.

#### Hand Placement

- When in the resting position or at end-range flexion, place the fingers of your medial hand over the proximal ulna on the volar surface; reinforce it with your other hand.
- To isolate the mobilization force to the humero-ulnar articulation, be sure that your hand is not in contact with the proximal radius.
- When at end-range extension, stand and place the base of your proximal hand over the proximal portion of the ulna and support the distal forearm with your other hand.

#### Mobilizing Force

Apply force against the proximal ulna at a 45° angle to the shaft of the bone.

### Humero-ulnar Distal Glide (Fig. 5.28 B)

#### Indication

To increase flexion.

**FIGURE 5.28—cont'd (B)** Humeroulnar distraction with distal glide (scoop motion).

### Patient Position and Hand Placement

- Supine, with the elbow over the edge of the treatment table.
- Begin with the elbow in resting position. Progress by positioning it at the end-range of flexion.
- Place the fingers of your medial hand over the proximal ulna on the volar surface; reinforce it with your other hand. To isolate the mobilization force to the humeroulnar articulation, be sure that your hand is not in contact with the proximal radius.

### Mobilizing Force

First apply a distraction force to the joint at a 45° angle to the ulna, then while maintaining the distraction, direct the force in a distal direction along the long axis of the ulna using a scooping motion.

### Humeroulnar Radial Glide

#### Indication

To increase varus. This is an accessory motion of the joint that accompanies elbow flexion and is therefore used to progress flexion.

#### Patient Position

- Side-lying on the arm to be mobilized, with the shoulder laterally rotated and the humerus supported on the table.
- Begin with the elbow in resting position; progress to end-range flexion.

#### Hand Placement

Place the base of your proximal hand just distal to the elbow; support the distal forearm with your other hand.

#### Mobilizing Force

Apply force against the ulna in a radial direction.

### Humeroulnar Ulnar Glide

#### Indication

To increase valgus. This is an accessory motion of the joint that accompanies elbow extension and is therefore used to progress extension.

### Patient Position

- Same as for radial glide except a block or wedge is placed under the proximal forearm for stabilization (using distal stabilization).
- Initially, the elbow is placed in resting position and is progressed to end-range extension.

### Mobilizing Force

Apply force against the distal humerus in a radial direction, causing the ulna to glide ulnarly.

### Humeroradial Articulation VIDEO 5.8

The convex capitulum articulates with the concave radial head (see Fig. 5.26).

**Resting position.** Elbow is extended and forearm is supinated to the end of the available range.

**Treatment plane.** The treatment plane is in the concave radial head perpendicular to the long axis of the radius.

**Stabilization.** Fixate the humerus with one of your hands.

### Humeroradial Distraction (Fig. 5.29)

#### Indications

To increase mobility of the humeroradial joint; to manipulate a pushed elbow (proximal displacement of the radius).

**FIGURE 5.29** Humeroradial joint: distraction.

### Patient Position

Supine or sitting, with the arm resting on the treatment table.

### Therapist Position and Hand Placement

- Position yourself on the ulnar side of the patient's forearm so you are between the patient's hip and upper extremity.
- Stabilize the patient's humerus with your superior hand.
- Grasp around the distal radius with the fingers and thenar eminence of your inferior hand. Be sure you are not grasping around the distal ulna.

### Mobilizing Force

Pull the radius distally (long-axis traction causes joint traction).

## Humeroradial Dorsal/Volar Glides (Fig. 5.30)

### Indications

Dorsal glide head of the radius to increase elbow extension; volar glide to increase flexion.

**FIGURE 5.30** Humero-radial joint: dorsal and volar glides. This may also be done sitting, as in Figure 5.32, with the elbow positioned in extension and the humerus stabilized by the proximal hand (rather than the ulna).

### Patient Position

Supine or sitting with the elbow extended and supinated to the end of the available range.

### Hand Placement

- Stabilize the humerus with your hand that is on the medial side of the patient's arm.
- Place the palmar surface of your lateral hand on the volar aspect and your fingers on the dorsal aspect of the radial head.

### Mobilizing Force

- Move the radial head dorsally with the palm of your hand or volarly with your fingers.
- If a stronger force is needed for the volar glide, realign your body and push with the base of your hand against the dorsal surface in a volar direction.

## Humeroradial Compression (Fig. 5.31)

### Indication

To reduce a pulled elbow subluxation.

### Patient Position

Sitting or supine.

### Hand Placement

- Approach the patient right hand to right hand or left hand to left hand. Stabilize the elbow posteriorly with the other

**FIGURE 5.31** Humero-radial joint: compression mobilization. This is a quick thrust with simultaneous supination and compression of the radius.

hand. If supine, the stabilizing hand is under the elbow supported on the treatment table.

- Place your thenar eminence against the patient's thenar eminence (locking thumbs).

### Mobilizing Force

Simultaneously, extend the patient's wrist, push against the thenar eminence, and compress the long axis of the radius while supinating the forearm.

**NOTE:** To replace an acute subluxation, an HVT is used.

## Proximal Radioulnar Joint

The convex rim of the radial head articulates with the concave radial notch on the ulna (see Fig. 5.26).

**Resting position.** The elbow is flexed 70°, and the forearm is supinated 35°.

**Treatment plane.** The treatment plane is in the radial notch of the ulna, parallel to the long axis of the ulna.

**Stabilization.** Proximal ulna is stabilized.

## Proximal Radioulnar Dorsal/Volar Glides (Fig. 5.32) VIDEO 5.8

### Indications

Dorsal glide to increase pronation; volar glide to increase supination.

### Patient Position

- Sitting or supine, begin with the elbow flexed 70° and the forearm supinated 35°.
- Progress by placing the forearm at the limit of the range of pronation or supination prior to administering the respective glide.

**FIGURE 5.32** Proximal radioulnar joint: dorsal and volar glides.

### Hand Placement

- Approach the patient from the dorsal or volar aspect of the forearm. Fixate the ulna with your medial hand around the medial aspect of the forearm.
- With your other hand, grasp the head of the radius between your flexed fingers and palm of your hand.

### Mobilizing Force

- Force the radial head volarly or dorsally by pushing with your palm or pulling with your fingers.
- If a stronger force is needed, rather than pulling with your fingers, move to the other side of the patient, switch hands, and apply the force with the palm of your hand.

## Distal Radioulnar Joint

The concave ulnar notch of the radius articulates with the convex head of the ulna.

**Resting position.** The resting position is with the forearm supinated 10°.

**Treatment plane.** The treatment plane is the articulating surface of the radius, parallel to the long axis of the radius.

**Stabilization.** Distal ulna.

### Distal Radioulnar Dorsal/Volar Glides (Fig. 5.33)

#### Indications

Dorsal glide to increase supination; volar glide to increase pronation.

#### Patient Position

Sitting, with the forearm on the treatment table. Begin in the resting position and progress to end-range pronation or supination.

#### Hand Placement

Stabilize the distal ulna by placing the fingers of one hand on the dorsal surface and the thenar eminence and thumb on the volar surface. Place your other hand in the same manner around the distal radius.

**FIGURE 5.33** Distal radioulnar joint: dorsal and volar glides.

### Mobilizing Force

Glide the distal radius dorsally to increase supination or volarly to increase pronation parallel to the ulna.

## Wrist and Hand Complex

When mobilizing the wrist, begin with general distractions and glides that include the proximal row and distal row of carpals as a group. For full ROM, individual carpal mobilizations/manipulations may be necessary. They are described following the general mobilizations. For a review of the mechanics of the wrist complex, see Chapter 19 (Fig. 5.34).

**FIGURE 5.34** Bones and joints of the wrist and hand.

## Radiocarpal Joint

The concave distal radius articulates with the convex proximal row of carpals, which is composed of the scaphoid, lunate, and triquetrum.

**Resting position.** The resting position is a straight line through the radius and third metacarpal with slight ulnar deviation.

**Treatment plane.** The treatment plane is in the articulating surface of the radius perpendicular to the long axis of the radius.

**Stabilization.** Distal radius and ulna.

### Radiocarpal Distraction (Fig. 5.35)

#### Indications

Testing; initial treatment; pain control; general mobility of the wrist.

**FIGURE 5.35** Wrist joint: general distraction.

#### Patient Position

Sitting, with the forearm supported on the treatment table and wrist over the edge of the table.

#### Hand Placement

- With the hand closest to the patient, grasp around the styloid processes and fixate the radius and ulna against the table.
- Grasp around the distal row of carpals with your other hand.

#### Mobilizing Force

Pull in a distal direction with respect to the arm.

### Radiocarpal Joint: General Glides and Progression

#### Indications

Dorsal glide to increase flexion (Fig. 5.36 A); volar glide to increase extension (Fig. 5.36 B); radial glide to increase

**FIGURE 5.36** Wrist joint: general mobilization. (A) Dorsal glide; (B) Volar glide.

ulnar deviation; ulnar glide to increase radial deviation (Fig. 5.37).

#### Patient Position and Hand Placement

- Sitting with forearm resting on the table in pronation for the dorsal and volar techniques and in midrange position for the radial and ulnar techniques.

**FIGURE 5.37** Wrist joint: general mobilization—ulnar glide.

- Progress by moving the wrist to the end of the available range and gliding in the defined direction.
- Specific carpal gliding techniques described in the next sections are used to increase mobility at isolated articulations.

### Mobilizing Force

The force comes from the hand around the distal row of carpals.

### Specific Carpal Mobilizations (Figs. 5.38 and 5.39)

Specific techniques to mobilize individual carpal bones may be necessary to gain full ROM of the wrist. Specific biomechanics of the radiocarpal and intercarpal joints are described in Chapter 19. To glide one carpal on another or on the radius, utilize the following guidelines.

### Patient and Therapist Positions

- The patient sits.
- Stand and grasp the patient's hand so the elbow hangs unsupported.

**FIGURE 5.38** Specific carpal mobilizations: stabilization of the distal bone and volar glide of the proximal bone. Shown is stabilization of the scaphoid and lunate with the index fingers and a volar glide to the radius with the thumbs to increase wrist flexion: **(A)** Drawing of the side view, with the arrow depicting placement of thumbs on the radius and the "x" depicting placement of stabilizing index fingers; **(B)** Illustrates superior view of overlapping thumbs on the radius.

- The weight of the arm provides slight distraction to the joints, so you then need only to apply the glides.

### Hand Placement and Indications

Identify the specific articulation to be mobilized and place your index fingers on the volar surface of the bone to be stabilized. Place the overlapping thumbs on the dorsal surface of the bone to be manipulated. The rest of your fingers hold the patient's hand so it is relaxed.

**To increase flexion.** Place the stabilizing index fingers under the bone that is *convex* (on the volar surface) and the mobilizing thumbs overlapped on the dorsal surface of the bone that is *concave*.

- Thumbs on the dorsum of the concave radius, index fingers stabilize scaphoid.
- Thumbs on the dorsum of the concave radius, index fingers stabilize lunate (see Fig. 5.38).

**FIGURE 5.39** Specific carpal mobilizations: stabilization of the proximal bone and volar glide of the distal bone. Shown is stabilization of the lunate with the index fingers and volar glide to the capitate with the thumbs to increase extension: **(A)** Drawing of the side view, with the arrow depicting placement of thumbs on the capitate and the "x" depicting placement of stabilizing index fingers; **(B)** Illustrates superior view of overlapping thumbs on the capitate.

- Thumbs on dorsum of trapezium-trapezoid unit, index fingers stabilize scaphoid.
- Thumbs on dorsum of concave lunate, index fingers stabilize capitate.
- Thumbs on dorsum of concave triquetrum, index fingers stabilize hamate.

**To increase extension.** Place the stabilizing index fingers under the bone that is *concave* (on the volar surface). Overlap the thumbs and place on the dorsal surface of the bone that is *convex*. The thumbs provide the manipulating force.

- Thumbs on dorsum of convex scaphoid, index fingers stabilize radius.
- Thumbs on dorsum of convex lunate, index fingers stabilize radius.
- Thumbs on dorsum of convex scaphoid, index fingers stabilize trapezium-trapezoid unit.
- Thumbs on dorsum of convex capitate, index fingers stabilize lunate (see Fig. 5.39).
- Thumbs on dorsum of convex hamate, index fingers stabilize triquetrum.

#### Mobilizing Force

- In each case, the force comes from the overlapping thumbs on the dorsal surface.
- By applying force from the dorsal surface, pressure against the nerves, blood vessels, and tendons in the carpal tunnel and Guyon's canal is minimized, and a stronger mobilization force can be used without pain.
- An HVT technique can be used by providing a quick downward and upward flick of your wrists and hands while pressing against the respective carpals.

#### Ulnar-Meniscal-Triquetral Articulation

To unlock the articular disk, which may block motions of the wrist or forearm, apply a glide of the ulna volarly on a fixed triquetrum.

### Carpometacarpal and Intermetacarpal Joints of Digits II to V

Opening and closing of the hand and maintenance of the arches in the hand requires general mobility between the carpals and metacarpals.

#### Carpometacarpal Distraction (Fig. 5.40)

##### Stabilization and Hand Placement

Stabilize the respective carpal with thumb and index finger of one hand. With your other hand, grasp around the proximal portion of a metacarpal.

##### Mobilizing Force

Apply long-axis traction to the metacarpal.

FIGURE 5.40 Carpometacarpal joint: distraction.

### Carpometacarpal and Intermetacarpal: Volar Glide

#### Indication

To increase mobility of the arch of the hand.

#### Stabilization and Hand Placement

Stabilize the carpals with the thumb and index finger of one hand; place the thenar eminence of your other hand along the dorsal aspect of the metacarpals to provide the mobilization force.

#### Mobilizing Force

Glide the proximal portion of the metacarpal volar ward. See also the stretching technique for cupping and flattening the arch of the hand described in Chapter 4.

### Carpometacarpal Joint of the Thumb

The CMC of the thumb is a saddle joint. The trapezium is concave, and the proximal metacarpal is convex for palmar abduction/adduction (metacarpal moving perpendicular away from and toward the palm of the hand). The trapezium is convex, and the proximal metacarpal is concave for radial abduction/adduction (metacarpal moving in the plane of the hand away and toward the radius; previously called flexion/extension).

**Resting position.** The resting position is midway between radial abduction/adduction and between palmar abduction/adduction.

**Stabilization.** Fixate the trapezium with the hand that is closer to the patient.

**Treatment plane.** The treatment plane is in the trapezium for abduction-adduction and in the proximal metacarpal for flexion-extension.

#### Carpometacarpal Distraction (Thumb)

##### Indications

Testing; initial treatment; pain control; general mobility.

**Patient Position**

The patient is positioned with forearm and hand resting on the treatment table.

**Hand Placement**

- Fixate the trapezium with the hand that is closer to the patient.
- Grasp the patient's metacarpal by wrapping your fingers around it (see Fig. 5.41 A).

**Mobilizing Force**

Apply long-axis traction to separate the joint surfaces.

**Carpometacarpal Glides (Thumb) (Fig. 5.41)****Indications**

- Ulnar glide to increase radial adduction.
- Radial glide to increase radial abduction.
- Dorsal glide to increase palmar abduction.
- Volar glide to increase palmar adduction.

**Patient Position and Hand Placement**

- Stabilize the trapezium by grasping it directly or by wrapping your fingers around the distal row of carpals.
- Place the thenar eminence of your other hand against the base of the patient's first metacarpal on the side opposite the desired glide. For example, as pictured in Figure 5.41 A,

the surface of the thenar eminence is on the radial side of the metacarpal to cause an ulnar glide.

**Mobilizing Force**

Apply the force with your thenar eminence against the base of the metacarpal. Adjust your body position to line up the force as illustrated in Figure 5.41 A through D.

**Metacarpophalangeal and Interphalangeal Joints of the Fingers**

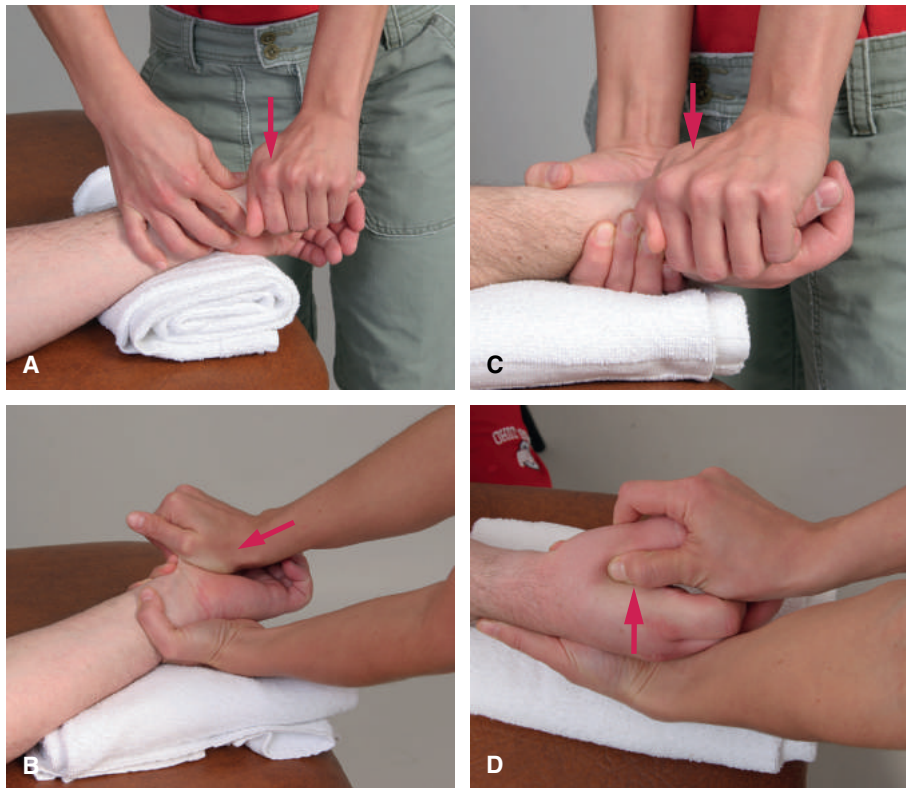

In all cases, the distal end of the proximal articulating surface is convex and the proximal end of the distal articulating surface is concave.

**NOTE:** Because all the articulating surfaces are the same for the digits, all techniques are applied in the same manner to each joint.

**Resting position.** The resting position is in light flexion for all joints.

**Treatment plane.** The treatment plane is in the distal articulating surface.

**Stabilization.** Rest the forearm and hand on the treatment table; fixate the proximal articulating surface with the fingers of one hand.

**FIGURE 5.41** Carpometacarpal joint of the thumb. (A) Ulnar glide to increase radial adduction; (B) Radial glide to increase radial abduction; (C) Dorsal glide to increase palmar abduction; (D) Volar glide to increase palmar adduction. Note that the thumb of the therapist is placed in the web space between the index and thumb of the patient's hand to apply a volar glide.

## Metacarpophalangeal and Interphalangeal Distraction (Fig. 5.42)

### Indications

Testing; initial treatment; pain control; general mobility.

**FIGURE 5.42** Metacarpophalangeal joint: distraction.

### Hand Placement

Use your proximal hand to stabilize the proximal bone; wrap the fingers and thumb of your other hand around the distal bone close to the joint.

### Mobilizing Force

Apply long-axis traction to separate the joint surface.

## Metacarpophalangeal and Interphalangeal Glides and Progression

### Indications

- Volar glide to increase flexion (Fig. 5.43).
- Dorsal glide to increase extension.
- Radial or ulnar glide (depending on finger) to increase abduction or adduction.

**FIGURE 5.43** Metacarpophalangeal joint: volar glide.

### Mobilizing Force

The glide force is applied by the thumb or thenar eminence against the proximal end of the bone to be moved. Progress by taking the joint to the end of its available range and applying slight distraction and the glide force. Rotation may be added prior to applying the gliding force.

## Hip Joint

The concave acetabulum receives the convex femoral head (Fig. 5.44). Biomechanics of the hip joint are reviewed in Chapter 20.

**FIGURE 5.44** Bones and joints of the pelvis and hip.

**Resting position.** The resting position is hip flexion 30°, abduction 30°, and slight external rotation.

**Stabilization.** Fixate the pelvis to the treatment table with belts.

**Treatment plane.** The treatment is in the acetabulum.

### Hip Distraction of the Weight-Bearing Surface, Caudal Glide (Fig. 5.45)

Because of the deep configuration of this joint, traction applied perpendicular to the treatment plane causes lateral glide of the superior, weight-bearing surface. To obtain separation of the weight-bearing surface, a caudal glide is used.

### Indications

Testing; initial treatment; pain control; general mobility.

### Patient Position

Supine, with the hip in resting position and the knee extended.

**PRECAUTION:** In the presence of knee dysfunction, this position should not be used; see alternate position following.

### Therapist Position and Hand Placement

Stand at the end of the treatment table; place a belt around your trunk and then cross the belt over the patient's foot and around the ankle. Place your hands proximal to the malleoli,

**FIGURE 5.45** Hip joint: distraction of the weight-bearing surface.

under the belt. The belt allows you to use your body weight to apply the mobilizing force.

#### Mobilizing Force

Apply a long-axis traction by pulling on the leg as you lean backward.

#### Alternate Position and Technique for Hip Caudal Glide

- Patient supine with hip and knee flexed and foot resting on table.
- Wrap your hands around the epicondyles of the femur and distal thigh. Do not compress the patella.
- The force comes from your hands and is applied in a caudal direction as you lean backward.

#### Hip Posterior Glide (Fig. 5.46) VIDEO 5.9 🌐

##### Indications

To increase flexion; to increase internal rotation.

##### Patient Position

- Supine, with hips at the end of the table.
- The patient helps stabilize the pelvis and lumbar spine by flexing the opposite hip and holding the thigh against the chest with the hands.
- Initially, the hip to be mobilized is in resting position; progress to the end of the range.

##### Therapist Position and Hand Placement

- Stand on the medial side of the patient's thigh.
- Place a belt around your shoulder and under the patient's thigh to help hold the weight of the lower extremity.
- Place your distal hand under the belt and distal thigh. Place your proximal hand on the anterior surface of the proximal thigh.

**FIGURE 5.46** Hip joint: posterior glide.

#### Mobilizing Force

Keep your elbows extended and flex your knees; apply the force through your proximal hand in a posterior direction.

#### Hip Anterior Glide (Fig. 5.47) VIDEO 5.10 🌐

##### Indications

To increase extension; to increase external rotation.

##### Patient Position

Prone, with the trunk resting on the table and hips over the edge. The opposite foot is on the floor.

**FIGURE 5.47** Hip joint: anterior glide. (A) Prone;

### Therapist Position and Hand Placement

- Stand on the medial side of the patient's thigh.
- Place a belt around your shoulder and the patient's thigh to help support the weight of the leg.
- With your distal hand, hold the patient's leg.
- Place your proximal hand posteriorly on the proximal thigh just below the buttock.

### Mobilizing Force

Keep your elbow extended and flex your knees; apply the force through your proximal hand in an anterior direction.

### Alternate Position

- Position the patient side-lying with the thigh comfortably flexed and supported by pillows.
- Stand posterior to the patient and stabilize the pelvis across the anterior superior iliac spine with your cranial hand.
- Push against the posterior aspect of the greater trochanter in an anterior direction with your caudal hand.

FIGURE 5.47—cont'd (B) Side-lying.

## Knee Joint Complex

The knee joint consists of two articulating surfaces between the femoral condyles and tibial plateaus with a fibrocartilaginous disc between each articulation, as well as the articulation of the patella with the femoral groove (Fig. 5.48). As the knee flexes, medial rotation of the tibia occurs, and as it extends, lateral rotation of the tibia occurs. In addition, the patella must glide caudally against the femur during flexion and glide cranially during extension for normal knee mobility. These mechanics are described in Chapter 21.

FIGURE 5.48 Bones and joints of the knee and leg.

### Tibiofemoral Articulations

The concave tibial plateaus articulate on the convex femoral condyles. Biomechanics of the knee joint are described in Chapter 21.

**Resting position.** The resting position is 25° flexion.

**Treatment plane.** The treatment plane is along the surface of the tibial plateaus; therefore, it moves with the tibia as the knee angle changes.

**Stabilization.** In most cases, the femur is stabilized with a belt or by the table.

### Tibiofemoral Distraction: Long-Axis Traction (Fig. 5.49)

#### Indications

Testing; initial treatment; pain control; general mobility.

#### Patient Position

- Sitting, supine, or prone, beginning with the knee in the resting position.
- Progress to positioning the knee at the limit of the range of flexion or extension.
- Rotation of the tibia may be added prior to applying the traction force. Use internal rotation at end-range flexion and external rotation at end-range extension.

#### Hand Placement

Grasp around the distal leg, proximal to the malleoli with both hands.

#### Mobilizing Force

Pull on the long axis of the tibia to separate the joint surfaces.

**FIGURE 5.49** Tibiofemoral joint: distraction. (A) Sitting; (B) Supine; (C) Prone.

### Tibiofemoral Posterior Glide (Fig. 5.50)

#### Indications

Testing; to increase flexion.

**FIGURE 5.50** Tibiofemoral joint: posterior glide (drawer).

#### Patient Position

Supine, with the foot resting on the table. The position for the drawer test can be used to mobilize the tibia either anteriorly or posteriorly, although no grade I distraction can be applied with the glides in this position.

#### Therapist Position and Hand Placement

Sit on the table with your thigh fixating the patient's foot. With both hands, grasp around the tibia, fingers pointing posteriorly and thumbs anteriorly.

#### Mobilizing Force

Extend your elbows and lean your body weight forward; push the tibia posteriorly with your thumbs.

### Tibiofemoral Posterior Glide: Alternate Positions and Progression (Fig. 5.51)

#### Patient Position

- Sitting, with the knee flexed over the edge of the treatment table, beginning in the resting position (Fig. 5.51). Progress to near 90° flexion with the tibia positioned in internal rotation.
- When the knee flexes past 90°, position the patient prone; place a small rolled towel proximal to the patella to minimize compression forces against the patella during the mobilization.

#### Therapist Position and Hand Placement

- When in the resting position, stand on the medial side of the patient's leg. Hold the distal leg with your distal hand and place the palm of your proximal hand along the anterior border of the tibial plateaus.

**FIGURE 5.51** Tibiofemoral joint: posterior glide, sitting.

- When near 90°, sit on a low stool; stabilize the leg between your knees and place one hand on the anterior border of the tibial plateaus.
- When prone, stabilize the femur with one hand and place the other hand along the border of the tibial plateaus.

#### Mobilizing Force

- Extend your elbow and lean your body weight onto the tibia, gliding it posteriorly.
- When progressing with medial rotation of the tibia at the end of the range of flexion, the force is applied in a posterior direction against the medial side of the tibia.

#### Tibiofemoral Anterior Glide (Fig. 5.52)

**VIDEO 5.11** 

#### Indication

To increase extension.

#### Patient Position

- Prone, beginning with the knee in resting position; progress to the end of the available range. Place a small pad under the distal femur to prevent patellar compression.
- The drawer test position can also be used. The mobilizing force comes from the fingers on the posterior tibia as you lean backward (see Fig. 5.50).

#### Hand Placement

Grasp the distal tibia with the hand that is closer to it and place the palm of the proximal hand on the posterior aspect of the proximal tibia.

**FIGURE 5.52** Tibiofemoral joint: anterior glide.

#### Mobilizing Force

Apply force with the hand on the proximal tibia in an anterior direction. The force may be directed to the lateral or medial tibial plateau to isolate one side of the joint.

#### Alternate Position and Technique

- If the patient cannot be positioned prone, position him or her supine with a fixation pad under the tibia.
- The mobilizing force is placed against the femur in a posterior direction.

### Patellofemoral Joint

The patella must have mobility to glide distally on the femur for normal knee flexion, and glide proximally for normal knee extension.

#### Patellofemoral Joint, Distal Glide (Fig. 5.53)

##### Patient Position

Supine, with knee extended; progress to positioning the knee at the end of the available range in flexion.

##### Hand Placement

Stand next to the patient's thigh, facing the patient's feet. Place the web space of the hand that is closer to the thigh around the superior border of the patella. Use the other hand for reinforcement.

##### Mobilizing Force

Glide the patella in a caudal direction, parallel to the femur.

**FIGURE 5.53** Patellofemoral joint: distal glide.

**PRECAUTION:** Do not compress the patella into the femoral condyles while performing this technique.

### Patellofemoral Medial or Lateral Glide (Fig. 5.54)

#### Indication

To increase patellar mobility.

#### Patient Position

Supine with the knee extended. Side-lying may be used to apply a medial glide (see Fig. 21.10).

**FIGURE 5.54** Patellofemoral joint: lateral glide.

#### Hand Placement

Place the heel of your hand along either the medial or lateral aspect of the patella. Stand on the opposite side of the table to position your hand along the medial border and on the same side of the table to position your hand along the lateral border. Place the other hand under the femur to stabilize it.

#### Mobilizing Force

Glide the patella in a medial or lateral direction, against the restriction.

## Leg and Ankle Joints

The joints of the leg consist of the proximal and distal tibiofibular joints; accessory motions at these joints occur during all ankle and subtalar joint motions (see Fig. 5.48 and Fig. 5.57 A). The complex mechanics of the leg, foot, and ankle in weight-bearing and nonweight-bearing conditions are described in Chapter 22.

### Tibiofibular Joints

#### Proximal Tibiofibular Articulation: Anterior (Ventral) Glide (Fig. 5.55)

#### Indications

To increase movement of the fibular head; to reposition a posteriorly subluxed head.

**FIGURE 5.55** Proximal tibiofibular joint: anterior glide.

### Patient Position

- Side-lying, with the trunk and hips rotated partially toward prone.
- The top leg is flexed forward so the knee and lower leg are resting on the table or supported on a pillow.

### Therapist Position and Hand Placement

- Stand behind the patient, placing one of your hands under the tibia to stabilize it.
- Place the base of your other hand posterior to the head of the fibula, wrapping your fingers anteriorly.

### Mobilizing Force

Apply the force through the heel of your hand against the posterior aspect of the fibular head, in an anterior-lateral direction.

### Distal Tibiofibular Articulation: Anterior (Ventral) or Posterior (Dorsal) Glide (Fig. 5.56)

#### Indication

To increase mobility of the mortise when it is restricting ankle dorsiflexion.

**FIGURE 5.56** Distal tibiofibular articulation: posterior glide.

### Patient Position

Supine or prone.

### Hand Placement

Working from the end of the table, place the fingers of the more medial hand under the tibia and the thumb over the tibia to stabilize it. Place the base of your other hand over the lateral malleolus, with the fingers underneath.

### Mobilizing Force

Press against the fibula in an anterior direction when prone and in a posterior direction when supine.

## Talocrural Joint (Upper Ankle Joint) (Fig. 5.57)

The convex talus articulates with the concave mortise made up of the tibia and fibula.

**FIGURE 5.57** (A) Anterior view of the bones and joints of the lower leg and ankle; (B) Medial view; (C) Lateral view of the bones and joint relationships of the ankle and foot.

**Resting position.** The resting position is 10° plantarflexion.

**Treatment plane.** The treatment plane is in the mortise, in an anterior-posterior direction with respect to the leg.

**Stabilization.** The tibia is strapped or held against the table.

### Talocrural Distraction (Fig. 5.58) VIDEO 5.12

#### Indications

Testing; initial treatment; pain control; general mobility.

#### Patient Position

Supine, with the lower extremity extended. Begin with the ankle in resting position. Progress to the end of the available range of dorsiflexion or plantarflexion.

#### Therapist Position and Hand Placement

- Stand at the end of the table; wrap the fingers of both hands over the dorsum of the patient's foot, just distal to the mortise.
- Place your thumbs on the plantar surface of the foot to hold it in resting position.

#### Mobilizing Force

Pull the foot along the long axis of the leg in a distal direction by leaning backward.

**FIGURE 5.58** Talocrural joint: distraction.

### Talocrural Dorsal (Posterior) Glide (Fig. 5.59)

#### Indication

To increase dorsiflexion.

**FIGURE 5.59** Talocrural joint: posterior glide.

#### Patient Position

Supine, with the leg supported on the table and the heel over the edge.

#### Therapist Position and Hand Placement

- Stand to the side of the patient.
- Stabilize the leg with your cranial hand or use a belt to secure the leg to the table.
- Place the palmar aspect of the web space of your other hand over the talus just distal to the mortise.
- Wrap your fingers and thumb around the foot to maintain the ankle in resting position. Grade I distraction force is applied in a caudal direction.

#### Mobilizing Force

Glide the talus posteriorly with respect to the tibia by pushing against the talus.

### Talocrural Ventral (Anterior) Glide (Fig. 5.60)

#### Indication

To increase plantarflexion.

#### Patient Position

Prone, with the foot over the edge of the table.

**FIGURE 5.60** Talocrural joint: anterior glide.

#### Therapist Position and Hand Placement

- Working from the end of the table, place your lateral hand across the dorsum of the foot to apply a grade I distraction.
- Place the web space of your other hand just distal to the mortise on the posterior aspect of the talus and calcaneus.

#### Mobilizing Force

Push against the calcaneus in an anterior direction (with respect to the tibia); this glides the talus anteriorly.

#### Alternate Position

- Patient is supine. Stabilize the distal leg anterior to the mortise with your proximal hand.
- The distal hand cups under the calcaneus.
- When you pull against the calcaneus in an anterior direction, the talus glides anteriorly.

### Subtalar Joint (Talocalcaneal), Posterior Compartment

The articulations between the calcaneus and talus are divided by the tarsal canal. The complex mechanics of these separate articulations are described in Chapter 22. Only mobilization of the posterior compartment is described here. The calcaneus is convex, articulating with a concave talus in the posterior compartment.

**Resting position.** The resting position is midway between inversion and eversion.

**Treatment plane.** The treatment plane is in the talus, parallel to the sole of the foot.

**Stabilization.** Dorsiflexion of the ankle stabilizes the talus. Alternatively, the talus is stabilized with one of your hands.

### Subtalar Distraction (Fig. 5.61) VIDEO 5.13

#### Indications

Testing; initial treatment; pain control; general mobility for inversion/eversion.

**FIGURE 5.61** Subtalar (talocalcaneal) joint: distraction.

#### Patient and Therapist Positions and Hand Placement

- Supine, with the leg supported on the table and heel over the edge.
- Externally rotate the patient's hip so the talocrural joint can be stabilized in dorsiflexion with pressure from your thigh against the plantar surface of the patient's forefoot.
- The distal hand grasps around the calcaneus from the posterior aspect of the foot. The other hand fixes the talus and malleoli against the table.

#### Mobilizing Force

Pull the calcaneus distally with respect to the long axis of the leg.

### Subtalar Medial Glide or Lateral Glide (Fig. 5.62)

#### Indications

Medial glide to increase eversion; lateral glide to increase inversion.

#### Patient Position

Side-lying or prone, with the leg supported on the table.

#### Therapist Position and Hand Placement

- Align your shoulder and arm parallel to the bottom of the foot.
- Stabilize the talus with your proximal hand.
- Place the base of the distal hand on the side of the calcaneus medially to cause a lateral glide and laterally to cause a medial glide.
- Wrap the fingers around the plantar surface.

#### Mobilizing Force

Apply a grade I distraction force in a caudal direction and then push with the base of your hand against the side of the calcaneus parallel to the plantar surface of the heel.

#### Alternate Position

Same as the position for distraction, moving the calcaneus in the medial or a lateral direction with the base of the hand.

### Intertarsal and Tarsometatarsal Joints

When moving in a dorsal-plantar direction with respect to the foot, all of the articulating surfaces are concave and convex in the same direction. For example, the proximal articulating surface is convex, and the distal articulating surface is concave.

**FIGURE 5.62** Subtalar joint: lateral glide. (A) Prone; (B) Side-lying.

The technique for mobilizing each joint is the same. The hand placement is adjusted to stabilize the proximal bone partner so the distal bone partner can be moved.

### Intertarsal and Tarsometatarsal Plantar Glide (Fig. 5.63)

#### Indication

To increase plantarflexion accessory motions (necessary for supination).

**FIGURE 5.63** Plantar glide of a distal tarsal bone on a stabilized proximal bone. Shown is stabilization of the navicular with the therapist's index finger and plantar glide of the cuneiform to increase the arch of the foot: **(A)** Drawing of the medial side of the foot, with the "X" depicting placement of the stabilizing index finger and the arrow depicting the downward force from the thenar eminence of the therapist's hand; **(B)** Illustrates application of the technique.

#### Patient Position

Supine, with hip and knee flexed, or sitting, with knee flexed over the edge of the table and heel resting on your lap.

#### Stabilization and Hand Placement

- Fixate the more proximal bone with your index finger on the plantar surface of the bone.

- To mobilize the tarsal joints along the medial aspect of the foot, position yourself on the lateral side of the foot. Place the proximal hand on the dorsum of the foot with the fingers pointing medially, so the index finger can be wrapped around and placed under the bone to be stabilized.
- Place your thenar eminence of the distal hand over the dorsal surface of the bone to be moved and wrap the fingers around the plantar surface.
- To mobilize the lateral tarsal joints, position yourself on the medial side of the foot, point your fingers laterally, and position your hands around the bones as just described.

#### Mobilizing Force

Push the distal bone in a plantar direction from the dorsum of the foot.

### Intertarsal and Tarsometatarsal Dorsal Glide (Fig. 5.64)

#### Indication

To increase the dorsal gliding accessory motion (necessary for pronation).

#### Patient Position

Prone, with knee flexed.

#### Stabilization and Hand Placement

- Fixate the more proximal bone.
- To mobilize the lateral tarsal joints (e.g., cuboid on calcaneus), position yourself on the medial side of the patient's leg and wrap your fingers around the lateral side of the foot (as in Fig. 5.64).
- To mobilize the medial bones (e.g., navicular on talus), position yourself on the lateral side of the patient's leg and wrap your fingers around the medial aspect of the foot.

**FIGURE 5.64** Dorsal gliding of a distal tarsal on a proximal tarsal. Shown is stabilization of the calcaneus with compression through the talus, and dorsal glide of the cuboid: **(A)** Drawing of the lateral side of the foot, with "X" depicting the stabilization and the arrow depicting the downward (dorsal) force from the base of the therapist's hand;

**FIGURE 5.64—cont'd (B)** Illustrates application of the technique.

- Place your second metacarpophalangeal joint against the bone to be moved.

#### Mobilizing Force

Push from the plantar surface in a dorsal direction.

#### Alternate Technique

Same position and hand placements as for plantar glides, except the distal bone is stabilized and the proximal bone is forced in a plantar direction. This is a relative motion of the distal bone moving in a dorsal direction.

### Intermetatarsal, Metatarsophalangeal, and Interphalangeal Joints

The intermetatarsal, metatarsophalangeal, and interphalangeal joints of the toes are stabilized and mobilized in the same manner as the fingers. In each case, the articulating surface of the proximal bone is convex, and the articulating surface of the distal bone is concave. It is easiest to stabilize the proximal bone and glide the surface of the distal bone either plantarward for flexion, dorsalward for extension, and medially or laterally for adduction and abduction.

## Independent Learning Activities

### Critical Thinking and Discussion

1. An individual is immobilized in a cast for 4 to 6 weeks following a fracture. In general, what structures lose their elasticity, and what restrictions do you feel when testing range of motion, joint play, and flexibility?
2. Describe the normal arthrokinematic relationships for the extremity joints and define the location of the treatment plane for each joint.
3. Using the information from Activity 1, define a specific fracture, such as a Colle's fracture of the distal forearm. Identify what techniques are necessary to gain joint mobility and ROM in the related joints such as the wrist, forearm, and elbow joints, connective tissues, and muscles. Practice using each of the techniques.
4. Explain the rationale for using passive joint techniques to treat patients with limitations because of pain and muscle guarding or to treat patients with restricted capsular or ligamentous tissue. What is the difference in the way the techniques are applied in each case?
5. Describe how joint mobilization techniques fit into the total plan of therapeutic intervention for patients with impaired joint mobility.
6. Explain the difference between passive joint mobilization techniques and MWM techniques.

### Laboratory Practice

With a partner, practice mobilizing each joint in the upper and lower extremities.

**PRECAUTION:** Do not practice on an individual with a hypermobile or unstable joint.

1. Begin with the joint in its resting position and apply distraction techniques at each intensity (sustained grades I, II, and III) to develop a feel for “very gentle,” “taking up the slack,” and “stretch.” Do not apply a vigorous stretch to someone with a normal joint. Be sure to use appropriate stabilization.
2. With the joint in its resting position, practice all appropriate glides for that joint. Be sure to use a grade I distraction with each gliding technique. Vary the techniques between sustained and oscillation.
3. Practice progressing each technique by taking the joint to a point that you determine to be the “end of the range” and:
  - Apply a distraction technique with the extremity in that position.
  - Apply the appropriate glide at that range (be sure to apply a grade I distraction with each glide).
  - Add rotation (e.g., external rotation for shoulder abduction) and then apply the appropriate glide.

- Isokinetic Testing and Training Equipment 238

## Independent Learning Activities 239

**M**uscle performance is the capacity of a muscle to do work (force  $\times$  distance).<sup>9</sup> Despite the simplicity of the definition, muscle performance is a complex component of functional movement and is influenced by all of the body systems. Factors that affect muscle performance include the morphological qualities of muscle; neurological, biochemical, and biomechanical influences; and metabolic, cardiovascular, respiratory, cognitive, and emotional function. A healthy and fully functioning muscular system is critical for not only meeting the physical demands imposed on the body, but for allowing individuals to be mobile, recreate, work, and pursue meaningful experiences.

The key elements of muscle performance are *strength*, *power*, and *endurance*.<sup>9</sup> If any one or more of these elements is impaired, activity limitations and participation restriction or increased risk of dysfunction may ensue. Factors such as injury, disease, immobilization, disuse, and inactivity may impair muscle performance, leading to weakness and muscle atrophy. When deficits in muscle performance are present, resistance exercises are an appropriate therapeutic intervention to select.

*Resistance exercise* is an activity in which dynamic or static muscle contraction is resisted by an outside force applied manually or mechanically.<sup>95,236</sup> Resistance exercise, also referred to as *resistance training*,<sup>6,7,161</sup> is an essential element of rehabilitation programs for persons with impaired function. In addition, resistance exercise is an integral component of conditioning programs for those who wish to promote or maintain health and physical well-being, enhance performance of motor skills, and reduce the risk of injury and disease.<sup>6,7,231</sup>

A comprehensive examination and evaluation of the patient or client are the foundations on which a therapist determines whether a program of resistance exercise is warranted and likely to be effective. Many factors will influence this determination and decisions about how the exercises are designed, implemented, and progressed. Factors such as the underlying pathology; the extent and severity of muscle performance impairments; the presence of other deficits; the stage of tissue healing after injury or surgery; and the patient's or client's age, overall level of fitness, and ability to cooperate and learn must all be considered. Once a resistance exercise program is developed and prescribed, the therapist should initially implement the program directly or teach and supervise the exercises to ensure a smooth transition to an independent, home-based program.

This chapter provides a foundation of information on resistance exercise, identifies the determinants of resistance training programs, summarizes the principles and guidelines for application of manual and mechanical resistance exercise, and explores a variety of regimens for resistance training. It also addresses the available scientific evidence on the relationship between improvements in muscle performance and enhanced functional abilities. The specific techniques described and illustrated in this chapter focus on manual resistance exercise for the extremities, primarily

used during the early phase of rehabilitation. Additional exercises performed independently by the patient or client using resistance equipment are described and illustrated in Chapters 16 through 23.

## Muscle Performance and Resistance Exercise: Definitions and Guiding Principles

The three elements of muscle performance<sup>9</sup>—strength, power, and endurance—can all be enhanced by resistance exercise. To what extent each of these elements is altered by exercise depends on how the principles of resistance training are applied and how factors such as the intensity, frequency, and duration of exercise are manipulated. Because the physical demands of work, recreation, and everyday living usually involve all three aspects of muscle performance, most resistance training programs should address the optimum proportion of strength, power, and muscular endurance that will meet an individual's needs and goals. In addition to positively impacting muscle performance, resistance training can produce many other benefits.<sup>6,7,8</sup> These potential benefits are listed in Box 6.1. After a brief description of the three elements of muscle performance, the guiding principles of exercise prescription and training are discussed in this section.

### Strength, Power, and Endurance

#### Strength

*Muscle strength* is a broad term that refers to the extent that the contractile elements of muscle produce force. Implicit in this definition is the idea that with adequate strength, the contractile tissue generates enough force to meet the physical and functional demands placed on the system.<sup>175,184,202</sup> In practice, muscle strength is the greatest measurable force that is exerted by a muscle or muscle group to overcome resistance during a *single* maximum effort.<sup>9</sup> *Functional strength* relates to the ability of the neuromuscular system to produce the appropriate amount of force, during functional activities in a smooth and coordinated manner.<sup>41,211</sup> Insufficient muscular strength can contribute to major functional losses of even the most basic activities of daily living.

**Strength training.** The development of muscle strength is an integral component of most rehabilitation or conditioning programs for individuals of all ages and abilities.<sup>6,8,83,162,213</sup> *Strength training (strengthening exercise)* is the systematic practice of using muscle force to raise, lower, or control heavy external loads for a relatively low number of repetitions or over a short period of time.<sup>7,32,95</sup> The most common adaptation to strength training is an increase in the maximum force-producing capacity of muscle, primarily the result of neural adaptations and increased muscle fiber size.<sup>7,8,184</sup>

### BOX 6.1 Benefits of Resistance Exercise

- Enhanced muscle performance through restoration, improvement or maintenance of muscle strength, power, and endurance
- Increased strength of connective tissues: tendons, ligaments, and intramuscular connective tissue
- Increased bone mineral density and/or less bone demineralization
- Decreased joint stress during physical activity
- Reduced risk of soft tissue injury during physical activity
- Improved capacity for repair and healing of damaged soft tissues and for tissue remodeling
- Improved balance
- Enhanced physical performance during daily living, occupational, and recreational activities
- Positive changes in body composition: ↑ lean muscle mass or ↓ body fat
- Enhanced feeling of physical well-being
- Positive perception of disability and quality of life

### Power

*Muscle power* is related to the strength and speed of movement and is defined as the work (force × distance) produced by a muscle per unit of time (force × distance/time).<sup>175,184,202</sup> In other words, power is the *rate* of performing work. The rate at which a muscle produces a force and the relationship between force and velocity are key factors that affect muscle power.<sup>32,202</sup> Because work can be produced over a very brief or a very long period of time, power can represent a single burst of high-intensity activity (such as lifting a heavy piece of luggage onto an overhead rack or performing a high jump) or repeated bursts of less intense activity (such as climbing a flight of stairs). The terms *anaerobic power* and *aerobic power*, respectively, are sometimes used to differentiate these two aspects of power.<sup>184</sup>

**Power training.** Many motor tasks are somewhat ballistic movements that involve both strength and speed. Therefore, re-establishing muscle power may be an important priority in a rehabilitation program. Muscle strength is a necessary foundation for developing muscle power. Power can be gained by either increasing the work a muscle must perform during a specified period of time or reducing the amount of time required to produce the work. The greater the intensity (force and/or distance) of the exercise and the shorter the time period taken to generate force, the greater is the muscle power. For power training regimens, such as *plyometric training* or *stretch-shortening drills*, the time of movement is the variable that is most often manipulated<sup>277</sup> (see Chapter 23).

### Endurance

*Endurance* is a broad term that refers to the ability to perform repetitive or sustained activities over a prolonged period of time. *Cardiopulmonary endurance (total body endurance)* is associated with repetitive, dynamic motor activities, such as

walking, cycling, swimming, or upper extremity ergometry, which involve use of the large muscles of the body.<sup>6,7</sup> This aspect of endurance is explored in Chapter 7.

*Muscle endurance* (sometimes referred to as *local endurance*) is the ability of a muscle to contract repeatedly against an external load, generate and sustain tension, and resist fatigue over an extended period of time.<sup>6,7,224</sup> The term *aerobic power* sometimes is used interchangeably with muscle endurance. Maintenance of balance and proper alignment of the body segments requires endurance of the postural muscles. In fact, almost all daily living tasks require some degree of both muscle and cardiopulmonary endurance.

Although muscle strength and endurance are associated, they do not always correlate well with each other. Just because a muscle group is strong, it is still possible for muscular endurance to be impaired. For example, a worker may have the strength to lift a 10-lb object several times, but they may not have sufficient endurance of the upper extremity or trunk muscles to lift 10-lb objects several hundred times during the course of a day's work without excessive fatigue or potential injury.

**Endurance training.** *Endurance training (endurance exercise)* is the systematic practice of using muscle force to raise, lower, or control a light external load for many repetitions over an extended period of time.<sup>7,8,184,202,248</sup> The key parameters of endurance training are low-intensity muscle contractions, a high number of repetitions, and a prolonged time period. Unlike strength training, muscles adapt to endurance training by increases in their oxidative and metabolic capacities, which allows better delivery and use of oxygen. For many patients with impaired muscle performance, endurance training has a more positive impact on improving function than strength training. In addition, using lower levels of resistance in an exercise program minimizes potentially harmful joint reaction forces, produces less irritation to soft tissues, and is more comfortable for the patient than heavy resistance exercise.

## Overload Principle

### Description

The overload principle is a foundational element that guides the use of resistance exercise in improving muscle performance. The overload principle states that if muscle performance is to improve, a resistance load that exceeds the metabolic capacity of the muscle must be applied—that is, the muscle must be challenged to perform at a level greater than that to which it is accustomed.<sup>7,8,123,162,184,198</sup> If the external demands remain constant after the muscle has adapted to exercise, the level of muscle performance can be maintained but not increased.

### Application of the Overload Principle

The overload principle focuses on progressively loading muscle by manipulating factors such as the intensity or volume of exercise. The *intensity* of resistance exercise refers to how much external resistance is imposed on the muscle, whereas

the *volume* of exercise includes variables such as repetitions, sets, or frequency, any combination of which can be adjusted to progressively increase the demands on the muscle.

- In a strength training program, the amount of external resistance applied to the muscle is incrementally and progressively increased.
- For endurance training, emphasis is placed on increasing the *time* a muscle contraction is sustained or the *number of repetitions* performed rather than the amount of external resistance.

**PRECAUTION:** To ensure safety, the application of the overload principle must always be done in the context of the underlying pathology, age of the patient, stage of tissue healing, the patient response, and the overall abilities and goals of the patient. The muscle and related body systems must be given time to *adapt* to the demands of increased intensity or volume before subsequent increases.

## Specific Adaptation to Imposed Demands (SAID) Principle

The SAID principle<sup>7,184</sup> is another foundational element applied to a muscle performance program. This principle refers to the concept that to improve a specific muscle performance element, the resistance program should be matched to that element's constructs. For example, to increase muscle power the exercise program should consist of interventions that increase work demands while decreasing the time that work is accomplished. This principle applies to all body systems and is an extension of Wolff's law (i.e., body systems adapt over time to the stresses placed on them). The SAID principle guides therapists to determine the exercise parameters that will create specific training effects to best meet the patient's functional needs and goals.

### Specificity of Training

Specificity of training, also referred to as specificity of exercise, is a widely accepted concept suggesting that the adaptive effects of training, such as improvement of strength, power, and endurance, are highly specific to the training method employed.<sup>7,176</sup> Whenever possible, exercises incorporated in a program should mimic the anticipated function. For example, if the desired functional activity requires greater muscular endurance than strength, lower intensity exercises performed over a longer time should be emphasized.

Specificity of training must also incorporate the optimal mode (type) and velocity of exercise,<sup>24,74,197,217</sup> the patient or joint position,<sup>155,156,270</sup> and the movement patterns used during exercise. For example, if the desired functional outcome is the ability to ascend and descend stairs, exercise should be performed eccentrically and concentrically in a weight-bearing pattern and progressed to the desired speed. Regardless of the simplicity or complexity of the motor task performed, task-specific practice always must be emphasized. It has been suggested that the basis of specificity of

training is related to morphological and metabolic changes in muscle as well as neural adaptations to the training stimulus associated with motor learning.<sup>210</sup>

### Transfer of Training

In contrast to the SAID principle, carryover of training effects from one variation of exercise or task to another also has been reported. This phenomenon is called transfer of training, overflow, or a cross-training effect. Transfer of training has been reported to occur on a very limited basis with respect to the velocity of training<sup>137,260</sup> and the type or mode of exercise.<sup>74</sup> Furthermore, it has been suggested that a cross-training effect can occur from an exercised limb to a nonexercised, contralateral limb in a resistance training program.<sup>268,269</sup>

A muscle strengthening program has been shown to have a transfer effect by moderately improving muscular endurance.<sup>17</sup> In contrast, endurance training has little to no cross-training effect on muscle strength.<sup>7,16,95</sup> In fact, when endurance training and strength training are combined, there appears to be a detrimental effect on the ability to improve strength.<sup>102,146</sup> Strength training at one speed of exercise has been shown to provide some improvement in strength at higher or lower speeds of exercise.<sup>137,260</sup> However, the overflow effects are substantially less than the effects that result from using specificity of training principles.

Despite the evidence that a small degree of transfer of training occurs from a resistance exercise program, most studies support the importance of designing an exercise program that most closely replicates the desired functional activities.

### Reversibility Principle

Adaptive changes in the body's systems in response to a resistance exercise program are transient unless training-induced improvements are regularly used for functional activities or unless an individual participates in a maintenance program of resistance exercises.<sup>6,7,45,82,184</sup>

*Detraining*, reflected by reductions in muscle performance, begins a week or two after the cessation of resistance exercises and continues until training effects are lost.<sup>7,82,161,199</sup> For this reason, it is imperative that gains in strength and endurance are incorporated into daily activities as early as possible in a rehabilitation program. It is also advisable for patients to participate in a maintenance program of resistance exercises as an integral component of a lifelong fitness program.

## Skeletal Muscle Function and Adaptation to Resistance Exercise

Knowing the factors that influence the force-producing capacity of normal muscle during an active contraction is fundamental to understanding how the neuromuscular system

adapts to resistance training. This knowledge, in turn, provides a basis on which a therapist is able to make sound clinical decisions when designing resistance exercise programs for patients with weakness and functional limitations or to reduce injury risk in healthy individuals.

## Factors That Influence Tension Generation in Normal Skeletal Muscle

**NOTE:** For a brief review of the structure of skeletal muscle, refer to Chapter 4 of this textbook. For in-depth information on muscle structure and function, numerous resources are available.<sup>175,176,184,202</sup>

Morphological, biomechanical, neurological, metabolic, and biochemical factors all affect the tension-generating capacity of *normal* skeletal muscle. Each of these factors contributes to the *magnitude*, *duration*, and *speed* of force production and the muscles' susceptibility to fatigue. Properties of muscle and key neural factors and their impact on tension generation during an active muscle contraction are summarized in Table 6.1.<sup>7,175,176,184,202</sup>

Additional factors—such as the energy stores available to muscle; the influence of fatigue and recovery from exercise; and a person's age, gender, and psychological/cognitive status—affect a muscle's ability to develop and sustain tension. A therapist must recognize that these factors affect both a patient's performance during exercise and the potential outcomes of the exercise program.

### Energy Stores and Blood Supply

Muscle needs adequate sources of energy to contract, generate tension, and resist fatigue. Muscle also requires an adequate blood supply to provide the tissue with oxygen and nutrients and to transport waste products from muscle to other organs. The degree of vascularization is related to the predominant fiber type that constitutes the tissue, which directly affects the fatigue profile of the muscle. The three main energy systems (the ATP-PC system, the anaerobic/glycolytic/lactic acid system, and the aerobic system) are reviewed in Chapter 7.

### Fatigue

Fatigue is a complex phenomenon that affects muscle performance and must be considered in a resistance exercise

**TABLE 6.1** Determinants and Correlates That Affect Tension Generation of Skeletal Muscle

Factor	Influence
Cross-section and size of the muscle (includes muscle fiber number and size)	The larger the muscle diameter, the greater its tension-producing capacity
Muscle architecture—fiber arrangement and fiber length (also relates to cross-sectional diameter of the muscle)	Short fibers with pennate and multipennate design are typical in high force-producing muscles (ex. quadriceps, gastrocnemius, deltoid, biceps brachii)
	Long fibers with parallel design are typical in muscles with fast shortening rates but lower force production (ex. sartorius, lumbricals)
Fiber-type distribution of muscle—type I (tonic, slow-twitch) and type IIA & IIB (phasic, fast-twitch)	High percentage of type I fibers favors low force production, slow rate of maximum force development, resistance to fatigue
	High percentage of type IIA and IIB fibers favors rapid high force production and rapid fatigue
Length-tension relationship of muscle at time of contraction	Muscle produces greatest tension when it is near or at the physiological resting length at the time of contraction
Moment arm between muscle force vector and axis of joint rotation	Greater tension is produced with longer moment arm
Recruitment of motor units	The greater the number and synchronization of motor units firing, the greater the force production
Rate of motor unit firing	The higher the firing frequency, the greater the tension
Type of muscle contraction	Force output from greatest to least—eccentric, isometric, concentric muscle contraction
Speed of muscle contraction (force-velocity relationship)	Concentric contraction: ↑ speed → ↓ tension. Eccentric contraction: ↑ speed → ↑ tension

program. There are several types of fatigue, each with its own definition.

**Muscle (local) fatigue.** Most relevant to resistance exercise is the phenomenon of skeletal muscle fatigue. Muscle fatigue—the diminished response of muscle to a repeated stimulus—is reflected in a progressive decrement in the amplitude of motor unit potentials.<sup>176,184</sup> This occurs during exercise when a muscle repeatedly contracts statically or dynamically against an imposed load.

Muscle fatigue is an acute physiological response to exercise that is normal and reversible. It is characterized by a gradual decline in the force-producing capacity of the neuromuscular system. This is a temporary decline that leads to a decrease in muscle strength.<sup>23,52,176,241</sup>

The diminished contractile response of the muscle is caused by a complex combination of factors, which include disturbances in the contractile mechanism of the muscle itself (associated with a decrease in energy stores, insufficient oxygen, reduced sensitivity and availability of intracellular calcium, and a build-up of H<sup>+</sup>) and perhaps reduced excitability at the neuromuscular junction or inhibitory (protective) influences from the central nervous system (CNS).<sup>176,184,202</sup>

The fiber-type distribution of a muscle, which can be divided into two broad categories (type I and type II), affects its resistance to fatigue.<sup>176,184,202</sup> Type II (phasic, fast-twitch) muscle fibers are further divided into two additional classifications (types IIA and IIB) based on contractile and fatigue characteristics. In general, type II fibers generate a great amount of tension within a short period of time, with type IIB being geared toward anaerobic metabolic activity and having a tendency to fatigue more quickly than type IIA fibers. Type I (tonic, slow-twitch) muscle fibers generate a low level of muscle tension but can sustain the contraction for a long time. These fibers are geared toward aerobic metabolism, as are type IIA fibers. However, type I fibers are more resistant to fatigue than type IIA. Table 6.2 compares the characteristics of muscle fiber types.<sup>7,175,176,202</sup>

**TABLE 6.2** Muscle Fiber Types and Resistance to Fatigue

Characteristics	Type I	Type IIA	Type IIB
Resistance to fatigue	High	Intermediate	Low
Capillary density	High	High	Low
Energy system	Aerobic	Aerobic	Anaerobic
Diameter	Small	Intermediate	Large
Twitch rate	Slow	Fast	Fast
Maximum muscle-shortening velocity	Slow	Fast	Fast

Because muscles are composed of varying proportions of tonic and phasic fibers, their function becomes specialized. For example, a heavy distribution of type I (slow twitch, tonic) fibers is found in postural muscles, allowing them to sustain a low level of tension for extended periods of time. Functionally, postural muscles are suited to hold the body erect against gravity or stabilize against repetitive loads. On the other end of the fatigue spectrum, muscles with a large distribution of type IIB (fast twitch, phasic) fibers can produce high increases of tension over a relatively short time. These muscles function to move heavy loads but are susceptible to fatigue.

Clinical signs of muscular fatigue during exercise are summarized in Box 6.2.<sup>184,202</sup> When these signs and symptoms develop during resistance exercise, the therapist should decrease the load on the exercising muscle or stop the exercise and shift to another muscle group to allow time for the fatigued muscle to rest and recover. When resistance exercises are part of a home program, the therapist should teach the patient to recognize signs of fatigue and the strategies to minimize its effects.

**Cardiopulmonary (general) fatigue.** This type of fatigue is the systemic diminished response of an individual to a stimulus as the result of prolonged physical activity such as walking, jogging, cycling, or repetitive work. Cardiopulmonary fatigue is related to the body's ability to use oxygen efficiently. Cardiopulmonary fatigue associated with endurance training is probably caused by a combination of the following factors:<sup>23,108</sup>

- Decreased blood sugar (glucose) levels
- Decreased glycogen stores in muscle and liver
- Depletion of potassium, especially in the elderly patient

**Threshold for fatigue.** The threshold for fatigue is the level of exercise that cannot be sustained indefinitely.<sup>23</sup> A patient's threshold for fatigue could be noted as the length of time a contraction is maintained or the number of repetitions of an exercise that initially can be performed. This sets a baseline

### BOX 6.2 Signs and Symptoms of Muscle Fatigue

- An uncomfortable sensation in the muscle, with pain and cramping possible
- Shaking or trembling of the contracting muscle
- An unintentional slowing of contraction velocity with successive repetitions of an exercise
- Active movements are jerky or inconsistent
- Inability to complete the movement pattern through the full range of available motion during dynamic exercise against the same level of resistance
- Use of substitute motions—that is, incorrect movement patterns—to complete the activity
- Inability to continue low-intensity physical activity
- Decline in peak torque during isokinetic testing

from which adaptive changes in physical performance can be measured.

**Factors that influence fatigue.** A patient's health status, diet, or lifestyle (sedentary or active) all influence fatigue thresholds. In patients with neuromuscular, cardiopulmonary, inflammatory, cancer-related, or psychological disorders, the onset of fatigue is often irregular.<sup>3,52,90</sup> For instance, it may occur abruptly, more rapidly, or at predictable intervals.

It is advisable for a therapist to become familiar with the patterns of fatigue associated with different diseases and medications. In multiple sclerosis, for example, the patient usually awakens rested and functions well during the early morning. By mid-afternoon, however, the patient reaches a fatigue threshold and becomes notably weak. By early evening, fatigue often diminishes and strength returns. Patients with cardiac, peripheral vascular, and pulmonary diseases, as well as patients with cancer undergoing chemotherapy or radiation therapy, all have deficits that compromise the oxygen transport system. Therefore, these patients fatigue more readily and require a longer recovery period from exercise.<sup>3,90</sup>

Environmental factors, such as outside or room temperature, air quality, and altitude, also influence how quickly the onset of fatigue occurs and how much time is required for recovery from exercise.<sup>163,184</sup>

### Recovery From Exercise

Adequate time for recovery from fatiguing exercise must be built into every resistance exercise program. This applies to both intrasession and intersession recovery. After vigorous exercise, the body must be given time to restore itself to a state that existed prior to the exercise. Recovery from acute exercise, in which the force-producing capacity of muscle returns to 90% to 95% of the pre-exercise capacity, usually takes 3 to 4 minutes, with the greatest proportion of recovery occurring in the first minute.<sup>49,233</sup>

Oxygen and energy stores replenish quickly in muscle recovery. Lactic acid is removed from skeletal muscle and blood within approximately 1 hour after exercise, and glycogen stores are replaced over several days.

### FOCUS ON EVIDENCE

Studies over several decades have demonstrated that if light exercise is performed during the recovery period (*active recovery*), recovery from exercise occurs more rapidly than with total rest (*passive recovery*).<sup>28,49,107,233</sup> Faster recovery with light exercise is probably the result of neural as well as circulatory influences.<sup>49,233</sup>

### CLINICAL TIP

Muscle performance (strength, power, or endurance) only improves over time if a patient is allowed adequate time to recover from fatigue after each exercise session.<sup>28,107</sup> With insufficient

rest intervals during a resistance exercise program, a patient's performance plateaus or deteriorates. Evidence of overtraining or overwork weakness may become apparent (see additional discussion in the Overtraining and Overwork section of this chapter). It has also been shown that fatigued muscles are more susceptible to acute strains.<sup>182</sup>

### Age

Muscle performance capability will change across the life span. Whether the goal of a resistance training program is to remediate impairments and activity limitations or enhance fitness and performance, an understanding of "typical" changes in muscle performance and response to exercise during each phase of life is necessary to prescribe effective, safe resistance exercises for individuals of all ages. Key aspects of how muscle performance changes throughout life are discussed in this section and summarized in Box 6.3.

### Early Childhood and Preadolescence

In absolute terms, muscle strength increases *linearly* with chronological age in both boys and girls from birth through puberty.<sup>183,249,274</sup> Muscle endurance also increases linearly during the childhood years.<sup>274</sup> Much of these linear increases are attributed to the development of muscle mass. Muscle fiber number is essentially determined prior to or shortly after birth,<sup>231</sup> although there is speculation that fiber number may continue to increase into early childhood.<sup>274</sup> The rate of fiber growth (increase in cross-sectional area) is relatively consistent from birth to puberty. Change in fiber type distribution is relatively complete by the age of 1, shifting from a predominance of type II fibers to a more balanced distribution of type I and type II fibers.<sup>274</sup>

Throughout childhood, boys have slightly greater absolute and relative muscle mass (kilograms of muscle per kilogram of body weight) than girls, with boys approximately 10% stronger than girls from early childhood to puberty.<sup>183</sup> This difference may be associated with differences in relative muscle mass, although social expectations may also contribute to the observed difference in muscle strength.

It is well established that an appropriately designed resistance exercise program can improve muscle strength in children above and beyond gains attributable to typical growth and development. These training-induced strength gains in prepubescent children occur primarily as the result of neuromuscular adaptation—that is, without a significant increase in muscle mass.<sup>22,84</sup> Reviews of the literature<sup>83,85</sup> have cited many studies that support these findings. However, there is concern that children who participate in resistance training may be at risk for injuries, such as an epiphyseal or avulsion fractures, because the musculoskeletal system is immature.<sup>22,27,95,253</sup>

The American Academy of Pediatrics,<sup>5</sup> the American College of Sports Medicine (ACSM),<sup>6</sup> and the Centers for Disease Control and Prevention (CDC)<sup>36</sup> support youth participation in resistance training programs if they are designed appropriately, initiated at a reasonable age, and carefully supervised (Fig. 6.1). With this in mind, two important questions need

**BOX 6.3 Summary of Age-Related Changes in Muscle and Muscle Performance Through the Life Span****Infancy, Early Childhood, and Preadolescence**

- At birth, muscle accounts for about 25% of body weight.
- Total number of muscle fibers is established prior to birth or early in infancy.
- Postnatal changes in distribution of type I and type II fibers in muscle are relatively complete by the end of the first year of life.
- Muscle fiber size and muscle mass increase linearly from infancy to puberty.
- Muscle strength and muscle endurance increase linearly with chronological age in boys and girls throughout childhood until puberty.
- Muscle mass (absolute and relative) and muscle strength is approximately 10% greater in boys than girls from early childhood to puberty.
- Training-induced strength gains occur equally in both sexes during childhood *without* evidence of hypertrophy until puberty.

**Adolescence**

- Rapid acceleration in muscle fiber size and muscle mass, especially in boys. During puberty, muscle mass increases more than 30% per year.
- Rapid increase in muscle strength in both sexes.
- Marked difference in strength levels develops between boys and girls.
- In boys, muscle mass and body height and weight peak before muscle strength peaks; in girls, strength peaks before body weight peaks.
- Relative strength gains through resistance training are comparable between the sexes, with significantly greater muscle hypertrophy in boys.

**Young and Middle Adulthood**

- Muscle mass peaks in women between 16 and 20 years of age; muscle mass in men peaks between 18 and 25 years of age.

- Muscle mass constitutes approximately 40% of total body weight during early adulthood, with men having slightly more muscle mass than women.
- Muscle continues to develop into the second decade, especially in men.
- Muscle strength and endurance reach a peak during the second decade, earlier for women than men.
- Decreases in muscle mass begin to occur as early as 25 years of age.
- Starting in the third decade, strength declines between 8% and 10% per decade through the fifth or sixth decade.
- Strength and muscle endurance decline less rapidly in physically active adults.
- Improvements in strength and endurance are possible with only modest increases in physical activity.

**Late Adulthood**

- Muscle strength declines at a rate of 15% to 20% per decade during the sixth and seventh decades and declines at a rate of 30% per decade thereafter.
- By the eighth decade, skeletal muscle mass will have decreased by 50% compared to peak muscle mass.
- Muscle fiber size (cross-sectional area), type I and type II fiber quantity, and the number of alpha motoneurons all decrease.
- Preferential atrophy of type II muscle fibers occurs.
- Muscle contraction speed and peak power production both decrease.
- Endurance and maximum oxygen uptake gradually but progressively decrease.
- The force-producing capacity of muscle is reduced.
- Performance of functional skills begins to decline during the sixth decade.
- Significant deterioration in functional abilities by the eighth decade is associated with a decline in muscular endurance.
- With a resistance training program, significant improvements in muscle strength, power, and endurance is possible during late adulthood.

to be addressed: At what point during childhood is a resistance training program appropriate? And, what constitutes a safe training program?

There is general consensus that during the toddler, pre-school, and even the early elementary school years, free play and organized but age-appropriate physical activities are effective methods to promote fitness and improve muscle performance rather than structured resistance training programs. The emphasis throughout most or all of the first decade of life should be on recreation and learning motor skills.<sup>264</sup>

There is lack of agreement, however, on when and under what circumstances resistance training is an appropriate form of exercise for prepubescent children. Although age-appropriate physical activity on a regular basis has been recommended for children for some time,<sup>5,6,36</sup> it has become popular for older (preadolescent) boys and girls to participate in sport-specific training programs (including resistance

exercises) before, during, and even after the season. In theory, these training programs enhance athletic performance and reduce the risk of sport-related injury. Rehabilitation programs for prepubescent children who sustain injuries during everyday activities also may include resistance exercises. Consequently, an understanding of the effects of exercise in this age group must be the basis for establishing a safe program with realistic goals.

 **FOCUS ON EVIDENCE**

In the preadolescent age group, many studies have shown that improvements in strength and muscular endurance are similar to training-induced gains in young adults.<sup>27,85,86,141</sup> As with adults, when training stops strength levels gradually return to a pretraining level.<sup>82</sup> This suggests that some

**FIGURE 6.1** Resistance training, if initiated during the preadolescent years, should be performed using body weight or light weights and carefully supervised.

maintenance level of training could be useful in children as with adults.<sup>83</sup>

Although training-induced gains in strength and muscular endurance are well documented, there is insufficient evidence to suggest that a structured resistance training program for children, when coupled with a general sports conditioning program, reduces injuries or enhances sports performance.<sup>5</sup> However, other health-related benefits of a balanced exercise program have been noted, including increased cardiopulmonary fitness, decreased blood lipids levels, and improved psychological well-being.<sup>22,27,82,141</sup> These findings suggest that participation in a resistance training program during preadolescence may be of value if the program is performed at an appropriate level (low loads and repetitions), incorporates sufficient rest periods, and is closely supervised.<sup>5,22,83,253</sup>

### Adolescence

As hormonal levels change at puberty, there is rapid acceleration in the development of muscle strength, especially in boys. During this phase of development, typical strength levels

become markedly different in boys and girls, due in part to hormonal differences between the sexes. Strength in adolescent boys increases about 30% per year between ages 10 and 16, with muscle mass peaking before muscle strength.<sup>34,183</sup> In adolescent girls, peak strength develops before peak mass.<sup>88</sup> Overall, muscle mass increases more than 5-fold in boys and approximately 3.5-fold in girls during the adolescent years.<sup>34,183</sup> Although most longitudinal studies of growth stop at age 18, strength continues to develop, particularly in males, well into the second and even into the third decade of life.<sup>183</sup>

As with prepubescent children, resistance training during puberty also results in significant strength gains. During puberty, these gains average 30% to 40% above that which is expected as the result of normal growth and maturation.<sup>83</sup> A balanced training program for the adolescent involved in a sport often includes off-season and preseason aerobic conditioning and low-intensity resistance training, followed by more vigorous, sport-specific training during the season.<sup>22</sup> The benefits of strength training noted during puberty are similar to those that occur in prepubescent children.<sup>82,86</sup>

### Young and Middle Adulthood

Although data on typical strength and endurance levels during the second through the fifth decades of life are more often from studies of men than women, a few generalizations can be made that seem to apply to both sexes.<sup>178</sup> Strength peaks earlier in women than men, with women reaching a peak during the second decade and most men peaking by age 30. After these peaks, strength then declines approximately 1% per year,<sup>274</sup> or 8% per decade.<sup>100</sup> This decline in strength appears to be minor until about age 50<sup>264</sup> and tends to occur at a later age or slower rate in active adults versus those who are sedentary.<sup>104,274</sup> The potential for improving muscle performance with a resistance training program (Fig. 6.2 A and B) or by participation in even moderately demanding activities several times a week is high during this phase of life. Guidelines for young and middle-aged adults participating in resistance training as part of an overall fitness program have been published by the ACSM<sup>8</sup> and the CDC.<sup>35</sup>

### Late Adulthood

In most cases, the rate of decline in the tension-generating capacity of muscle accelerates to approximately 15% to 20% per decade for men and women in their sixties and seventies, and it increases to 30% per decade thereafter.<sup>104,178</sup> However, the rate of decline may be significantly less (only 0.3% decrease per year) in elderly men and women who maintain a high level of physical activity.<sup>113</sup> These findings suggest that loss of muscle strength during the advanced years may be due, in part, to progressively greater inactivity and disuse.<sup>39</sup> Loss of muscle in the lower extremity and trunk strength and stability during late adulthood—most notably during the seventies, eighties, and beyond—is associated with a gradual deterioration of functional abilities and an increase in the frequency of falling.<sup>39,125</sup>

The decline in muscle strength and endurance in the elderly is associated with many factors in addition to progressive

**FIGURE 6.2** Conditioning and fitness programs for active young and middle-aged adults include resistance training with a balance of (A) upper extremity and (B) lower extremity strengthening exercises.

disuse and inactivity. It is difficult to determine if these factors are causes or effects of an age-related decrease in strength. Neuromuscular factors include decreased muscle mass (atrophy), decreased number of type I and II muscle fibers with a corresponding increase in connective tissue in muscle, decreased cross-sectional size of muscle, selective atrophy of type II fibers, and change in the length-tension relationship of muscle associated more with loss of flexibility than with deficits in motor unit activation and firing rate.<sup>35,100,136,229,258,264,279</sup> The number of motor units also appears to decline after age 60.<sup>136</sup>

In addition to decreases in muscle strength, declines in the speed of muscle contraction, muscle endurance, and the ability to recover from muscular fatigue occur with advanced age.<sup>136,258</sup> The time needed to produce the same absolute and relative levels of torque output is longer in the elderly compared with younger adults, as is the time necessary to achieve relaxation after a voluntary contraction.<sup>100</sup> Consequently, as the rate of movement declines, so does the ability to generate muscle power during activities that require quick responses, such as rising from a low chair or making balance adjustments to prevent a fall. Deterioration of muscle power with age has a stronger relationship to functional limitations and disability than does muscle strength.<sup>220</sup>

Information on changes in muscle endurance with aging is limited. There is some evidence to suggest that the ability to sustain low-intensity muscular effort also declines with age, a change attributed to reduced blood supply and capillary density in muscle, decreased mitochondrial density, changes in enzymatic activity level, and decreased glucose transport.<sup>100</sup> As a result, muscle fatigue may tend to occur more readily in the elderly. In the healthy and active elderly population, the decline in muscle endurance appears to be minimal well into the seventies.<sup>136</sup>

During the past few decades, as the health-care community and the public have become more aware of the benefits of resistance training during late adulthood, a greater number of older adults are participating in fitness programs that include resistance exercises. ACSM and the CDC have published guidelines for resistance training for healthy adults over 60 to 65 years of age.<sup>6,37</sup> (For additional information on exercise in the older population, see Chapter 24.)

### Psychological and Cognitive Factors

An array of psychological factors can influence muscle performance and how easily, vigorously, or cautiously a person moves. Just as injury and disease adversely affect muscle performance, so can a person's mental status. For example, fear of pain, injury, or re-injury; depression related to physical illness; or impaired attention or memory as the result of age, head injury, or the side effects of medication can all adversely affect motor ability. In contrast, psychological factors can also positively influence physical performance.

The principles and methods employed to maximize motor performance and learning as functions of effective patient education are discussed in Chapter 1. These principles and methods should be applied in a resistance training program to develop a requisite level of muscle strength, power, and endurance for functional activities. The following interrelated psychological factors, as well as other aspects of motor learning, may influence muscle performance and the effectiveness of a resistance training program.

#### Attention

A patient must be able to focus on a given task to learn how to perform it correctly. Attention involves the ability to process relevant data while screening out irrelevant information from the environment and to respond to internal cues from the body. Both are necessary when first learning an exercise and later when carrying out an exercise program independently. Attention to form and technique during resistance training is necessary for patient safety and optimal long-term training effects.

#### Motivation and Feedback

If a resistance exercise program is to be effective, a patient must be willing to put forth and maintain sufficient effort and adhere to the program over time. Using meaningful activities that are perceived as having potential usefulness or periodically modifying an exercise routine help maintain a patient's interest in resistance training. Charting or graphing a patient's strength gains, for example, also helps sustain

motivation. Incorporating gains in muscle performance into functional activities as early as possible puts improvements in strength to practical use, thereby making those improvements meaningful.

The importance of feedback for learning an exercise or motor skill is discussed in Chapter 1. In addition, feedback can have a positive impact on a patient's motivation and subsequent adherence to an exercise program. For example, some computerized equipment, such as isokinetic dynamometers, provide visual or auditory signals that let the patient know if each muscle contraction during a particular exercise is within a specific range of intensity or work that is likely to cause a training effect. Documenting improvements over time, such as the amount of external resistance used during various exercises or walking distance or speed, also provides positive feedback to sustain a patient's motivation in a resistance exercise program.

## Physiological Adaptations to Resistance Exercise

The use of resistance exercise in rehabilitation and conditioning programs has a substantial impact on all systems of the body. Resistance training is equally important for patients with impaired muscle performance and individuals who wish to improve or maintain their level of fitness, enhance performance, or reduce their injury risk. When body systems

are exposed to a greater than usual, but appropriate level of resistance exercises, they initially react with a number of *acute* physiological responses before adapting—that is, body systems accommodate over time to the newly imposed physical demands.<sup>6,7,184</sup> Training-induced adaptations to resistance exercise, known as *chronic* physiological responses, are summarized in Table 6.3 and discussed in this section. Key differences in adaptations from strength training versus endurance training are noted.

Adaptations to overload create changes in muscle performance and, in part, determine the effectiveness of a resistance training program. The time course for these adaptations to occur varies from one individual to another depending on a person's health status and previous level of participation in a resistance exercise program.<sup>8</sup>

### Neural Adaptations

It is well accepted that the initial, rapid gain in the tension-generating capacity of skeletal muscle from a resistance training program is attributed largely to neural responses, not adaptive changes in muscle itself.<sup>103,176,195,225</sup> This is reflected by an increase in electromyographic (EMG) activity during the first 4 to 8 weeks of training, with little to no evidence of muscle fiber hypertrophy. It is also possible that increased neural activity is the source of additional gains in strength late in a resistance training program after muscle hypertrophy has plateaued.<sup>162,184</sup>

**TABLE 6.3** Physiological Adaptations to Resistance Exercise

Variable	Strength Training Adaptations	Endurance Training Adaptations
Skeletal muscle structure	Muscle fibers hypertrophy: greatest in type IIB fibers Possible hyperplasia of muscle fibers Fiber type composition: remodeling of type IIB to type IIA; no change in type I to type II distribution (i.e., no conversion) ↓ or no change in capillary bed density: ↓ in mitochondrial density and volume	Minimal or no muscle fiber hypertrophy ↑ in capillary bed density ↑ in mitochondrial density and volume (↑ number and size)
Neural system	Motor unit recruitment (↑ # of motor units firing) ↑ rate of firing (↓ twitch contraction time) ↑ synchronization of firing	No changes
Metabolic system and enzymatic activity	↑ ATP and PC storage ↑ myoglobin storage Triglycerides storage: change not known ↑ creatine phosphokinase ↑ myokinase	↑ ATP and PC storage: ↑ myoglobin storage ↑ of stored triglycerides ↑ creatine phosphokinase ↑ myokinase
Body composition	↑ lean (fat-free) body mass; ↓ % body fat	No change in lean body mass; ↓ % body fat
Connective tissue	↑ tensile strength of tendons, ligaments, and connective tissue in muscle ↑ bone mineral density; no change or possible ↑ in bone mass	↑ tensile strength of tendons, ligaments, and connective tissue in muscle ↑ in bone mineralization with land-based, weight-bearing activities

The initial neural responses to resistance exercise are attributed to motor learning and improved coordination<sup>103,161,163,184</sup> through *increased recruitment* in the number of motor units firing and an *increased rate and synchronization* of motor unit firing.<sup>103,161,217,225</sup> It is speculated that these changes are the result of decreased inhibition of the CNS, decreased sensitivity of the Golgi tendon organ, or changes at the myoneural junction of the motor unit.<sup>103,225</sup>

## Skeletal Muscle Adaptations

### Hypertrophy

As noted previously, the tension-producing capacity of muscle is directly related to the physiological cross-sectional area of the individual muscle fibers. *Hypertrophy* is an increase in the size of an individual muscle fiber caused by increased myofibrillar volume.<sup>198,258</sup> After an extended period of moderate- to high-intensity resistance training, usually by 4 to 8 weeks,<sup>1,271</sup> but possibly as early as 2 to 3 weeks with very high-intensity resistance training,<sup>243</sup> hypertrophy becomes an increasingly important adaptation that accounts for muscle strength gains.

Although the mechanism of hypertrophy is complex and the stimulus for growth is not clearly understood, hypertrophy of skeletal muscle appears to be the result of increased protein (actin and myosin) synthesis and decreased protein degradation. Hypertrophy is also associated with biochemical changes that stimulate uptake of amino acids.<sup>161,184,198,258</sup>

The greatest increases in protein synthesis and hypertrophy are associated with high-volume, moderate-resistance exercise performed eccentrically.<sup>161,223</sup> Furthermore, it is the type IIB muscle fibers that appear to increase in size most readily with resistance training.<sup>184,202</sup>

### Hyperplasia

Although the topic has been debated for many years and evidence of the phenomenon is sparse, there is some thought that a portion of the increase in muscle size that occurs with heavy resistance training is caused by *hyperplasia*, an increased number of muscle fibers. It has been suggested that this increase in fiber number, observed in laboratory animals,<sup>111,112</sup> is the result of longitudinal splitting of fibers.<sup>13,134,191</sup> It has been postulated that fiber splitting occurs when individual muscle fibers increase in size to a point at which they are inefficient and then subsequently split to form two distinct fibers.<sup>111</sup>

Critics of the concept of hyperplasia suggest that evidence of fiber splitting actually may be caused by inappropriate tissue preparation in the laboratory.<sup>109</sup> The general opinion in the literature is that hyperplasia either does not occur, or if it does occur to a slight degree, its impact is insignificant.<sup>96,176,181</sup>

### Muscle Fiber Type Adaptation

As previously mentioned, type IIB (phasic) muscle fibers preferentially hypertrophy with heavy resistance training. In addition, a substantial degree of plasticity exists in muscle fibers with respect to contractile and metabolic properties.<sup>229</sup> Transformation of type IIB to type IIA is common with endurance training,<sup>229</sup> as well as during the early weeks of heavy resistance training,<sup>243</sup> making the type II fibers more resistant to

fatigue. There is some evidence of type I to type II fiber type conversion in the denervated limbs of laboratory animals,<sup>208,286</sup> in humans with spinal cord injury, and after an extended period of weightlessness associated with space flight.<sup>229</sup> However, there is little to no evidence of type II to type I conversion under training conditions in rehabilitation or fitness programs.<sup>184,229</sup>

## Vascular and Metabolic Adaptations

Adaptations of the cardiovascular and respiratory systems as the result of low-intensity, high-volume resistance training are discussed in Chapter 7. Opposite to what occurs with endurance training, with muscle hypertrophy from high-intensity, low-volume training, capillary bed density actually decreases because of the increased number of myofilaments per fiber.<sup>7</sup> Athletes who participate in heavy resistance training actually have fewer capillaries per muscle fiber than endurance athletes and even untrained individuals.<sup>148,256</sup> Other changes associated with metabolism, such as a decrease in mitochondrial density, also occur with high-intensity resistance training.<sup>7,161</sup> This change is associated with reduced oxidative capacity of muscle.

## Adaptations of Connective Tissues

Although the evidence is limited, it appears that resistance training for muscle strength increases the tensile strength of tendons, ligaments, and bone.<sup>47,247,287</sup>

### Tendons, Ligaments, and Connective Tissue in Muscle

Increased tendon strength probably occurs at the musculotendinous junction, whereas increased ligament strength may occur at the ligament-bone interface. It is believed that tensile strength increases in these tissues from resistance training function to support the adaptive strength and size changes of muscle.<sup>287</sup> Consequently, the stronger ligaments and tendons may be less prone to injury. The connective tissue in muscle also thickens, giving more support to the enlarged fibers.<sup>184</sup> It is also thought that noncontractile soft tissue strength may develop more rapidly with eccentric resistance training than with other types of resistance exercises.<sup>246,247</sup>

### Bone

Numerous sources indicate that bone mineral density is highly correlated with muscle strength and the level of physical activity across the life span.<sup>228</sup> Consequently, physical activities and exercises, particularly those performed in weight-bearing positions, are typically recommended to minimize or prevent age-related bone loss<sup>218</sup> and to reduce the risk of fractures or improve bone density when osteopenia or osteoporosis is already present.<sup>51,228</sup>

## FOCUS ON EVIDENCE

Although the evidence from prospective studies is limited and mixed, resistance exercises performed with adequate intensity and with site-specific loading through weight bearing

have been shown to increase or maintain bone mineral density.<sup>150,154,168,190,201</sup> In contrast, a number of studies in young, healthy women<sup>222</sup> and postmenopausal women<sup>219,234</sup> have reported that there was no significant increase in bone mineral density with resistance training. However, the resistance exercises in these studies were not combined with site-specific weight bearing. In addition, the intensity of the weight training programs may not have been high enough to have an impact on bone density.<sup>168,228</sup> The time course of the exercise program also may not have been long enough. It has been suggested that it may take as long as 9 to 12 months of exercise for detectable and significant increases in bone mass to occur.<sup>8</sup> In the spine, although studies to date have not shown that resistance training prevents spinal fractures, there is some evidence to suggest that the strength of the back extensors closely correlates with vertebral bone mineral density.<sup>234</sup>

Research continues to determine the most effective forms of exercise to enhance bone density and prevent age-related bone loss and fractures. For additional information on prevention and management of osteoporosis, refer to Chapters 11 and 24.

## Determinants of Resistance Exercise

Many interrelated factors determine whether a resistance exercise program is appropriate, effective, and safe. This holds true when resistance training is a part of a rehabilitation program for individuals with known or potential impairments in muscle performance, when it is incorporated into a general conditioning program to improve the fitness level of healthy individuals, or as part of a comprehensive exercise program intended to increase performance and reduce injury risk.

Each factor discussed in this section and noted in Box 6.4 should be considered when designing a resistance program to improve one or more aspects of muscle performance and achieve desired functional outcomes. Appropriate *alignment* and *stabilization* are two constant factors for any exercise designed to improve muscle performance. A suitable *dosage* of exercise must also be determined. In resistance training, dosage includes *intensity*, *volume*, *frequency*, and *duration* of exercise. Each separate dosage factor is a mechanism by which the muscle can be progressively overloaded to improve muscle performance. The *velocity* of exercise and the *mode (type)* of exercise must also be considered. Finally, the appropriate *rest interval* between sessions must be determined. ACSM denotes the key determinants of a resistance training program by the acronym FITT, which represents frequency, intensity, time, and type of exercise.<sup>6</sup>

Consistent with the SAID principle discussed in the first section of this chapter, the determinants of resistance exercise must be specific to the patient's desired functional goals. Additional factors, such as the underlying cause of the muscle

### BOX 6.4 Determinants of a Resistance Exercise Program

- *Alignment* of body segments during each unique exercise
- *Stabilization* of proximal or distal joints to prevent substitute motions
- *Intensity*: the exercise load or level of resistance
- *Volume*: the total number of repetitions and sets in an exercise session
- *Exercise order*: the sequence in which muscle groups are exercised during a session
- *Frequency*: the number of exercise sessions per day or per week
- *Rest interval*: the time allotted for recuperation between exercise sets and sessions
- *Duration*: total time committed to a resistance training program
- *Mode*: the type of muscle contraction, type of resistance, arc of movement used, and primary energy system utilized during exercise
- *Velocity*: the rate at which each exercise is performed
- *Periodization*: the variation of intensity and volume during specific periods of resistance training
- *Integration of exercises into functional activities*: exercises that approximate or replicate functional demands

performance deficits; the extent of impairment; and the patient's age, medical history, mental status, and social situation, may also affect the design and implementation of a resistance exercise program.

### Alignment and Stabilization

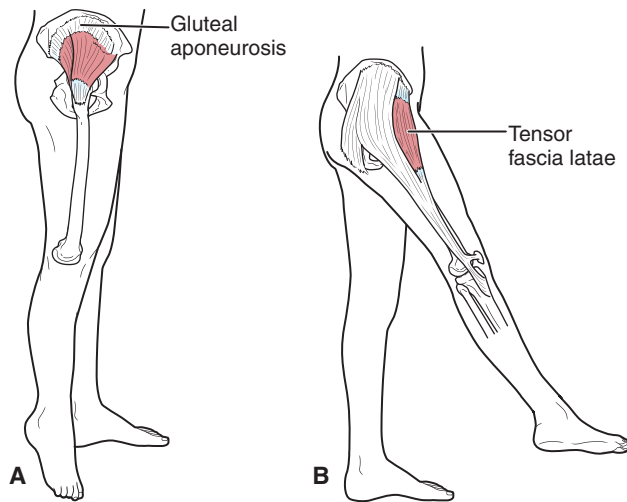

Just as correct alignment and effective stabilization are basic elements of manual muscle testing and dynamometry, they are also crucial in resistance exercise. To strengthen a specific muscle or muscle group effectively and avoid substitute motions, appropriate positioning of the body and alignment of a limb or body segment are essential. *Substitute motions* are compensatory movement patterns caused by muscle action of a stronger adjacent agonist or a muscle group that normally serves as a stabilizer.<sup>152</sup> Substitute motions must be avoided if the resistance exercises are to optimally benefit the target muscle or muscle group. If the principles of alignment and stabilization for manual muscle testing<sup>132,152</sup> are applied whenever possible during resistance exercise substitute motions can usually be avoided.

### Alignment

**Alignment and muscle action.** Proper alignment is determined by considering the fiber orientation, the line of pull, and the specific action desired of the muscle to be strengthened. The patient or body segment must be positioned so the direction of movement of a limb or segment of the body replicates the action of the muscle or muscle groups to be

strengthened. For example, to strengthen the gluteus medius, the hip must remain slightly extended and the pelvis must be shifted slightly forward as the patient abducts the lower extremity against the applied resistance. If the hip is flexed as the leg abducts, the adjacent tensor fasciae latae becomes the prime mover and detracts from the beneficial effect to the gluteus medius (Fig. 6.3).

**FIGURE 6.3** When performing hip abduction, emphasize maintaining the hip in extension and slight external rotation to (A) strengthen the gluteus medius. Allowing the hip to flex while attempting abduction (B) puts the TFL in line to abduct the hip and minimizes benefit to the gluteus medius.

**Alignment and gravity.** The alignment or position of the patient or limb with respect to gravity will also be important during some forms of resistance exercise, particularly if body weight or free weights (dumbbells, barbells, and cuff weights) are the source of resistance. The patient or limb should be positioned in a way that considers how both gravity and a weight provide external resistance to the muscle being strengthened.

Staying with the example of strengthening the gluteus medius, if a cuff weight is placed around the lower leg, the patient must be positioned in side-lying so that the muscle contraction overcomes the external resistance applied by both gravity and the cuff weight. However, if the patient were positioned in supine, the cuff weight and gravity's resistance force become oriented to optimally resist hip flexion rather than abduction.

### Stabilization

Stabilization refers to holding down a body segment or holding the body steady.<sup>152</sup> Effective stabilization is imperative during resistance exercise to maintain appropriate alignment, ensure the correct muscle action and movement pattern, and avoid unwanted substitute motions. Exercising on a stable surface, such as a firm treatment table, helps achieve stabilization. Body weight also provides a source of stability during exercise. It is most common to stabilize the body segment that

has the proximal attachment of the muscle being strengthened, but sometimes the distal segment is stabilized. For example, when strengthening the plantarflexors against the resistance of an elastic band in a long-sitting position, the proximal muscle attachment on the leg must be stabilized. However, if strengthening against the resistance of body weight and gravity while standing, the distal segment foot is now stabilized by contact with the ground.

Stabilization for resistance exercise can be achieved through external or internal means.

- **External stabilization** can be applied manually by the therapist or the patient with equipment such as belts and straps or by using gravity to hold the body against a firm support surface such as the back of a chair or the surface of a treatment table.
- **Internal stabilization** is achieved by an isometric contraction of an adjacent muscle group that does not impact the desired movement pattern but holds the proximal body segment of the muscle being strengthened firmly in place. For example, when performing a bilateral straight leg raise while positioned in supine, the abdominals contract to stabilize the pelvis and lumbar spine as the hip flexors raise the legs. This form of stabilization is effective only if the fixating muscle group is strong enough or not fatigued.

### Exercise Intensity

The *intensity* of exercise in a resistance training program is the amount of external resistance imposed on the contracting muscle during each repetition of an exercise. The amount of resistance is also referred to as the *exercise load* or *training load*—that is, the extent to which the muscle is loaded or how much weight is raised, lowered, or held.

Remember, consistent with the overload principle, muscle performance improves only if the muscle is subjected to an exercise load that is greater than what is usually experienced. One way to progressively overload a muscle is to gradually increase the amount of resistance used in the exercise program.<sup>6,8,95,162,163</sup>

### Submaximal Versus Maximal Exercise Loads

Many factors determine whether resistance exercise is carried out against submaximal or maximal muscle loading. These factors include the goals and expected functional outcomes of the exercise program; the cause and extent of muscle performance deficits; the stage of healing of injured tissues; and the patient's age, general health, and fitness level. In general, the level of resistance is lower in rehabilitation programs for persons with impairments than in conditioning programs for healthy individuals.

Indications for submaximal loading for moderate to low-intensity exercise versus near-maximal or maximal loading for high-intensity exercise are summarized in Table 6.4.

**PRECAUTION:** Resistance exercises that cause pain indicate that the intensity level is too great. Also, there is a direct

**TABLE 6.4** Indications for Low-Intensity Versus High-Intensity Exercise

Low Intensity	High Intensity
In the early stages of soft tissue healing when injured tissues must be protected	When the goal of exercise is to increase muscle strength and power and possibly increase muscle size
After prolonged immobilization when the articular cartilage is not able to withstand large compressive forces or when bone demineralization may have occurred, increasing the risk of pathological fracture	For otherwise healthy adults in the advanced phase of a rehabilitation program after a musculoskeletal injury in preparation for returning to high-demand occupational or recreational activities
To evaluate the patient's response to resistance exercise, especially after an extended period of inactivity	In a conditioning program for individuals with no known pathology
When initially learning an exercise to emphasize the correct form	For individuals training for competitive weight lifting or body building
For most children or older adults	
When the goal of exercise is to improve muscle endurance	
To warm-up and cool-down prior to and after a session of exercise	
During slow-velocity isokinetic training to minimize compressive forces on joints	

relationship between increasing exercise intensity requiring maximal effort and cardiovascular risks. Patients need continual reminders to incorporate rhythmic breathing into each repetition of an exercise to minimize these risks.

### Initial Exercise Load (Amount of Resistance) and Documentation of Training Effects

It is always challenging to estimate how much external resistance to apply during resistance exercises, particularly at the beginning of a strengthening program. When applying manual resistance, the decision is entirely subjective, based on the therapist's judgment about the patients' effort, performance, and response during exercise. In an exercise program using mechanical resistance, the determination can be made quantitatively.

#### Repetition Maximum

One method of calculating an appropriate exercise load for training is to determine a repetition maximum. This term was first reported decades ago by DeLorme in his investigations of an approach to resistance training called progressive resistive exercise (PRE).<sup>60,61</sup> A *repetition maximum* (RM) is defined as the greatest amount of weight or load that can be moved with control through the full, available range of motion (ROM) a specific number of times before fatiguing.

**Use of a RM.** There are two main reasons for determining a RM: (1) to identify an initial exercise load (amount of weight) to be used during exercise for a specified number of repetitions and (2) to document a baseline measurement of the dynamic strength of a muscle or muscle group against which exercise-induced improvements in strength can be compared.

DeLorme reported use of a 1-RM (the greatest amount of weight a subject can move through the available ROM just one time) as the baseline measurement of a subject's maximum effort but used a multiple RM, specifically a 10-RM, (the amount of weight that could be lifted and lowered 10 times through the ROM) during training.<sup>61</sup>

Despite criticism that establishing a 1-RM involves some trial and error, it is a frequently used method for measuring muscle strength in research studies and has been shown to be a safe and reliable measurement tool prior to beginning conditioning programs with healthy young adults and athletes<sup>95,163</sup> as well as active older adults.<sup>194,252,262</sup>

**PRECAUTION:** Use of a 1-RM as a baseline measurement of dynamic strength is inappropriate for some patient populations because one maximum effort may require an unsafe amount of exertion. For example, it is not safe for patients with joint impairments, patients who are recovering from or who are at risk for soft tissue injury, or patients with known or at risk for osteoporosis or cardiovascular pathology.

#### CLINICAL TIP

To avoid the trial and error associated with establishing a 1-RM or to eliminate the need for an at-risk patient to exert a single maximum effort, formulas have been developed and tables have been published<sup>16,135</sup> that enable a therapist to calculate a 1-RM for each muscle group to be strengthened based on the patient performing a greater number of repetitions against a reduced load.

Another practical, time-saving way to establish a baseline RM is for a therapist to select a specific amount of resistance (weight) and document how many repetitions can be completed through the full range before the muscle begins to fatigue. If six repetitions, for example, were completed, the baseline resistance would be based on a 6-RM. Remember, a sign of fatigue is the inability to complete the full, available ROM against the applied resistance.

### Alternative Methods of Determining Baseline Strength or an Initial Exercise Load

Cable tensiometry<sup>184</sup> and isokinetic or handheld dynamometry<sup>53</sup> are alternatives to a RM for establishing a baseline measurement of dynamic or static strength. A percentage of body weight has also been proposed to estimate the amount of external resistance to be used in a strength training program.<sup>226</sup> Some examples for several exercises are noted in Box 6.5. The percentages indicated are meant as guidelines for the advanced stage of rehabilitation and are based on 10 repetitions of each exercise at the beginning of an exercise program. Percentages vary for different muscle groups.

When a maximum effort is inappropriate, the level of perceived loading, as measured by the Borg CR10 scale,<sup>29</sup> is also a useful tool in estimating an appropriate level of resistance and sufficient exercise intensity for muscle strengthening.<sup>8</sup> Box 6.6 provides the category scale used with the Borg CR10.<sup>29</sup>

### Training Zone

After establishing the baseline RM, the amount of external resistance to be used at the initiation of resistance training is often calculated as a *percentage* of a 1-RM for a particular muscle group. At the beginning of an exercise program the percentage necessary to achieve training-induced adaptations in strength ranges from low (30% to 40%) for sedentary, untrained individuals to very high (>80%) for highly trained individuals. For healthy but untrained adults, a typical training zone usually falls between 40% and 70% of the baseline 1-RM.<sup>6,8,13</sup> The lower percentage of this range is safer at the beginning of a program to enable an individual to focus on learning correct exercise form and technique before progressing to higher loads.

Exercising at a low to moderate percentage of the established RM is recommended for children and the elderly.<sup>6,8</sup> For patients with significant deficits in muscle strength or to train for muscular endurance, using a low load—possibly at the 30% to 50% level—is safe yet challenging.

### BOX 6.5 Percentage of Body Weight as an Initial Exercise Load for Selected Exercises

- Universal bench press: 30% body weight
- Universal leg extension: 20% body weight
- Universal leg curl: 10% to 15% body weight
- Universal leg press: 50% body weight

### BOX 6.6 Borg CR10 Scale for Estimating Perceived Exertion<sup>29</sup>

0	Nothing at all	
0.3		
0.5	Extremely weak	Just noticeable
0.7		
1	Very weak	
1.5		
2	Weak	Light
2.5		
3	Moderate	
4		
5	Strong	Heavy
6		
7	Very strong	
8		
9		
10	Extremely strong	“Maximal”
11		
•	Absolute maximum	Highest possible

### Exercise Volume

In resistance training, the *volume* of exercise is the summation of the total number of repetitions and sets of a particular exercise during a single exercise session multiplied by the intensity of the exercise.<sup>6,8,162</sup> The same combination of repetitions and sets is not and should not be used for all muscle groups.

There is an inverse relationship between the sets and repetitions of an exercise and the intensity of the resistance. The higher the intensity or external resistance, the lower the number of repetitions and sets are possible. Conversely, the lower the external resistance, the greater the number of repetitions and sets are possible. Therefore, the external resistance directly dictates how many repetitions and sets are possible.

**Repetitions.** The number of repetitions in an exercise program refers to the number of times a particular movement is performed consecutively. More specifically, it is the number of muscle contractions performed to move the limb through a series of continuous and complete excursions against a specific exercise load.

If the RM designation is used, the number of repetitions at a specific exercise load is reflected in the designation. For example, 10 repetitions with a 20-lb load is designated as a 10-RM. If a 1-RM has been established as a baseline level of dynamic strength, the percentage of the 1-RM that is used as the exercise load will directly influence the number of repetitions a patient is able to perform before fatiguing. The

“average,” untrained adult, when exercising with a load that is equivalent to 75% of the 1-RM, is able to complete approximately 10 repetitions before needing to rest.<sup>16,184</sup> At 60% intensity, about 15 repetitions are possible, and at 90%, intensity only 4 or 5 repetitions are usually possible.

For practical reasons, after a beginning exercise load is selected, the target number of repetitions performed for each exercise before a brief rest is often within a range rather than an exact number of repetitions. For example, a patient might be able to complete between 8 and 10 repetitions against a specified load before resting. This is sometimes referred to as a *RM zone*<sup>184</sup> and gives the patient flexibility in their exercise program.

The target number of repetitions selected depends on the patient’s status and whether the goal of the exercise is to improve muscle strength or endurance. No optimal number of repetitions for strength training or endurance training has been identified, although greater strength has been reported for exercise programs using from a 2- to 3-RM to a 15-RM.<sup>16,164</sup>

**Sets.** A predetermined number of consecutive repetitions grouped together is known as a *set* or *bout* of exercise. After each set of a specified number of repetitions, there is a brief interval of rest. For example, during a single exercise session to strengthen a particular muscle group, a patient might be directed to lift an exercise load 8 to 10 times, rest, and then lift the load another 8 to 10 times. This sequence describes two sets of an 8- to 10-RM.

As with repetitions, there is no optimal number of sets per exercise session, but two to four sets are a common recommendation for adults.<sup>6</sup> As few as one set and as many as six sets have yielded positive training effects.<sup>8,162</sup> Single-set exercises at low intensities are most common in the very early phases of a resistance exercise program or in a maintenance program. Multiple-set exercises are used to progress the program and have been shown to be superior to single-set regimens in advanced training.<sup>164</sup>

### Training to Improve Strength, Power, or Endurance: Impact of Exercise Load and Repetitions

Because many variations of intensity and volume cause positive training-induced adaptations in muscle performance, there is a substantial amount of latitude for selecting an exercise load/repetition and set scheme for each exercise. Clinicians can improve their ability to select appropriate exercise volume parameters for their patients and clients by determining if their goal is to improve muscle strength, power, or endurance.

#### To Improve Muscle Strength

In DeLorme’s early studies,<sup>60,61</sup> three sets of a 10-RM performed for 10 repetitions over the training period led to strength gains. Current recommendations for strength training vary somewhat. One resource<sup>15</sup> suggests that a threshold of 40% to 60% of maximum effort is necessary for adaptive

strength gains to occur in a healthy but untrained individual. However, other resources recommend using a moderate exercise load (60% to 80% of a 1-RM) that causes fatigue after 8 to 12 repetitions for 2 or 3 sets.<sup>6,162</sup> When fatigue no longer occurs after the target number of repetitions has been completed, the level of resistance is increased to overload the muscle once again.

#### To Improve Muscle Power

Power can be developed and improved by modifying the intensity and speed of training. The recommended intensity for power training ranges for 20% to 70% of 1-RM, while the rate of exercises should be explosive or ballistic. The mean training combination from over 350 studies showing an overall small increase in power was 3.8 sets of 6.4 repetitions of an exercise performed rapidly at 81% of the 1-RM.<sup>188</sup> Not surprisingly, there is a linear relationship between increased training variables, especially resistance load, and improved power. Three to four sessions per week is recommended to increase power of both the upper and lower extremities.<sup>188</sup> Chapter 23 provides additional detail on strategies to improve power.

#### To Improve Muscle Endurance

Training to improve muscle endurance involves performing many repetitions of an exercise against a submaximal load.<sup>7,162,248</sup> For example, as many as 3 to 5 sets of 40 to 50 repetitions against a low amount of external resistance or a light grade of elastic resistance might be used. When increasing the number of repetitions or sets becomes inefficient, the load can be increased slightly.

Endurance training also can be accomplished by maintaining an isometric muscle contraction for incrementally longer periods of time. Because endurance training is performed against very low levels of resistance, it can be initiated very early in a rehabilitation program without risk of injury to healing tissues.

### CLINICAL TIP

When injured muscles are immobilized, type I (slow twitch) muscle fibers atrophy at a faster rate than type II (fast twitch) fibers.<sup>198</sup> There is also a slow to fast muscle fiber type conversion with disuse. These changes give rise to a much faster rate of atrophy of antigravity muscles compared with their antagonists,<sup>176</sup> underscoring the need for early initiation of endurance training following injury or surgery.

### Exercise Order

The sequence in which resistance exercises are performed during an exercise session has an impact on muscle fatigue and adaptive training effects. When several muscle groups are exercised in a single session, as is the case in most rehabilitation or conditioning programs, large muscle groups should be exercised before small muscle groups and multijoint exercises should be performed before single-joint exercises.<sup>8,95,161,162</sup>

In addition, after an appropriate warm-up, higher intensity exercises should be performed before lower intensity exercises.<sup>8</sup>

## Exercise Frequency

*Frequency* in a resistance exercise program refers to the number of exercise sessions per day or per week.<sup>6,8</sup> Frequency also may refer to the number of times per week specific muscle groups are exercised or certain exercises are performed.<sup>6,162</sup> As with other aspects of dosage, frequency is dependent on other determinants, such as intensity and volume, as well as the patient's goals, general health status, previous participation in a resistance exercise program, and response to training. The greater the intensity and volume of exercise, the more time is needed between exercise sessions to recover from the temporary fatigue effects. A common cause of a decline in performance from overtraining (see discussion later in the chapter) is excessive frequency, inadequate rest intervals, and progressive fatigue.

Some forms of exercise should be performed less frequently than others because they require greater recovery time. It has been known for some time that high-intensity *eccentric* exercise, for example, is associated with greater microtrauma to soft tissues and a higher incidence of delayed-onset muscle soreness than concentric exercise.<sup>14,99,204</sup> Therefore, rest intervals between exercise sessions are longer and the frequency of exercise is less for eccentric exercises than with other forms.

Although an optimal frequency per week has not been determined, a few generalizations can be made. Initially in an exercise program, short sessions of exercises sometimes can be performed on a daily basis several times per day as long as the intensity of exercise and number of repetitions are low. This frequency is often indicated for early postsurgical patients when the operated limb is immobilized and the extent of exercise is limited to nonresisted isometric (setting) exercises meant to minimize the risk of muscle atrophy. As the intensity and volume of exercise increases, a frequency of two to three times per week, every other day, or up to five exercise sessions per week is common.<sup>6,8,95,161</sup> A rest interval of 48 hours when training major muscle groups can be achieved by alternating sessions by exercising the upper extremities one day and the lower extremities the next day.

Frequency can be reduced for a maintenance program, usually to two times per week. With prepubescent children and the very elderly, frequency typically is limited to no more than two to three sessions per week.<sup>6,8,36,37</sup> Highly trained athletes involved in body building, power lifting, and weight lifting, who know their own response to exercise, often train at a high intensity and volume up to 6 days per week.<sup>8,162,164</sup>

## Exercise Duration

*Exercise duration* is the total number of weeks or months during which a resistance exercise program is carried out. Depending on the cause of impaired muscle performance, some

patients require only a month or two of training to return to the desired level of function or activity, whereas others need to continue the exercise program for a lifetime to maintain optimal function.

As noted earlier in the chapter, strength gains observed early in a resistance training program (after 2 to 3 weeks) are primarily the result of neural adaptation. For significant changes to occur in muscle, such as hypertrophy or increased vascularization, at least 6 to 12 weeks of resistance training is required.<sup>1,6,184</sup>

## Rest Interval (Recovery Period)

**Purpose of rest intervals.** Rest is a critical element of a resistance training program and is necessary to allow time for the body to recuperate from muscle fatigue or to offset adverse responses such as exercise-induced, delayed-onset muscle soreness. Only with an appropriate balance of progressive loading and adequate rest intervals can muscle performance improve. Therefore, rest between sets of exercise and between exercise sessions must be carefully implemented.

**Integration of rest into exercise.** Rest intervals for each exercising muscle group are dependent on the intensity and volume of exercise. In general, with a higher exercise intensity a longer rest interval is needed. For moderate-intensity resistance training, a 2- to 3-minute rest period after each set is recommended. A shorter rest interval is adequate after low-intensity exercise. Longer rest intervals (>3 minutes) are appropriate with high-intensity resistance training, particularly when exercising large, multijoint muscles.<sup>6,8</sup> While the muscle group that was just exercised is resting, resistance exercises can be performed by another muscle group in the same extremity or by the same muscle group in the opposite extremity.

Patients with pathological conditions that make them more susceptible to fatigue, as well as children and the elderly, should rest at least 3 minutes between sets by performing a nonresisted exercise, such as low-intensity cycling, or performing the same exercise with the opposite extremity. Remember, active recovery is more efficient for neutralizing the effects of muscle fatigue than passive recovery.

Rest between exercise sessions must also be considered. When strength training is initiated at moderate intensities (typically in the intermediate phase of a rehabilitation program after soft tissue injury), a 48-hour rest interval between exercise sessions—that is, training every other day—allows the patient adequate time for recovery.

## Mode of Exercise

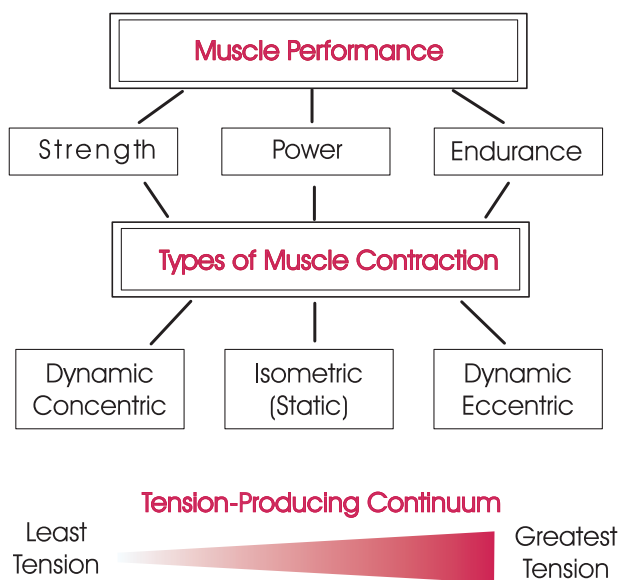

The *mode* of exercise in a resistance exercise program refers to the form of exercise, the type of muscle contraction that occurs, and the manner in which the exercise is carried out. For example, a patient may perform an exercise dynamically or statically or in a weight-bearing or nonweight-bearing position. Mode of exercise also encompasses the form of

resistance—that is, how the exercise load is applied. External resistance can be applied manually or mechanically.

As with other determinants of resistance training, the modes of exercise selected are based on a multitude of factors already highlighted throughout this section. A brief overview of the various modes of exercise is presented in this section. An in-depth explanation and analysis of each of these types of exercise can be found in the next section of this chapter and in Chapter 7.

### Type of Muscle Contraction

Figure 6.4 depicts the types of muscle contraction that may be performed in a resistance exercise program, with their relationships to each other and to muscle performance noted.<sup>175,202,236</sup>

**FIGURE 6.4** Types of muscle contractions: their relationships to muscle performance and their tension-generating capacities.

- Static or dynamic muscle contractions are two broad categories of exercise.
- Static contractions can refer to isometric contractions done internally—often called muscle setting—or against an unmovable external resistance.
- Dynamic resistance exercises can be performed using *concentric* (muscle shortening) or *eccentric* (muscle lengthening) contractions, or both.
- When the velocity of limb movement is held consistent by a rate-controlling device, the term *isokinetic* contraction is sometimes used.<sup>236</sup> An alternative perspective is that this is simply a dynamic (shortening or lengthening) contraction that occurs under controlled conditions.<sup>175</sup>

### Position for Exercise: Weight Bearing or Nonweight Bearing

The patient's body or extremity position relative to a weight-bearing surface also alters the mode of exercise. When a nonweight-bearing position is assumed and the distal

segment (foot or hand) moves freely during exercise, the term *open-chain exercise* is most often used. When a weight-bearing position is assumed and the body moves over a fixed distal segment, the term *closed-chain exercise* is commonly used.<sup>175,202,236</sup> Concepts and issues associated with the use of this terminology are addressed later in this chapter.

### Forms of Resistance

- *Manual* resistance and *mechanical* resistance are the two broad methods by which external resistance can be applied.
- A *constant* or *variable* load can be imposed through mechanical resistance such as free weights or weight machines.
- *Accommodating* resistance<sup>133</sup> can be implemented by use of an isokinetic dynamometer that controls the velocity by adjusting the external resistance to meet the internal effort during exercise.
- *Body weight* or partial body weight is also a source of resistance if the exercise occurs in an antigravity position. Although an exercise performed against only the resistance of the weight of a body segment (and no additional external resistance) is defined as an active rather than an active-resistive exercise, a substantial amount of resistance from the weight of the body can be imposed by altering a patient's position. For example, progressive loads can be placed on upper extremity musculature during push-ups by starting with wall push-ups while standing, progressing to push-ups while leaning against a countertop, push-ups in a horizontal position (Fig. 6.5), and finally push-ups with the feet elevated above the hands.

**FIGURE 6.5** Body weight serves as the source of resistance during a push-up.

### Energy Systems

Modes of exercise can also be classified by the energy systems used during the exercise. Anaerobic exercise involves high-intensity effort carried out over a low number of repetitions because muscles rapidly fatigue at near-maximal intensity. Strengthening exercises are categorized as anaerobic. Aerobic exercise is associated with low-intensity, high-repetition effort over an extended period of time. This mode of exercise primarily increases muscular and cardiopulmonary endurance. (Refer to Chapter 7 for an in-depth explanation.)

## Range of Movement: Short-Arc or Full-Arc Exercise

External resistance through the full joint range of movement (full-arc exercise) is necessary to develop strength over the entire ROM. However, sometimes resistance exercises are executed through only a portion of the available range, which is referred to as short-arc exercise. Short-arc exercise is used when a painful or unstable arc of motion must be avoided or to protect healing tissues after injury or surgery.

## Mode of Exercise and Application to Function

Mode-specific training is essential if a resistance training program is to have a positive impact on function. When tissue healing allows, the type of muscle contractions performed or the position in which an exercise is carried out should mimic the desired functional activity as closely as possible.<sup>197</sup>

## Velocity of Exercise

The velocity at which a muscle contracts significantly affects the tension that the muscle produces and subsequently affects muscular strength and power.<sup>209</sup> Exercise velocity is frequently manipulated in a resistance training program to prepare the patient for the variety of functional activities that occur across the wide spectrum of movement velocities.

## Force-Velocity Relationship

The force-velocity relationship is different during concentric and eccentric muscle contractions, as depicted in Figure 6.6.

### Concentric Muscle Contraction

During a maximum effort concentric muscle contraction, as muscle shortening velocity increases, the force the muscle can generate *decreases*. EMG activity and torque also decrease as a muscle shortens at faster contractile velocities, possibly

**FIGURE 6.6** Force-velocity curve for concentric and eccentric exercise. (From Levangie, PK, and Norkin, CC: *Joint Structure and Function—A Comprehensive Analysis*, ed. 5. Philadelphia: FA Davis, 2011, p. 121, with permission.)

because the muscle may not have sufficient time to develop peak tension.<sup>50,175,202,236,278</sup>

### Eccentric Muscle Contraction

During a maximum effort eccentric contraction, as the velocity of active muscle lengthening increases, force production in the muscle initially *increases* to a point but then *quickly levels off*.<sup>38,59,175,202,236</sup> The initial increase in force production may be a protective response of the muscle when it is first overloaded. It is thought that this increase may be important for shock absorption or rapid deceleration of a limb during quick changes of direction.<sup>72,236</sup> The force increase may also be caused by passive tension of the non-contractile tissue in muscle.<sup>59</sup> In contrast, other research indicates that eccentric force production is essentially unaffected by velocity and remains constant at slow and fast velocities.<sup>50,115</sup>

## Application to Resistance Training

A range of slow to fast exercise velocities should be integrated into an exercise program. Resistance training with free weights is safe and effective only at slow to medium velocities of limb movement so the patient can maintain control of the moving weight. Because many functional activities require higher velocities of limb movement, training at only slow velocities is inadequate. The development of the isokinetic dynamometer during the late 1960s<sup>133,192</sup> gave clinicians a tool to implement resistance training at fast as well as slow velocities. In recent years, some variable resistance exercise units (pneumatic and hydraulic) and elastic resistance products have provided additional options for safely training at fast velocities.

*Velocity-specific training* is fundamental to a successful rehabilitation program. Study results have shown that training-induced strength gains from a resistance exercise program primarily occur at the training velocities,<sup>24,74,142</sup> with limited transfer of training effects above and below the training velocities.<sup>137,260</sup> Accordingly, training velocities for resistance exercises should be chosen to match or approach the demands of the desired functional activities.<sup>53,142</sup>

Isokinetic training, using *velocity spectrum rehabilitation* regimens, and *plyometric training*, also known as *stretch-shortening drills*, often emphasize high-speed training. These approaches to exercise are discussed later in this chapter and in Chapter 23, respectively.

## Periodization and Variation of Training

Periodization, also known as *periodized training*, is an approach to resistance training that partitions a training program into specific time intervals and establishes *systematic variation* in exercise intensity and repetitions, sets, or frequency.<sup>94,162</sup> This approach to training was developed for highly trained athletes preparing for weight lifting or power lifting competition. The intention of periodization is to optimally progress training programs, prevent overtraining and psychological

staleness prior to competition, and optimize performance during competition.

Periodization breaks the training calendar into cycles, or phases, that sometimes extend over an entire year. The goal is to prepare for a “peak” performance at the time of competition. Different types of exercises at varying intensities, volume, frequency, and rest intervals are performed over each of the cycles. Although periodization is commonly implemented prior to a competitive event, evidence to support its efficacy is limited.<sup>94,164,184</sup> Periodized training concepts are introduced here because certain applications may be appropriate in the clinical setting for injured athletes during the advanced stage of rehabilitation.<sup>89</sup>

## Integration of Function

### Balance of Stability and Active Mobility

Functional movements and tasks require a balance of active movement superimposed on a stable background of neuromuscular control. Stability is also necessary to control quick changes of direction during functional movements. Stability is achieved through proper agonist and antagonist muscle activation at individual joints, while mobility requires the correct activation sequencing and intensity across multiple muscle groups. For example, a person must be able to hold the trunk erect and stabilize the spine to grasp, lift, and transport a heavy object. Because of this interaction among stability and active movement, a resistance exercise program must address both the static and dynamic strength of the trunk and extremities.

### Balance of Strength, Power, and Endurance

Functional tasks encompass many combinations of muscle strength, power, and endurance, requiring motor capabilities that produce slow and controlled movements, rapid movements, repeated movements, and long-term positioning. Analysis of the tasks a patient would like to be able to do provides the framework for a task-specific resistance exercise program.

### Task-Specific Movement Patterns With Resistance Exercise

To prepare the patient for the demands of their regular functional activities, resistance should be incorporated into task-specific movement patterns. Applying resistance during exercise in anatomical planes, diagonal patterns, and combined task-specific movement patterns is an important strategy in a carefully progressed resistance exercise program. Use of simulated functional movements under controlled, supervised conditions is a means to return a patient safely to independent functional activities.<sup>197</sup>

Pushing, pulling, lifting, and holding activities can initially be done against a low level of resistance for a low number of repetitions. Over time, the intensity and dose of the resistance is progressed until the patient returns to using the same

movements during functional activities in an unsupervised work or home setting. The key to successful self-management is to teach a patient how to judge the speed, level, and duration of muscle force in combination with the appropriate timing necessary to perform a motor task safely and efficiently.

## Types of Resistance Exercise

The types of resistance exercise selected for a rehabilitation or training program are contingent on many factors, including the cause and extent of primary and secondary impairments. Deficits in muscle performance; the stage of tissue healing; the tolerance of joints to compression and movement; the general abilities (physical and cognitive) of the patient; the availability of equipment; and, of course, the patient’s goals and the intended functional outcomes of the program must all be considered. A therapist has a large spectrum of exercises from which to choose for a resistance exercise program that will meet the individual needs of each patient. There is no one best form or type of resistance training. Prior to selecting specific types of resistance exercise for a patient’s rehabilitation program, a therapist should consider the questions listed in Box 6.7.

Application of the SAID principle is key to making sound exercise decisions. In addition to selecting the appropriate types of exercise, a therapist must also make informed decisions about the intensity, volume, order, frequency, rest interval, and other factors discussed in the previous section of this chapter for effective progression of resistance training. Table 6.5 summarizes general guidelines for progression of exercise.

The types of exercise presented in this section are static and dynamic, concentric and eccentric, isokinetic, and open-chain and closed-chain. In addition, manual and mechanical, and constant and variable resistance exercise will also be discussed. The benefits, limitations, and applications of each of these forms of resistance exercise are analyzed and discussed. When available, supporting evidence from the scientific literature is summarized.

## Manual and Mechanical Resistance Exercise

From a broad perspective, a load can be applied to a contracting muscle in two ways: manually or mechanically. The benefits and limitations of these two forms of resistance training are summarized in a later section of this chapter (see Boxes 6.15 and 6.16).

### Manual Resistance Exercise

Manual resistance exercise is a type of active-resistive exercise in which external resistance is provided by a therapist or other health professional. A patient can also be taught to apply

**BOX 6.7 Selecting Types of Resistance Exercise: Questions to Consider**

- Based on the results of your examination and evaluation, what are the type and extent of muscle performance deficits you will need to address?
- Based on the underlying pathology causing the deficits in muscle performance or on the stage of tissue healing, what types of resistance exercise would be most appropriate?
- What are the goals and anticipated functional outcomes of the resistance training program?
- Will dynamic strength or static strength be more effective to achieve the desired outcomes?
- Which types of resistance exercise are most compatible with the desired goals?
- Are there restrictions or limitations to the patients' positioning during resistance exercise?
  - Is weight bearing contraindicated, restricted, or fully permissible?
- Is there hypomobility of affected or adjacent joints (due to pain or contracture) that may affect how the patient is positioned?
- Is there a portion of the ROM in which the patient cannot safely or comfortably perform resistance exercises due to hypermobility?
- Are there cardiovascular or respiratory impairments that may affect positioning?
- Will the patient be expected to perform the exercises independently using mechanical resistance, or will manual resistance applied by the therapist be most appropriate?
- What types of equipment will be available or needed for exercises?
- What types of exercises will replicate or approximate the functional activities required by the patient?

**TABLE 6.5** Progression of a Resistance Training Program: Factors to Consider

Factors	Progression
Intensity (exercise load)	Submaximal → maximal (or near-maximal) Low load → high load
Body position (nonweight bearing or weight bearing)	Variable: depending on pathology and impairments, weight-bearing restrictions (pain, swelling, instability) and goals of the rehabilitation program
Repetitions and sets	Low volume → high volume
Frequency	Variable: depends on intensity and volume of exercise
Type of muscle contraction	Static → dynamic Concentric and eccentric: variable progression
Range of motion	Short arc → full arc Stable portion of range → unstable portion of range
Plane of movement	Uniplanar → multiplanar
Velocity of movement	Slow → fast velocities
Neuromuscular control	Proximal → distal control
Functional movement patterns	Simple → complex Single joint → multijoint Proximal control → distal control

self-generated manual resistance to certain muscle groups. Although the amount of resistance cannot be measured quantitatively, this technique is useful in the early stages of an exercise program when the muscle to be strengthened is weak and can overcome only minimal to moderate resistance. It is also useful when the range of joint movements needs to be carefully controlled. The amount of external resistance provided is limited only by the strength of the therapist.

**NOTE:** Techniques for application of manual resistance exercises in anatomical planes and diagonal patterns are presented in later sections of this chapter.

### Mechanical Resistance Exercise

Mechanical resistance exercise is a form of active-resistive exercise in which external resistance is applied through the use of equipment or mechanical apparatus. The amount of

resistance can often be measured quantitatively and incrementally progressed over time. Mechanical resistance is useful when the amount of external resistance necessary is greater than what the therapist can apply manually.

**NOTE:** Systems and regimens of resistance training that involve the use of mechanical resistance, such as PRE, circuit weight training, and velocity spectrum rehabilitation, and the advantages and disadvantages of various types of resistance equipment are addressed later in this chapter.

## Isometric Exercise (Static Exercise)

*Isometric exercise* is a static form of exercise in which a muscle contracts and produces force without an appreciable change in the length of the muscle and without visible joint motion.<sup>175,202</sup> Although there is no mechanical work accomplished (force  $\times$  distance), a measurable amount of tension and force output are produced by the muscle. Sources of external resistance for isometric exercise include a manually applied force, a weight held in a static joint position, body weight, or an immovable object.

*Repetitive* isometric contractions, for example a set of 20 per day, held for 6 seconds each against near-maximal resistance, has been shown to be an effective method to improve isometric strength. A *cross-exercise effect* (a limited increase in strength of the contralateral, unexercised muscle group), as the result of transfer of training, also has been observed with maximum isometric training.<sup>63</sup>

### Rationale for Use of Isometric Exercise

The need for static strength and endurance is apparent in almost all aspects of body control during functional activities. Recall that most functional activities require a combination of static control at one body region and dynamic activity at another. Loss of static muscle strength occurs rapidly with immobilization and disuse, with estimates from 8% per week<sup>180</sup> to as much as 5% per day.<sup>200</sup>

Functional demands often involve the need to hold a position against either a high level of resistance for a short period of time or a low level of resistance over a prolonged period of time. Of these two aspects of static muscle performance, it is suggested that muscular endurance plays a more important role than muscle strength in maintaining sufficient postural stability and preventing injury during daily living tasks.<sup>184</sup> For example, the postural muscles of the trunk and lower extremities contract isometrically to maintain the body's upright position against gravity and provide stability for balance and functional movements. Dynamic stability of joints during functional activities is achieved by activating and maintaining a low level of co-contraction—that is, concurrent isometric contractions of antagonist muscles that surround joints.<sup>186</sup> The importance of isometric strength and endurance in the elbow, wrist, and finger musculature, for example, is apparent when a person holds and carries a heavy object for an extended period of time.

With these examples in mind, there can be no doubt that isometric exercises are an important part of a rehabilitation program designed to improve functional abilities. The rationale and indications for isometric exercise in rehabilitation are summarized in Box 6.8.

### Types of Isometric Exercise

Several forms of isometric exercise can be used to serve different therapeutic purposes during successive phases of rehabilitation. All but one type—muscle setting—incorporate some form of significant resistance and therefore are used to improve static strength or develop sustained muscular control. Because no appreciable resistance is applied during muscle setting, this type of isometric contraction is technically not a form of resistance exercise. However, it is included in this discussion to show a continuum of isometric exercise that can be used for multifaceted goals in a rehabilitation program.

**Muscle-setting exercises.** Setting exercises involve low-intensity isometric contractions performed against little to no resistance. They are used to decrease muscle pain and spasm and to promote relaxation and circulation during the *acute* stage of healing after soft tissue injury. A common example of muscle setting is the activation of the quadriceps muscles after a knee injury or surgery.

Because muscle setting is performed against no appreciable resistance, it does not improve muscle strength except in very weak muscles. However, setting exercises can slow muscle atrophy and maintain mobility between muscle fibers when a joint is immobilized to protect healing tissues during the very early phase of rehabilitation.

**Stabilization exercises.** This form of isometric exercise is used to develop a submaximal but sustained level of co-contraction to improve postural stability or dynamic joint stability. Stabilization exercises typically consist of isometric contractions against resistance in antigravity or weight-bearing positions if weight bearing is permissible.<sup>186</sup> External resistance is usually provided by body weight or applied manually.

#### BOX 6.8 Isometric Exercise: Summary of Rationale and Indications

- To minimize muscle atrophy when joint movement is restricted by external immobilization (casts, orthotics, or skeletal traction)
- To begin re-establishing neuromuscular control of healing tissues when joint movement is not advisable after soft tissue injury or surgery
- To develop postural or joint stability
- To improve muscle strength when use of dynamic resistance exercise could compromise joint integrity or cause joint pain
- To develop static muscle strength at particular points in the ROM consistent with specific task-related needs

Several terms are used to describe specific types of stabilization exercises. They include *rhythmic stabilization* and *alternating isometrics*, two techniques associated with proprioceptive neuromuscular facilitation (PNF) described later in the chapter.<sup>212,272</sup> Stabilization exercises that focus on trunk/postural control are often referred to as *dynamic*, *core*, and *segmental* stabilization exercises. Applications of these exercises are addressed in Chapter 16. Equipment, such as the BodyBlade® (see Fig. 6.50) and stability balls, are designed for dynamic stabilization exercises.

**Multiple-angle isometrics.** This term refers to a system of isometric exercise in which resistance is applied at multiple joint positions within the available ROM.<sup>53</sup> This approach is used when the goal of exercise is to improve strength throughout the ROM when joint motion is permissible but dynamic resistance exercise is painful or inadvisable.

### Characteristics and Effects of Isometric Training

Effective use of isometric exercise in a resistance training program depends on an understanding of its characteristics, potential benefits, and limitations.

**Intensity of muscle contraction.** The amount of tension that can be generated during an isometric muscle contraction depends in part on joint position and the subsequent length of the muscle at the time of contraction.<sup>270</sup> The greatest amount of isometric force will be generated at the joint angle at which there is maximum actin and myosin protein overlap and the best potential for cross-bridge formation. Isometric force potential decreases as the joint angle moves progressively further away from this optimal angle. An exercise intensity of at least 60% of a muscle's maximum voluntary contraction is sufficient to improve strength.<sup>156,270</sup> The amount of external resistance against which the muscle is able to hold varies by joint angle and needs to be adjusted at different points in the range. As strength increases from isometric exercise, the external resistance must be progressively increased to continue to overload the muscle.

#### CLINICAL TIP

When performing isometric exercises, to avoid potential injury to the contracting muscle, apply and release the resistance gradually. This helps to grade the muscle tension and ensures that the muscle contraction is pain-free. This technique also minimizes the risk of uncontrolled joint movement at the onset or completion of the exercise.

**Duration of muscle activation.** To achieve adaptive changes in static muscle performance, an isometric contraction should be held for 6 seconds and no more than 10 seconds because muscle fatigue develops rapidly. This duration allows sufficient time for peak tension to develop and for metabolic changes to occur in the muscle.<sup>128,184</sup> A 10-second

contraction allows a 2-second rise time, a 6-second hold time, and a 2-second fall time.<sup>53</sup>

**Repetitive contractions.** Sets of repetitive contractions, held for 6 to 10 seconds each, decreases muscle cramping and increases the effectiveness of the isometric regimen.

**Joint angle and mode specificity.** Gains in muscle strength occur only at or closely adjacent to the joint angle at which resistance is applied—known as the training angle.<sup>155,156,270</sup> Physiological overflow is minimal, occurring no more than 10° in either direction from the training angle.<sup>156</sup> Therefore, when performing multiple-angle isometrics, resistance at four to six different angles in the joint ROM is recommended. Additionally, isometric resistance training is mode specific, causing increases in static strength with little to no impact on dynamic strength.

**Sources of resistance.** It is possible to perform a variety of isometric exercises with or without equipment. For example, multiple-angle isometrics can be carried out against manual resistance or by simply having the patient push against an immovable object, such as a doorframe or a wall.

Equipment designed for dynamic exercise can be adapted for isometric exercise. A weight-pulley system that provides resistance greater than the force-generating capacity of a muscle leads to a resisted isometric exercise. Most isokinetic devices can be set up with the velocity set at 0° per second at multiple joint angles for isometric resistance at multiple points in the ROM.

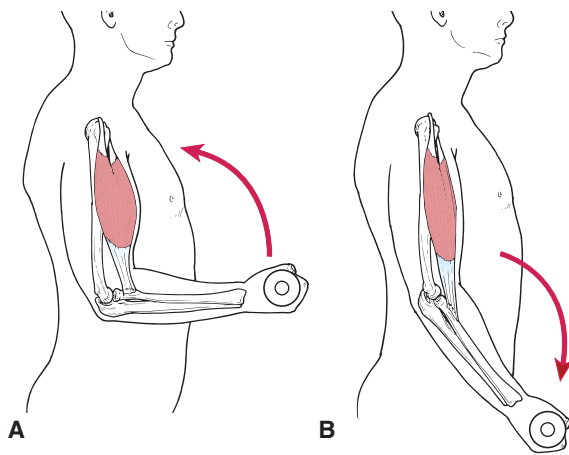

**PRECAUTION:** Patients will often hold their breath during isometric exercise, particularly when performed against substantial external resistance. This is likely to cause a pressor response as the result of the Valsalva maneuver, causing a rapid increase in blood pressure.<sup>87</sup> Rhythmic breathing, emphasizing exhalation during the contraction, should always be performed by the patient during isometric exercise to minimize this response.

**CONTRAINDICATION:** High-intensity isometric exercises are contraindicated for patients with a history of cardiac or vascular disorders.

### Dynamic Exercise: Concentric and Eccentric

A muscle causes joint movement and excursion of a body segment through two unique contraction types—concentric or eccentric. As represented in Figure 6.7, the term *concentric exercise* refers to a form of dynamic muscle activation in which tension develops and physical shortening of the muscle occurs as an external resistance is overcome by internal force, as when lifting a weight. In contrast, *eccentric exercise* involves dynamic muscle activation and tension production that is below the level of external resistance so that physical lengthening of the muscle occurs as it controls the load, as when lowering a weight.

During concentric and eccentric exercise, resistance can be applied in several ways: (1) constant resistance, such as body

**FIGURE 6.7** (A) Concentric and (B) eccentric strengthening of the elbow flexors occurs as a weight is lifted and lowered.

weight, a free weight, or a simple weight-pulley system; (2) a weight machine or elastic bands that provide variable resistance; or (3) an isokinetic device that maintains the velocity of limb movement.

**NOTE:** Although the term *isotonic* (meaning equal tension) has been used frequently to describe a resisted, dynamic muscle contraction, application of this terminology is incorrect. In fact, when a body segment moves through its available range, the tension that the muscle is capable of generating *varies* through the range as the muscle shortens or lengthens. This is due to the changing length-tension relationship of the muscle and the changing torque of the external load.<sup>175,202,236</sup> Therefore, in this textbook “isotonic” is not used to describe dynamic resistance exercise.

### Rationale for Use of Concentric and Eccentric Exercise

Both concentric and eccentric exercises have distinct value in rehabilitation and conditioning programs. Concentric muscle contractions accelerate body segments, whereas eccentric contractions decelerate body segments. Eccentric contractions also act as a source of energy absorption during high-impact activities.<sup>59,169</sup>

A combination of concentric and eccentric muscle action is used in many daily activities, such as walking up and down inclines, ascending and descending stairs, rising from a chair and sitting back down, or picking up or setting down an object. It is therefore advisable to incorporate a variety of concentric and eccentric resistance exercises in a rehabilitation progression for patients with impaired muscle performance.

### Special Considerations for Eccentric Training

Eccentric training is considered an essential component of rehabilitation programs. Eccentric exercises are appropriate following musculoskeletal injury or surgery and in conditioning programs to reduce the risk of injury or re-injury associated

with activities that involve high-intensity deceleration, quick changes of direction, or repetitive eccentric muscle contractions.<sup>10,169,205,242</sup> Eccentric training also is thought to improve sport-related physical performance.<sup>8,169</sup>

Traditionally, training that emphasizes high-intensity eccentric loading, such as eccentric isokinetic training or *plyometric training* (see Chapter 23), has been initiated during the advanced phase of rehabilitation to prepare a patient for high-demand sports or work-related activities.<sup>169</sup> Recently, however, progressive eccentric training early in the rehabilitation process has been advocated to more effectively reduce the deficits in strength and physical performance that often persist following a musculoskeletal injury or surgery. However, the safety of early implementation of eccentric resistance exercise is still being evaluated in controlled studies.

### FOCUS ON EVIDENCE

Gerber and colleagues<sup>105</sup> conducted a randomized, prospective clinical trial to evaluate a gradually progressed, eccentric exercise program initiated during the *early* phase of rehabilitation (approximately 2 to 3 weeks postoperatively) following arthroscopically assisted anterior cruciate ligament (ACL) reconstruction. All study participants began a 15-week traditional, but “accelerated” (early weight-bearing and ROM) exercise program immediately after surgery. After the first 2 to 3 postoperative weeks, half of the participants (experimental group) performed 12 weeks of gradually progressed, lower extremity training on a motorized eccentric ergometer. A control group followed the same 12 week graduated program on a standard exercise cycle that provided only concentric resistance.

Knee effusion and stability and knee and thigh pain were measured preoperatively and at 15 and 26 weeks postoperatively. Quadriceps strength and single-leg long jump distance were measured prior to surgery and at 26 weeks postoperatively. Results of the study indicated that there were no significant differences in knee or thigh pain and knee effusion and stability between groups at any point during the investigation. Importantly, quadriceps strength and physical performance improved significantly in the eccentric training group but not in the control group. This study demonstrated that the addition of progressively graduated eccentric resistance training during early rehabilitation following ACL reconstruction was safe and effective in reducing strength deficits and improving physical performance.

A 1-year follow-up study by Gerber and colleagues<sup>106</sup> involving 80% of the original study participants demonstrated that quadriceps strength and physical performance continued to be superior in the eccentric training group.

### Characteristics and Effects of Concentric and Eccentric Exercise

A summary of the characteristics and effects of eccentric versus concentric resistance exercise is noted in Box 6.9.

### BOX 6.9 Eccentric Versus Concentric Exercise: Summary of Characteristics

- Greater external loads can be controlled with eccentric exercise.
- Training-induced gains in muscle strength and mass are greater with maximum-effort eccentric training than with maximum-effort concentric training.
- Adaptations associated with eccentric training are more mode and velocity specific than are adaptations from concentric training.
- Eccentric muscle contractions are more efficient metabolically and generate less fatigue than concentric contractions.
- Following *unaccustomed*, high-intensity eccentric exercise, there is greater incidence and severity of delayed-onset muscle soreness than there is after concentric exercise.

**Exercise load and strength gains.** A maximum concentric contraction produces less force than a maximum eccentric contraction under the same conditions (see Fig. 6.6). In other words, greater loads can be lowered than lifted. This difference in the magnitude of loads that can be controlled by concentric versus eccentric muscle contractions may be associated with the contributions of the contractile and noncontractile components of muscle. When a load is lowered during an eccentric exercise, the force exerted by the load is controlled not only by the active, contractile components of muscle, but also by the noncontractile connective tissue in and around the muscle. In contrast, when a weight is lifted during concentric exercise, only the contractile components of the muscle contribute to lifting the load.<sup>59</sup>

With a concentric contraction, greater numbers of motor units must be recruited to control the same load compared with an eccentric contraction, suggesting that concentric exercise has less mechanical efficiency than eccentric exercise.<sup>59,72</sup> Consequently, it requires more effort by a patient to control the same load during concentric exercise than during eccentric exercise. As a result, when a weight is lifted and lowered, maximum resistance during the concentric phase of an exercise does not provide a maximum load during the eccentric phase.

If a resistance exercise program involves maximum effort during eccentric and concentric exercise and if the exercise load is increased gradually, eccentric training increases eccentric strength over the duration of a program to a greater degree than concentric training increases concentric strength. This may occur because greater loads can be used for eccentric than concentric training.<sup>223</sup>

#### CLINICAL TIP

Given that eccentric exercise requires recruitment of fewer motor units to control a load than does concentric exercise, when a muscle is very weak—less than a fair (3/5) muscle

grade—active eccentric muscle contractions against no external resistance (other than gravity) can be used to generate active muscle contractions and develop a beginning level of strength and neuromuscular control. In other words, in the presence of substantial muscle weakness, it may be easier to lower the limb against gravity than to raise the limb.

**PRECAUTION:** There is greater stress on the cardiovascular system (i.e., increased heart rate and arterial blood pressure) during eccentric exercise than during concentric exercise,<sup>59</sup> possibly because greater loads can be used for eccentric training. This underscores the need for rhythmic breathing during high-intensity exercise. (Refer to the Contraindications to Resistance Exercise section of this chapter for additional information on cardiovascular precautions.)

**Velocity of exercise.** The velocity at which dynamic exercises are performed directly affects the force-generating capacity of the neuromuscular unit.<sup>50,72</sup> Consider that a certain amount of external resistance will result in a contraction of zero velocity (isometric) for a muscle group. If that amount of external resistance is decreased slightly, a concentric contraction will now be able to raise the load, but only with a slow-velocity, high-tension contraction. As the external resistance decreases further, a concentric contraction requires still lower levels of tension to overcome the load and can do so with greater shortening velocity. In contrast, if the amount of external resistance that generates the isometric contraction is increased slightly, an eccentric contraction can lower the external load with high tension at a slow velocity. Progressive increases in the external load will demand increasingly greater eccentric tension at increased velocity until force generating capacity plateaus (see Fig. 6.6).

#### CLINICAL TIP

A common misconception regarding high-intensity resistance training is that if a weight is lifted quickly (concentric contraction) and lowered slowly (eccentric contraction), the slow eccentric contraction will increase strength because it generates greater tension. In fact, if the load is constant, less tension is generated during the eccentric than the concentric phase. The only way to develop greater tension is to increase the weight of the applied load during the eccentric phase of each exercise cycle. This usually requires assistance from an exercise partner to help lift the load during each concentric contraction. This is a highly intense form of exercise and should be undertaken only by healthy individuals training for high-demand sports or weight lifting competition. This technique is not appropriate for individuals recovering from musculoskeletal injuries.

**Energy expenditure.** Compared across similar exercise loads, eccentric exercise is more efficient at a metabolic level than concentric exercise<sup>223</sup>—that is, eccentric muscle contractions

consume less oxygen and energy stores than concentric contractions.<sup>40</sup> Therefore, the use of eccentric activities such as downhill running may improve muscular endurance more efficiently than similar concentric activities because muscle fatigue occurs less quickly with eccentric exercise.<sup>59,223</sup>

**Specificity of training.** It is not yet known if the training effects of exercises using concentric or eccentric contractions are mode specific. Although there is substantial evidence to support specificity of training,<sup>25,74,197,230,261</sup> there is also some evidence to suggest that training using one mode leads to strength gains in the other mode.<sup>78</sup> For the most part, however, eccentric training is more mode specific than concentric training.<sup>223</sup> Eccentric exercise also appears to be more velocity specific than concentric exercise.<sup>223</sup> Therefore, because transfer of training in general is quite limited, selection of exercises that simulate the functional movements needed by the patient is always a prudent choice.

**Cross-training effect.** Both concentric<sup>268</sup> and eccentric<sup>269</sup> training have a cross-training effect—that is, a slight increase in strength occurs over time in the same muscle group of the contralateral, unexercised extremity. This effect also occurs with high-intensity exercise using a combination of concentric and eccentric contractions (lifting and lowering a weight).

The cross-training effect may be caused by repeated contractions of the unexercised extremity in an attempt to stabilize the body during high-effort exercise. Although cross-training is an interesting phenomenon, there is no evidence to suggest that it has a positive impact on a patient's functional capabilities.

**Exercise-induced muscle soreness.** Repeated and rapidly progressed, high-intensity eccentric muscle contractions are associated with a significantly higher incidence and severity of delayed-onset muscle soreness (DOMS) than occurs with high-intensity concentric exercise.<sup>14,42,99,204</sup> Why DOMS occurs more readily with eccentric exercise is speculative, but it may be the result of greater damage to muscle and connective tissue when heavy loads are controlled and lowered.<sup>14,42</sup> It also has been suggested that the higher incidence of DOMS may adversely affect the training-induced gains in muscle strength.<sup>59,74,99</sup>

It should be noted that there is at least limited evidence to suggest that if the intensity and volume of concentric and eccentric exercise are equal, there is no significant difference in the degree of DOMS after exercise.<sup>92</sup> Further, if the intensity and volume of eccentric exercise is progressed gradually, DOMS does not occur.<sup>105</sup>

## Dynamic Exercise: Constant and Variable Resistance

The most common system of dynamic resistance training is *progressive resistance exercise* (PRE). A later section of this chapter, which covers systems of training using mechanical resistance, addresses PRE.

### Dynamic Exercise: Constant External Resistance

Dynamic exercise against constant external resistance (DCER) is a form of resistance training in which a limb moves through a ROM against a constant external load,<sup>162</sup> provided by free weights such as a handheld or cuff weight, weight machines, or weight-pulley systems.

This terminology—DCER exercise—is used in place of the term “isotonic (equal tension)” exercise because although the external load does not change, the torque imposed by the weight and the tension generated by the muscle both change throughout the range of movement.<sup>175,236</sup> If the imposed load is less than the torque generated by the muscle, the muscle contracts concentrically and accelerates the load; if the load exceeds the muscle's torque production, the muscle contracts eccentrically to decelerate the load (see Fig. 6.7).

DCER exercise has an inherent limitation. When lifting or lowering a constant load, the contracting muscle is challenged maximally at only the one point in the ROM in which the maximum torque of the resistance matches the maximum torque output of the muscle. A therapist needs to be aware of the changing external torque of the exercise and the changing length-tension relationship of the muscle and modify body position and external resistance accordingly to match where in the range the maximum load needs to be applied (see Figs. 6.46 and 6.47). Despite this limitation, DCER exercise has been and continues to be a mainstay of rehabilitation and fitness programs for effective muscle loading and subsequent training-induced improvements in muscle performance.

### Variable Resistance Exercise

Variable resistance exercise, a form of dynamic exercise, addresses the primary limitation of dynamic exercise against a constant external load. Specially designed resistance equipment imposes varying levels of resistance to the contracting muscles to load the muscles more effectively at multiple points in the ROM. The resistance is altered throughout the range by means of a weight-cable system that moves over an asymmetrically shaped cam, by a lever arm system (Fig. 6.8), or by hydraulic or pneumatic mechanisms.<sup>237</sup> How effectively this equipment varies the resistance to match muscle torque curves is questionable.

Dynamic exercise with elastic resistance products (bands and tubing) can also be thought of as variable resistance exercise because of the inherent properties of the elastic material and its response to stretch.<sup>139,145,232</sup> In addition to the progressive resistance increases inherent to elastic bands or tubing, the change in the orientation that the force is applied to the body will also contribute to the variable resistance profile of these products. (Refer to the final section of this chapter for additional information on exercise with elastic resistance devices.)

**NOTE:** When dynamic exercise is performed against manual resistance, a skilled therapist can vary the load applied to

**FIGURE 6.8** Cybex/Eagle Fitness Systems shoulder press provides variable resistance throughout the range of motion. (Courtesy of Cybex, Division of Lumex, Ronkonkoma, NY.)

the contracting muscle throughout the ROM. The therapist adjusts the resistance based on the patient's effort and response so the muscle is appropriately loaded throughout the ROM.

### Special Considerations for DCER and Variable Resistance Exercise

**Excursion of limb movement.** During either DCER or variable resistance exercise, the excursion of limb movement is controlled exclusively by the patient (with the exception of exercising on resistance equipment that has a range-limiting device). When free weights, weight-pulley systems, and elastic devices are used, additional muscles may be recruited to control the arc and direction of limb movement.

**Velocity of exercise.** Although most daily living, occupational, and sport activities occur at medium to fast velocities of limb movement, dynamic exercises are most often performed at a relatively slow velocity to avoid momentum and uncontrolled movements, which could jeopardize the safety of the patient. (As a point of reference, dynamic exercise with a free weight typically is performed at about 60° per second.<sup>53</sup>) Consequently, the training-induced improvements in muscle strength that occur only at slow velocities may not prepare the patient for activities that require rapid bursts of strength or quick changes of direction.

### CLINICAL TIP

Hydraulic and pneumatic variable resistance equipment and elastic resistance products allow safe, moderate- to high-velocity resistance training.

### Isokinetic Exercise

*Isokinetic exercise* is a form of dynamic exercise in which the velocity of the joint angular velocity is predetermined and held constant by a rate-limiting device known as an isokinetic dynamometer (Fig. 6.9).<sup>53,76,133,192</sup> The term *isokinetic* refers to movement that occurs at a constant velocity. Unlike DCER exercise in which a specific amount of resistance is selected and superimposed on the contracting muscle, in isokinetic exercise the *velocity* of limb movement—not the load—is maintained during the effort. The external resistance force encountered by the muscle will vary according to the amount of force applied to the equipment.<sup>4,133</sup>

Because the external resistance adjusts to the effort applied to the equipment, isokinetic exercise is also called *accommodating resistance exercise*.<sup>133</sup> If an individual gives maximum effort during exercise, the torque they produce will vary across the range of joint motion due to changes in muscle length and internal moment arms. An isokinetic dynamometer quantifies this variable torque and accommodates or adjusts the external resistance so that velocity is held constant. When the movement being performed is in the vertical plane, the dynamometer will adjust to the combination of gravity and muscle force. Although early advocates of isokinetic training suggested it was superior to resistance training with free weights or weight-pulley systems, this claim has not been well supported by evidence. Today, isokinetic training is regarded as one of many tools that can be integrated into the later stages of rehabilitation.<sup>5</sup>

**FIGURE 6.9** Biodex isokinetic dynamometer is used for testing and training. (Courtesy of Biodex Medical Systems, Inc., Shirley, NY.)

## Characteristics of Isokinetic Training

A brief overview of the key characteristics of isokinetic exercise is provided in this section. For more detailed information on isokinetic testing and training, a number of resources are available.<sup>4,53,75,76,116</sup>

**Constant velocity.** Fundamental to the concept of isokinetic exercise is that joint angular velocity is preset and controlled by the unit and remains relatively constant throughout the ROM. Due to limb inertia, there is usually a short period at the start and end ranges of exercise motion where angular velocity is not constant.

**Range and selection of training velocities.** Isokinetic dynamometry affords a wide range of exercise velocities. Current dynamometers can adjust the velocity of limb movement from 0° per second (isometric mode) up to 500° per second. As shown in Table 6.6, training velocities are classified as slow, medium, and fast. This range provides a mechanism by which a patient can prepare for the demands of functional activities that occur across a range of movement velocities.

Training velocities should be matched as specifically as possible to the demands of the anticipated functional tasks. The faster training velocities are similar to the velocities of limb movements inherent in some functional motor skills such as walking or lifting.<sup>4,283</sup> For example, the average angular velocity of the lower extremity during walking has been calculated at 230° to 240° per second.<sup>5,53,283</sup> Despite this example, the velocity of limb movements during many functional activities far exceeds the fastest training velocities available with dynamometry.

The training velocities selected may also be based on the mode of exercise (concentric or eccentric) to be performed. As noted in Table 6.6, the range of training velocities recommended for concentric exercise is greater than the range of velocities for eccentric training.<sup>4,76,116</sup>

**Reciprocal versus isolated muscle training.** One advantage of isokinetic dynamometry is the ability to provide resistance to opposing muscle groups at a joint, referred to as reciprocal training. For example, the training parameter can be set so the patient performs concentric contraction of the quadriceps

followed by concentric contraction of the hamstrings. This differs from DCER training where the same muscle group performs concentric and eccentric contractions for each repetition of exercise. The isokinetic dynamometer can also be set to target the same muscle group in the concentric mode, followed by the eccentric mode, mimicking DCER training with the benefit of constant velocity and accommodating resistance.<sup>282</sup> Both of these approaches have merit for rehabilitation and functional training.

**Specificity of training.** Isokinetic training for the most part is velocity specific<sup>23,116,142</sup> with only limited evidence of significant overflow from one training velocity to another.<sup>137,260</sup> Evidence of mode specificity (concentric versus eccentric) with isokinetic exercise is less clear.<sup>10,76,115,197,230</sup>

Because isokinetic exercise tends to be velocity specific, patients typically exercise at several velocities (between 90° and 360° per second) using a system of training known as *velocity spectrum rehabilitation*.<sup>4,53,76</sup> (This approach to isokinetic training is discussed later in the Isokinetic Regimens section.)

**Compressive forces on joints.** During concentric exercise the compressive forces across the moving joint are lower at faster angular velocities than they are at slower velocities.<sup>4,53,75,76</sup> This effect is consistent with the constructs that muscle force decreases as movement velocity increases during concentric contractions and that lower muscle forces minimize joint reaction forces.

**Accommodation to fatigue.** Because the external resistance encountered is directly proportional to the force applied to the resistance arm of the isokinetic unit, lower muscle force output does not necessarily result in cessation of motion. This means that as the contracting muscle fatigues, the patient is still able to perform additional repetitions at the constant velocity even though the force output of the muscle is diminishing.

**Accommodation to a painful arc.** If a patient experiences transient pain at some portion of the arc of motion during exercise and uses less force to move through that arc, isokinetic training accommodates by reducing the external resistance applied to the limb. If the patient stops a resisted motion because of the sudden onset of pain, the external resistance is eliminated as soon as the patient stops pushing against the torque arm of the dynamometer.

## Training Effects and Carryover to Function

Numerous studies have shown that isokinetic training is effective for improving one or more of the muscle performance parameters (strength, power, and endurance).<sup>10,24,76,137,185,197</sup> In contrast, only a limited number of studies have investigated the relationship between isokinetic training and improvement in the performance of functional skills. Two such studies indicated that high-velocity concentric and eccentric isokinetic training was associated with increased velocity of a tennis serve and throwing a ball.<sup>78,193</sup>

**TABLE 6.6** Classification of Velocity of Training in Concentric Isokinetic Exercises\*

Classification	Angular Velocity
Isometric	0°/sec
Slow	30°–60°/sec
Medium	60°–180° or 240°/sec
Fast	180 or 240°–360°/sec or greater

\*Training velocities tend to be substantially slower for eccentric training, ranging from 30° to 120°/sec with most eccentric training initiated between 60° and 120°/sec.

**Limitations in carryover.** Several factors inherent in the design of most types of isokinetic equipment may limit the extent to which isokinetic training carries over to improvements in functional performance. Although isokinetic training affords a spectrum of velocities for training, the velocity of limb movement during many daily living and sport-related activities far exceeds the maximum velocity settings available on isokinetic equipment. In addition, limb movements during most functional tasks occur at multiple velocities, not at a constant velocity, depending on the conditions of the task.

Furthermore, isokinetic exercise usually isolates a single muscle or opposing muscle groups, involves movement of a single joint, is uniplanar, and does not involve weight bearing. Although isolation of a single muscle can be beneficial in remediating strength deficits, most functional activities require contraction of multiple muscle groups and movement spanning multiple joints in several planes of motion. It is important to note, however, that some of these limitations can be addressed by adapting the setup of the equipment to allow multi-axis movements in diagonal planes, multijoint resisted movements, or closed-chain training.

## Special Considerations for Isokinetic Training

### Availability of Equipment

From a pragmatic perspective, one limitation of isokinetic exercise is that a patient can incorporate this form of exercise into a rehabilitation program only by going to a facility where the equipment is available. In addition, the patient will require assistance to set up the equipment and may need supervision during exercise. These availability considerations contribute to the high costs associated with a rehabilitation program using isokinetic dynamometry.

### Appropriate Setup

The positioning recommended by the product manufacturers may need to be altered to ensure that the exercise is safe for a particular joint. For example, although the 90°/90° position of the shoulder and elbow is recommended for strengthening the shoulder rotators, it may be safer to exercise the patient in the resting position or with the arm at the side.

### Initiation and Progression of Isokinetic Training During Rehabilitation

Isokinetic training typically is begun in the later stages of rehabilitation, when active motion through the full or available ROM is pain-free. Suggested guidelines for implementation and progression are summarized in Box 6.10.<sup>4,53,76,116</sup>

## Open Kinetic Chain and Closed Kinetic Chain Exercise

### Background

In clinical practice and the rehabilitation literature, functional activities and exercises are often categorized as having weight-bearing or nonweight-bearing characteristics. The descriptors

### BOX 6.10 Progression of Isokinetic Training for Rehabilitation

- Initially, to keep resistance low, submaximal isokinetic exercise is implemented before maximal effort isokinetic exercise.
- When avoiding an unstable or painful portion of the ROM is necessary, short-arc movements are used before full-arc motions.
- Slow to medium training velocities (60°–180°/sec) are used before progressing to faster velocities.
- Maximal concentric contractions at multiple velocities are performed before introducing eccentric isokinetic exercises for the following reasons:
  - Concentric isokinetic exercise is easier to learn and is fully under the control of the patient.
  - The velocity of movement of the resistance arm is not controlled by the patient during eccentric isokinetic exercise but is robotically controlled by the dynamometer.

closed kinetic chain and open kinetic chain are commonly used and are similar in meaning to weight bearing and nonweight bearing, respectively. These concepts, extended to the analysis of human movement during the 1950s by Steindler,<sup>244</sup> were proposed to provide a system for classifying two unique approaches to function and exercise.

Steindler<sup>244</sup> described the open kinetic chain as the combination of sequentially arranged joints in which the terminal segment is free to move. He proposed that the term applies to completely unrestricted movement in space of a peripheral segment of the body, as in waving the hand or swinging the leg. Open-chain exercises typically focus on motion at a single joint. In contrast, closed kinetic chain exercises are those in which the terminal segment meets considerable external resistance such that distal movement is restrained. This implies that with the terminal segment fixed, external resistance moves proximal segments and joints over the stationary distal segment. Closed kinetic chain exercises are said to emphasize joint compression and are considered more functional in nature than open kinetic chain exercises. Both Steindler and Brunnstrom noted that the action of a muscle changes when the terminal segment is free to move versus when it is fixed in place. For example, in an open kinetic chain the tibialis posterior muscle functions to invert and plantarflex the foot and ankle. In contrast, during the stance phase of gait, the tibialis posterior functions to first decelerate pronation of the subtalar joint and then supinate the same joint to improve foot rigidity for terminal push-off.

### Controversy and Inconsistency in Use of Open-Chain and Closed-Chain Terminology

Although this terminology to describe exercises is prevalent in clinical practice and the rehabilitation literature, there is lack of consensus about how—or even if—it should be used

and about what constitutes an open kinetic chain versus a closed kinetic chain exercise.<sup>25,67,68,118,239,275</sup>

One source of inconsistency is whether or not weight bearing is an inherent component of closed kinetic chain activities. Steindler<sup>244</sup> did not specify that weight bearing must occur for a motion to be categorized as closed kinetic chain, but many of his examples, particularly in the lower extremities, involved weight bearing. In the rehabilitation literature, closed kinetic chain exercises both do<sup>57,93</sup> and do not<sup>122,239</sup> include weight bearing as a necessary element. One resource suggests that all weight-bearing exercises involve some elements of closed kinetic chain activity, but not all closed kinetic chain exercises are performed in weight-bearing positions.<sup>239</sup> For example, squat exercises are considered a weight-bearing and closed kinetic chain activity, while leg press exercises are not weight bearing yet may be considered closed kinetic chain.

Another point of ambiguity is whether or not the terminal segment must be absolutely fixed in place on a surface to be classified as a closed kinetic chain motion. Although Steindler<sup>244</sup> described this as one condition of a closed kinetic chain motion, another condition allows that if the “considerable external resistance” is overcome, there can be movement of the terminal segment. These two concepts can appear to be at odds with each other, creating uncertainty regarding the correct use of this terminology.

Lifting a handheld weight or pushing against the force arm of an isokinetic dynamometer are consistently cited in the literature as examples of open kinetic chain exercises.\* Although there is no axial loading in these exercises, if the terminal segment is overcoming considerable external resistance an argument could be made for calling these closed kinetic chain exercises.\*<sup>56,57,79,93,122,221,245,275,280</sup>

Given the complexity of human movement, it is not surprising that a single classification system using two descriptors cannot adequately classify the multitude of movements found in functional activities and therapeutic exercise interventions.

### Alternatives to Open Kinetic Chain and Closed Kinetic Chain Terminology

To address the unresolved issues associated with this terminology, several authors have offered alternative or additional terms to classify activities and exercises. One suggestion is to use the terms, *distally fixated* and *nondistally fixated* instead of closed kinetic chain and open kinetic chain.<sup>196</sup> The terms *distal segment fixed* and *distal segment free* are also commonly used substitutes. Another suggestion is to add a third descriptor dubbed *partial kinetic chain*<sup>275</sup> to describe exercises in which the distal segment (hand or foot) meets resistance but is not absolutely stationary, such as using a leg press machine, stepping machine, or slide board. The term *closed kinetic chain* is then reserved for instances when the terminal segment does not move.

Another classification system categorizes exercises as either *joint isolation exercises* (movement of only one joint segment)

or *kinetic chain exercises* (simultaneous movement of multiple segments linked by more than one joint).<sup>153,213</sup> Boundaries of movement of the distal segment (movable or stationary) or loading conditions (weight bearing or nonweight bearing) are not parameters of this terminology. However, other, more complex classification systems do take these conditions into account.<sup>68,174</sup>

An additional option is to describe the specific conditions of exercises, where most open kinetic chain exercises are described as single-joint nonweight-bearing exercises and most closed kinetic chain exercises are identified as multiple-joint weight-bearing exercises.<sup>126</sup>

Despite the suggested alternatives, open and closed kinetic chain terminology continues to be widely used in clinical practice and the literature.† Therefore, recognizing the inconsistencies and limitations of the terminology and that many exercises and functional activities involve a combination of “open” and “closed” conditions, the authors of this textbook will continue to use open and closed kinetic chain terminology to describe exercises. The commonly used shortened versions (open-chain and closed-chain) will also be used throughout the text.†<sup>26,32,56,57,70,76,77,118,122,143,189,250,280</sup>

### Characteristics of Open Kinetic Chain and Closed Kinetic Chain Exercises

The following operational definitions and characteristics of open- and closed-chain exercises are presented for clarity and as the basis for the discussion of exercises described throughout this textbook. The parameters of the definitions are those most frequently noted in the current literature. Common characteristics of open- and closed-chain exercises are compared in Table 6.7.

#### Open-Chain Exercises

Open-chain exercises involve motions in which the distal segment (hand or foot) is free to move in space, without necessarily causing simultaneous motions at adjacent joints.<sup>56,77,79,93,153</sup> Limb movement only occurs *distal* to the moving joint, and muscle activation occurs in the muscles that cross the moving joint. For example, during knee flexion in an open-chain exercise (Fig. 6.10), the action of the hamstrings is independent of recruitment of other hip or ankle musculature. Open-chain exercises also are typically performed in nonweight-bearing positions.<sup>57,93,189,285</sup> During resistance training, the external load is applied to the moving distal segment.<sup>56,77,79,93,122,153,189,239,275</sup>

#### Closed-Chain Exercises

Closed-chain exercises involve motions in which the body or proximal segments move on a distal segment that is fixed or stabilized on a support surface. Movement at one joint causes simultaneous motions at distal and proximal joints in a relatively predictable manner. For example, when performing a bilateral short-arc squatting motion (mini-squat) (Fig. 6.11) and then returning to an erect position, as the knees flex and extend, the hips and ankles move in predictable patterns.

**TABLE 6.7** Characteristics of Open-Chain and Closed-Chain Exercises

Open-Chain Exercises	Closed-Chain Exercises
Distal segment moves in space	Distal segment remains fixed or in contact with support surface
Independent joint movement; no predictable joint motion in adjacent joints	Interdependent joint movements; relatively predictable movement patterns in adjacent joints
Movement of body segments distal to the moving joint only	Movement of body segments may occur distal and/or proximal to the moving joint
Muscle activation occurs predominantly in the prime mover and is isolated to muscles crossing the moving joint	Muscle activation occurs in multiple muscle groups, both distal and proximal to the moving joint
Typically performed in nonweight-bearing positions	Typically but not always performed in weight-bearing positions
Resistance is applied to the moving distal segment	Resistance is applied simultaneously to multiple moving segments
External rotary loading of joints is typical	Axial loading of joints through body-weight is typical
External stabilization (manually or with equipment) often required	Internal stabilization by means of muscle action, joint compression and congruency, and postural control

**FIGURE 6.10** Open-chain resisted knee flexion.

Closed-chain exercises are typically performed in weight-bearing positions.<sup>56,78,93,122,189,285</sup> Examples in the upper extremities include balance activities in quadruped, press-ups from a chair, wall push-offs, or prone push-ups; examples in the lower extremities include lunges, squats, step-up or step-down exercises, or heel rises.

**NOTE:** In this textbook, the scope of closed-chain exercises includes weight-bearing activities in which the distal segment *moves but remains in contact with the support surface*, as when using a bicycle, cross-country ski machine, or stair-stepping machine. In the upper extremities, chin-ups at an overhead bar qualify as a nonweight-bearing closed-chain activity.

**FIGURE 6.11** Bilateral closed-chain resisted hip and knee flexion/extension.

### Rationale for Use of Open-Chain and Closed-Chain Exercises

The rationale for selecting open- or closed-chain exercises is based on the goals of an individualized rehabilitation program and a critical analysis of the potential benefits and

limitations inherent in either form of exercise. Because functional activities involve many combinations of both open- and closed-chain motions, it is appropriate to include task-specific open- and closed-chain exercises into rehabilitation and conditioning programs. Both types can be successfully integrated into treatment sessions and home programs to add training variation and appropriately challenge the patient.

### FOCUS ON EVIDENCE

There is no evidence to support the global assumption that closed-chain exercises are “more functional” than open-chain exercises. A review of the literature by Davies<sup>54</sup> indicated there is a substantial body of evidence that both open- and closed-chain exercises are effective for reducing upper and lower extremity muscle performance deficits. However, of these studies, very few randomized, controlled trials demonstrated that the muscle performance improvements were associated with a reduced functional limitation or improved physical performance.

A summary of the benefits and limitations of open- and closed-chain exercises and the rationale for their use follows. Whenever possible, presumed benefits and limitations or comparisons of both forms of exercise are analyzed in light of existing scientific evidence. Some of the reported benefits and limitations are supported by evidence, while others are often based on opinion or anecdotal reports.

**NOTE:** Most reports and investigations comparing or analyzing open- or closed-chain exercises have focused on the knee, in particular the ACL or patellofemoral joint. Far fewer articles have addressed the application or impact of open- and closed-chain exercises on the upper extremities.

### Isolation of Muscle Groups

Open-chain exercises improve the performance of individual muscles or muscle groups more effectively than closed-chain exercises. The potential for substitute motions that compensate for and mask strength deficits of individual muscles is likely greater with closed-chain exercise than open-chain exercise.

### FOCUS ON EVIDENCE

In a study of the effectiveness of a closed-chain-*only* resistance training program after ACL reconstruction, residual muscle weakness of the quadriceps femoris was identified.<sup>238</sup> The investigators suggested that this residual strength deficit might have been avoided with the inclusion of open-chain quadriceps training in the postoperative rehabilitation program.

### Control of Movements

During open-chain resisted exercises, a greater level of motion control is possible with a *single* moving joint than with multiple moving joints, as occurs during closed-chain training.

With open-chain exercises, stabilization is usually applied externally by a therapist’s manual contacts or with belts or straps. In contrast, during closed-chain exercises the patient most often uses muscular stabilization to control joints or structures proximal and distal to the targeted joint. This improved ability to isolate motion to the target joint during open-chain training is particularly advantageous during the early phases of rehabilitation.

### Joint Approximation

Almost all muscle contractions include a compressive component that approximates the joint surfaces and provides stability to the joint in both open- or closed-chain situations.<sup>175,202,236</sup> Additional joint approximation occurs during weight bearing and is associated with lower levels of shear forces at a moving joint. This has been demonstrated at the knee, with decreased anterior or posterior tibiofemoral translation during weight-bearing activities.<sup>284,285</sup> The joint approximation that occurs with the axial loading and weight bearing during closed-chain exercises is thought to cause an increase in joint congruency, which in turn contributes to stability during the exercise.<sup>56,77</sup>

### Co-activation and Dynamic Stabilization

Because most closed-chain exercises are performed in weight-bearing positions, it is widely assumed that they stimulate joint and muscle mechanoreceptors, facilitate co-activation of agonists and antagonists (co-contraction), and consequently promote dynamic stability.<sup>212,251,265</sup> During a standing squat, for example, the quadriceps and hamstrings contract concurrently to control knee and hip motion, respectively, making this exercise an appropriate choice for improving knee stability. In studies of muscle activation during lower extremity closed-chain exercises, these assumptions have been both supported<sup>31,48,276</sup> and refuted.<sup>80</sup>

Upper extremity closed-chain exercises are also thought to promote co-activation of the scapular and glenohumeral stabilizers and improve dynamic stability of the shoulder complex.<sup>77,275</sup> While plausible, evidence of shoulder girdle muscle co-contraction during weight-bearing exercises, such as a prone push-up or a press-up from a chair, is limited.<sup>170</sup> Some open-chain exercises are also thought to encourage muscle co-contraction. Exercises such as alternating isometrics associated with PNF,<sup>212,251,265</sup> stretch-shortening drills performed in nonweight-bearing positions,<sup>277</sup> use of a Body-Blade® (see Fig. 6.50), and high-velocity isokinetic training may all stimulate co-activation of muscle groups and promote dynamic stability. Evidence of a co-contraction effect using these open-chain approaches is currently limited.

In studies of high-velocity, concentric isokinetic training of knee musculature,<sup>71,117</sup> co-activation of agonist and antagonist muscle groups was noted briefly at the end the range of knee extension. Investigators speculated that the knee flexors contracted eccentrically to decelerate the limb just before contact was made with the extension ROM stop. In contrast, there was no evidence of co-activation of knee musculature during maximum effort, slow-velocity (60° per second)

isokinetic training.<sup>167</sup> It is possible that only high-velocity isokinetic exercise elicits this co-contraction effect.

**PRECAUTION:** High-load, open-chain exercise may have an adverse effect on unstable, injured, or recently repaired joints, as demonstrated in the ACL-deficient knee.<sup>80,143,276,284</sup>

### Proprioception, Kinesthesia, Neuromuscular Control, and Balance

Conscious awareness of joint position and movement is one of the foundations of motor learning during the early phase of training for neuromuscular control of functional movements. After soft tissue or joint injury, proprioception and kinesthesia may be disrupted and alter neuromuscular control. Re-establishing the use of sensory information from the injured region to effectively initiate and control movement is a high priority in rehabilitation.<sup>173</sup> Studies have shown that proprioception and kinesthesia improve after rehabilitation of the ACL-reconstructed knee.<sup>17,171</sup>

It is thought that closed-chain training elicits greater proprioceptive and kinesthetic feedback than open-chain training. Theoretically, because multiple muscle groups are activated across several moving joints, closed-chain exercises trigger sensory receptors in a greater number of muscles and intra-articular and extra-articular structures. The weight-bearing element of closed-chain exercises, which increases joint approximation, is believed to stimulate the mechanoreceptors and enhance sensory input for the control of movement.<sup>122,171-174,221,251,276</sup>

### FOCUS ON EVIDENCE

Despite the assumption that proprioception and kinesthesia are enhanced to a greater extent under closed-chain than open-chain conditions, the evidence is mixed. One study<sup>172</sup> demonstrated that kinesthesia in patients with unstable shoulders improved to a greater extent with a program of closed-chain *and* open-chain exercises compared with a program of open-chain exercises only. In contrast, subjects evaluated for their ability to detect knee position showed no significant differences during closed- versus open-chain conditions.<sup>255</sup>

Lastly, closed-chain training is the obvious choice to improve upright balance and postural control. Balance training is an essential element of rehabilitation for patients after musculoskeletal injuries or surgery to restore functional abilities and reduce the risk of re-injury.<sup>149</sup> Activities and parameters to challenge the body's balance mechanisms are discussed in Chapter 8.

### Carryover to Function and Injury Prevention

There is ample evidence to demonstrate that both open- and closed-chain exercises effectively improve muscle strength, power, and endurance.<sup>54,56,57</sup> Evidence also suggests that if there is a comparable level of external loading applied to a muscle group, EMG activity is similar regardless of whether open-chain or closed-chain exercises are performed.<sup>25,68</sup>

That being said, and consistent with the principles of motor learning and task-specific training, if exercises are to have a beneficial effect on functional outcomes, they should be selected based on their ability to simulate the patients' functional requirements and goals.<sup>56,118,239,275</sup>

### FOCUS ON EVIDENCE

In a study of 24 healthy subjects, closed-chain barbell squats and open-chain isokinetic knee extension were compared for their effects on a vertical jump test. Subjects were randomized into two groups and trained twice each week for 6 weeks, progressively increasing the amount of external resistance used for exercise. The closed chain group improved 10% in their vertical jump performance, while the open-chain group did not improve relative to their baseline performance.<sup>15</sup> Closed-chain training, specifically a program of jumping activities, has also been shown to decrease landing forces through the knees and reduce the risk of knee injuries in female athletes.<sup>129</sup>

### Implementation and Progression of Open-Chain and Closed-Chain Exercises

Principles and general guidelines for the implementation and progression of open-chain and closed-chain exercises are similar with respect to variables such as intensity, volume, frequency, and rest intervals. These variables were discussed earlier in the chapter. Relevant features of closed-chain exercises and guidelines for progression are summarized in Table 6.8.

#### Introduction of Open-Chain Training

Because open-chain training typically is performed in non-weight-bearing postures, it may be the only option when weight bearing is contraindicated or must be significantly restricted. Soft tissue pain and swelling or restricted motion of any segment of the chain may also necessitate the use of open-chain exercises at adjacent joints. For example, after a tibia fracture the lower extremity is usually immobilized in a long leg cast and weight bearing is restricted for at least a few weeks. During this period, open-chain hip strengthening exercises can still be initiated and gradually progressed until partial weight-bearing and closed-chain activities are permissible.

Any activity that involves open-chain motions can be easily replicated with open-chain exercises, first by developing isolated control and strength of the weak musculature and then by combining motions to simulate functional patterns.

#### Closed-Chain Exercises and Weight-Bearing Restrictions: Use of Unloading

If weight bearing must be restricted, a safe alternative to open-chain exercises may be to perform closed-chain exercises while partial weight bearing on the involved extremity. This is simple to achieve in the upper extremity; but in the lower extremity, because the patient is in an upright position during

**TABLE 6.8** Parameters and Progression of Closed-Chain Exercises

Parameters	Progression
% Body weight	Partial → full weight-bearing (LE: aquatic exercise, parallel bars, overhead harnessing; UE: wall push-up → modified prone push-up → prone push-up) Full weight bearing + additional weight (weighted vest or belt, handheld or cuff weights, elastic resistance)
Base of support	Wide → narrow Bilateral → unilateral Fixed on support surface → sliding on support surface
Support surface	Stable → unstable/moving (LE: floor → rocker board, wobble board, sideboard, treadmill) (UE: floor, table or wall → rocker or side board, ball) Rigid → soft (floor, table → carpet, foam) Height: ground level → increasing height (low step → high step)
Balance	With external support → no external support Eyes open → eyes closed
Excursion of limb movement	Small → large ranges Short arc → full arc (if appropriate)
Plane or direction of movement	Uniplanar → multiplanar Anterior → posterior → diagonal (forward walking → retrowalking; forward step-up → backward step-up) Sagittal → frontal or transverse (forward-backward sliding → side to side sliding; forward or backward step-up → lateral step-up)
Speed of movement or directional changes	Slow → fast

closed-chain exercises, axial loading in one or both lower extremities must be reduced.

Two methods for reducing lower extremity weight bearing during closed-chain exercise are aquatic therapy, as described in Chapter 9, or using parallel bars to unload the limb during standing. The buoyancy of water assists with lower extremity unloading, but the resistance of the water can limit movement velocity and pools are not always accessible. A limitation of using parallel bars is the difficulty in controlling the amount

of weight bearing during exercises. An alternative strategy, if available, is the use of a bodyweight-supported treadmill training system to unload the lower extremities.<sup>151</sup> These systems enable the patient to perform a variety of closed-chain exercises and to begin ambulation at functional speeds early in rehabilitation.

### Progression of Closed-Chain Exercises

The parameters and suggestions for progression of closed-chain activities noted in Table 6.8 are not all inclusive and are flexible. As a rehabilitation program progresses, more advanced forms of closed-chain training, such as plyometric training and agility drills (discussed in Chapter 23), can be introduced.<sup>58,79</sup> The selection and progression of activities is always based on the discretion of the therapist as they consider the patient's response to the current exercises and their functional needs.

## General Principles of Resistance Training

The principles of resistance training presented in this section apply to both manual and mechanical resistance exercises for persons of all ages, but they are not hard and fast rules. There are many instances when these principles may need to be modified based on therapist judgment. Additional guidelines specific to the application of manual resistance exercise, PNF, and mechanical resistance exercise are addressed in later sections of this chapter.

### Examination and Evaluation

As with all forms of therapeutic exercise, a comprehensive examination and evaluation is the cornerstone of an individualized resistance training program. Therefore, prior to initiating any form of resistance exercise:

- Perform a thorough examination of the patient, including a health history, systems review, and selected tests and measurements.
  - Determine qualitative and quantitative baselines of strength, muscular endurance, ROM, and overall level of functional performance against which progress can be measured.
  - Administer a standardized outcome measure that is valid and reliable for the patient's condition.
- Evaluate the findings to determine if the use of resistance exercise is appropriate or inappropriate at this time. Some questions that may help with this interpretation are noted in Box 6.11. Be sure to identify the most functionally relevant impairments, the goals the patient is seeking to achieve, and the expected functional outcomes of the exercise program.
- Establish how resistance training will be integrated into the plan of care with other therapeutic exercise interventions,

### BOX 6.11 Is Resistance Training Appropriate? Questions to Consider

- Were deficits in muscle performance identified? If so, do these deficits appear to be contributing to limitations of functional abilities that you have observed or that the patient or family has reported?
- Could identified muscle performance deficits cause future functional limitations?
- What is the irritability and current stage of healing of involved tissues?
- Is there evidence of tissue swelling?
- Is there pain? If so, is pain present at rest or with movement, noted at a specific portion of the ROM, or located in specific tissues?
- Are there other deficits such as impaired mobility, balance, sensation, coordination, or cognition that are adversely affecting muscle performance?
- What are the patient's goals or desired functional outcomes? Are they realistic in light of the identified muscle performance deficits?
- Given the patient's current status, are resistance exercises indicated? Contraindicated?
- Will the identified muscle performance deficits be eliminated or minimized with resistance exercises?
- Should one type of muscle performance be emphasized over another?
- Will the patient require supervision or assistance over the course of the exercise program or can the program be carried out independently?
- What is the expected frequency and duration of the resistance training program? Will a maintenance program be necessary?
- Are there any precautions specific to the patient's physical status, general health, or age that may warrant special consideration?

such as stretching, joint mobilization techniques, balance training, and cardiopulmonary conditioning exercises.

- Re-evaluate periodically to document progress and determine if and how the dosage of exercises (intensity, volume, frequency, and rest) and the types of resistance exercise should be adjusted to continue to challenge the patient.

### Preparation for Resistance Exercises

- Select and prescribe the forms of resistance exercise that are appropriate and expected to be effective, such as choosing manual or mechanical resistance exercises, or both.
- If implementing mechanical resistance exercise, determine what equipment is needed and available.
- Review the anticipated goals and expected functional outcomes with the patient.
- Explain the exercise plan and procedures. Be sure that the patient and/or family understands and gives consent.

- Have the patient wear nonrestrictive clothing and supportive shoes appropriate for exercise.
- If possible, select a firm but comfortable support surface for exercise.
- Demonstrate each exercise and the desired movement pattern.

### Implementation of Resistance Exercises

**NOTE:** These general guidelines apply to the use of *dynamic* exercises against manual *or* mechanical resistance. In addition to these guidelines, refer to special considerations and guidelines unique to the application of manual and mechanical resistance exercises in the chapter sections that follow.

#### Warm-Up

Warm-up prior to resistance exercises using light, repetitive, dynamic, site-specific movements without applying resistance. For example, prior to lower extremity resistance exercises, have the patient walk on a treadmill for 5 to 10 minutes followed by flexibility exercises for the trunk and lower extremities.

#### Placement of Resistance

- Resistance is most often applied to the distal end of the segment on which the muscle to be strengthened attaches. For example, to strengthen the anterior deltoid, resistance is applied to the distal humerus as the patient flexes the shoulder (Fig. 6.12). Distal placement of resistance generates the greatest amount of external torque with the least amount of manual or mechanical resistance.
- Resistance may be applied across an intermediate joint if that joint is stable and pain-free and if there is adequate muscle strength supporting the joint. For example, to strengthen the anterior deltoid using mechanical resistance, a handheld weight is a common source of resistance.

**FIGURE 6.12** Resistance (R) is applied to the distal end of the segment being strengthened. Resistance is applied in the *direction opposite* to that of limb movement to resist a concentric muscle contraction and in the *same direction* as limb movement to resist an eccentric contraction.

- If pressure from the external load is uncomfortable for the patient, the therapist can either change the location of resistance or enlarge the area over which the resistance is applied.

### Direction of Resistance

During concentric exercise resistance is applied in the direction directly opposite to the desired motion, whereas during eccentric exercise resistance is applied in the same direction as the desired motion (see Fig. 6.12). When using manual resistance, the force will be most mechanically effective if applied perpendicular to the segment through the entire arc of motion.

### Stabilization

Stabilization is necessary to avoid unwanted, substitute motions.

- For nonweight-bearing resisted exercises, external stabilization is applied to the proximal segment on which the muscle to be strengthened attaches. For example, with biceps brachii muscle strengthening, stabilization should occur at the anterior shoulder as elbow flexion is resisted (Fig. 6.13). When appropriate, belts or straps can be effective sources of external stabilization.
- During multijoint resisted exercises in weight bearing, the patient must use muscle activation and control to stabilize nonmoving segments.

**FIGURE 6.13** Stabilization is applied at the proximal attachment of the muscle being strengthened. In this figure, the proximal humerus and scapula are stabilized as elbow flexion is resisted.

### Intensity of Exercise/Amount of Resistance

**NOTE:** The intensity of the exercise must be consistent with the intended goals of resistance training and the type of muscle contraction as well as other aspects of dosage.

- Initially, have the patient practice the movement pattern against a minimal load to learn the correct exercise technique.
- Have the patient exert a forceful but controlled and pain-free effort. The level of resistance should be such that movement performance is smooth and nonballistic.
- Adjust the alignment, stabilization, or the amount of resistance if the patient is unable to complete the available ROM, muscular tremor develops, or substitute motions occur.

### Number of Repetitions, Sets, and Rest Intervals

- In general, for most adults, use 8 to 12 repetitions of a specific motion against a moderate exercise load. This quantity typically induces the expected acute and chronic responses of muscular fatigue and adaptive gains in muscular strength.
- Decrease the amount of resistance if the patient cannot complete the minimum target number of 8 repetitions.
- After a brief rest, perform additional repetitions—a second set of 8 to 12 repetitions, if possible.
- For progressive overloading, initially increase the number of repetitions or sets; at a later point in the exercise program, gradually increase the resistance.

### Verbal or Written Instructions

When teaching an exercise using mechanical resistance or when applying manual resistance, use simple instructions that are easily understood. Do not use medical terminology or jargon. For example, tell the patient to “Bend and straighten your elbow” rather than “Flex and extend your elbow.” Be sure that descriptions of resistance exercises to be performed as part of a home program are written and clearly illustrated.

### Monitoring the Patient

Observe the patient execute the exercises and modify any ineffective or incorrectly performed techniques (position, stabilization, speed, and fatigue). Assess the patient’s responses before, during, and after exercise using combinations of subjective and objective information. Regularly monitor the patient’s vital signs to evaluate the physiological responses to exercise relative to subjective and objective information. Adhere to relevant precautions discussed in the next section of the chapter.

### Cool-Down

Cool-down after a series of resistance exercises using rhythmic, unresisted movements such as arm swinging, walking, or stationary cycling. Gentle stretching is also appropriate after resistance exercise.

## Precautions for Resistance Exercise

Regardless of the goals of a resistance exercise program and the types of exercises prescribed and implemented, the exercises must not only be effective but *safe*. The therapist's interpretation of the examination's findings will help determine effectiveness, while awareness of precautions maximizes patient safety. General precautions for resistance training are summarized in Box 6.12. Additional information about several of these precautions is presented in the following section.

### Valsalva Maneuver

The Valsalva maneuver or phenomenon, defined as an expiratory effort against a closed glottis, must be avoided during resistance exercise. The Valsalva maneuver is characterized by the following sequence. A deep inspiration is followed by

#### BOX 6.12 General Precautions During Resistance Training

- Keep the ambient temperature of the exercise setting comfortable for vigorous exercise.
- Select clothing for exercise that facilitates heat dissipation and sweat evaporation.
- Caution the patient that pain should *not* occur *during* exercise.
- Do not initiate resistance training at a maximal level of resistance, particularly with eccentric exercise to minimize delayed-onset muscle soreness (DOMS). Use light to moderate exercise during the recovery period.
- Avoid use of heavy resistance during exercise for children, older adults, and patients with osteoporosis.
- Do not apply resistance across an unstable joint or distal to a fracture site that is not completely healed.
- Have the patient avoid breath-holding during resisted exercises to prevent the Valsalva maneuver; emphasize exhalation during exertion.
- Avoid uncontrolled, ballistic movements as they compromise safety and effectiveness.
- Prevent incorrect or substitute motions by adequate stabilization and an appropriate level of resistance.
- Avoid exercises that place excessive, unintended secondary stress on the back.
- Be aware of medications a patient is using that can alter acute and chronic responses to exercise.
- Avoid cumulative fatigue due to excessive frequency of exercise and the effects of overtraining or overwork. Incorporate adequate rest intervals between exercise sessions to allow adequate time for recovery.
- Discontinue exercises if the patient experiences pain, dizziness, or unusual or precipitous shortness of breath.

closure of the glottis and contraction of the abdominal muscles. This increases intra-abdominal and intrathoracic pressures, which in turn forces blood from the heart, causing an abrupt, temporary increase in arterial blood pressure.<sup>144</sup>

During exercise the Valsalva phenomenon occurs most often with *high-effort* isometric<sup>87</sup> and dynamic<sup>179</sup> muscle contractions. It has been shown that the rise in blood pressure induced by an isometric muscle contraction is proportional to the percentage of maximum voluntary force exerted.<sup>179</sup> A Valsalva maneuver superimposed on a maximum effort contraction will increase the risk of cardiovascular injury. Although the Valsalva phenomenon is thought to occur most often with isometric<sup>87,144</sup> and eccentric<sup>59</sup> resistance exercise, a recent study<sup>179</sup> indicated that the rise in blood pressure appears to be based more on extent of effort—not strictly on the type (mode) of muscle contraction.

### At-Risk Patients

The risk of complications from a rapid rise in blood pressure is particularly high in patients with a history of coronary artery disease, myocardial infarction, cerebrovascular disorders, or hypertension. Also at risk are patients who have undergone neurosurgery or eye surgery or who have intervertebral disk pathology. The breathing of high-risk patients must be monitored closely during exercise.

#### CLINICAL TIP

Although resistance training is often recommended for individuals at risk for or a history of cardiovascular disorders, it is important to determine those individuals for whom resistance training is safe and appropriate. In addition to knowledge of screening guidelines for resistance training,<sup>6</sup> close communication with a patient's physician is essential. After clearance for exercise, low-intensity resistance training (30% to 40% intensity for upper body exercises and 50% to 60% intensity for lower body exercises) is recommended.<sup>6</sup>

### Risk Prevention During Resistance Exercise

- Caution the patient about breath-holding.
- Ask the patient to breathe rhythmically, count, or talk during exercise.
- Have the patient exhale when lifting and inhale when lowering an exercise load.<sup>8</sup>
- Restrict high-risk patients from doing high-intensity resistance exercises.

### Substitute Motions

When the external resistance is too great for the target muscle to manage during exercise, substitute motions can occur. Similarly, when muscle performance declines during exercise because of fatigue or pain, a patient may recruit other muscles or use alternate movements to compensate.<sup>152</sup> For example,

if the deltoid or supraspinatus muscles are weak or abduction of the arm is painful, a patient may elevate the scapula and laterally flex the trunk to the opposite side to elevate the arm. To avoid substitute motions during exercise, the appropriate amount of resistance must be applied and correct stabilization must be used.

## Overtraining and Overwork

Exercise programs, in which heavy resistance is applied or exhaustive training is performed repeatedly, must be progressed cautiously to avoid a problem known as overtraining or overwork. These terms refer to deterioration in muscle performance and physical capabilities (either temporary or permanent) that can occur in healthy individuals or in patients with certain neuromuscular disorders.

In most instances, the uncomfortable sensation associated with acute muscle fatigue induces an individual to cease exercising. This is not necessarily the case in highly motivated athletes who are said to be *overreaching* in their training program<sup>101</sup> or in patients who may not adequately sense fatigue because of impaired sensation associated with a neuromuscular disorder.<sup>211</sup>

### Overtraining

The term *overtraining* is commonly used to describe a decline in physical performance in healthy individuals participating in high-intensity, high-volume strength and endurance training programs.<sup>101,166</sup> The terms *chronic fatigue*, *staleness*, and *burnout* are also used to describe this phenomenon. When overtraining occurs, the individual progressively fatigues more quickly and requires more time to recover from strenuous exercise because of physiological and psychological factors.

Overtraining is brought on by inadequate rest intervals between exercise sessions, too rapid progression of exercises, and inadequate diet and fluid intake. Fortunately, in healthy individuals, overtraining is a preventable, reversible phenomenon that can be resolved by periodically decreasing the volume and frequency of exercise.<sup>101,161,164,166</sup>

### Overwork

The term *overwork*, sometimes called *overwork weakness*, refers to progressive deterioration of strength in muscles already weakened by nonprogressive neuromuscular disease.<sup>211</sup> This phenomenon was first observed more than 50 years ago in patients recovering from polio who were actively involved in rehabilitation.<sup>21</sup> In many instances the decrement in strength that was noted was permanent or prolonged. More recently, overwork weakness has been reported in patients with other nonprogressive neuromuscular diseases, such as Guillain-Barré syndrome.<sup>52</sup> Postpolio syndrome is also thought to be related to long-term overuse of weak muscles.<sup>90</sup>

Overwork weakness has been experimentally produced in laboratory animals,<sup>124</sup> providing some insight into its cause. When strenuous exercise was initiated soon after a peripheral nerve lesion, the return of functional motor strength was

slowed, suggesting excessive protein breakdown in the denervated muscle.

Prevention is the key to dealing with overwork weakness. Patients in resistance exercise programs who have impaired neuromuscular function or a systemic, metabolic, or inflammatory disease that increases susceptibility to muscle fatigue must be monitored closely, progressed slowly and cautiously, and re-evaluated frequently to determine their response to resistance training. These patients should not exercise to exhaustion and should be given longer and more frequent rest intervals during and between exercise sessions.<sup>3,52</sup>

## Exercise-Induced Muscle Soreness

Almost every individual who begins a resistance training program experiences muscle soreness. This effect is especially common in those who are unaccustomed to exercise and if the program includes eccentric exercise. Exercise-induced muscle soreness falls into two categories: acute and delayed onset.

### Acute Muscle Soreness

Acute muscle soreness develops during or directly after strenuous exercise performed to the point of muscle exhaustion.<sup>43</sup> This response occurs from the inadequate blood flow and oxygenation, combined with a temporary build-up of metabolites such as lactic acid and potassium in the exercised muscle.<sup>7,43</sup> The sensation is characterized as a feeling of burning or aching in the muscle. It is thought that the noxious metabolic waste products stimulate free nerve endings and cause pain. This soreness experienced during intense exercise is transient and subsides quickly after stopping the exercise when adequate blood flow and oxygen are restored to the muscle. An appropriate cool-down period of low-intensity exercise (active recovery) can facilitate this process.<sup>49</sup>

### Delayed-Onset Muscle Soreness

With vigorous and unaccustomed resistance training or any form of muscular overexertion, DOMS, which is noticeable in the muscle belly or at the myotendinous junction,<sup>66,97,138</sup> develops approximately 12 to 24 hours after the exercise session. As was already pointed out in the discussion of concentric and eccentric exercise in this chapter, high-intensity eccentric muscle contractions consistently cause the most severe DOMS symptoms.<sup>14,59,72,92,97,207</sup> Box 6.13 lists the signs and symptoms over the time course of DOMS. Although the time course varies, the signs and symptoms, which can last up to 10 to 14 days, gradually dissipate.<sup>14,72,92</sup>

**Etiology of DOMS.** Despite years of research dating back to the early 1900s, the underlying mechanisms (mechanical, neural, or/or cellular) of tissue damage associated with DOMS is still unclear.<sup>42,187</sup> Several theories have been proposed, with some subsequently refuted. Early investigators proposed the *metabolic waste accumulation theory*, which suggested that both acute and delayed-onset muscle soreness

### BOX 6.13 Delayed-Onset Muscle Soreness: Clinical Signs and Symptoms

- Muscle soreness and aching beginning 12 to 24 hours after exercise, peaking at 48 to 72 hours, and subsiding 2 to 3 days later
- Tenderness with palpation throughout the involved muscle belly or at the myotendinous junction
- Increased soreness with passive lengthening or active contraction of the involved muscle
- Local edema and warmth
- Muscle stiffness reflected by spontaneous muscle shortening<sup>62</sup> before the onset of pain
- Decreased ROM during the time course of muscle soreness
- Decreased muscle strength prior to onset of muscle soreness that persists for up to 1 to 2 weeks after soreness has remitted<sup>39</sup>

was caused by a build-up of lactic acid in muscle after exercise. Although this is a source of muscle pain with acute exercise, this theory has been disproved as a cause of DOMS.<sup>266</sup> Multiple studies have shown that it requires only about 1 hour of recovery after exercise to exhaustion to remove almost all lactic acid from skeletal muscle and blood.<sup>97</sup>

The *muscle spasm theory* was also proposed as the cause of DOMS, suggesting that a feedback cycle of pain caused by ischemia and a build-up of metabolic waste products during exercise led to muscle spasm.<sup>65</sup> This build-up, it was hypothesized, caused the DOMS sensation and an ongoing reflex pain-spasm cycle that lasted for several days after exercise. The muscle spasm theory has been discounted in subsequent research that showed no increase in EMG activity and, therefore, no evidence of spasm in muscles with delayed soreness.<sup>2</sup>

Although studies on the specific etiology of DOMS continue, current research seems to suggest that DOMS is linked to some form of contraction-induced, mechanical disruption or microtrauma of muscle fibers and/or connective tissue in and around muscle that results in tissue degeneration.<sup>42,99</sup> Evidence of tissue damage such as elevated blood serum levels of creatine kinase is present for several days after exercise and is accompanied by inflammation and edema.<sup>2,98,99</sup>

The temporary loss of strength and the perception of soreness associated with DOMS appear to occur independently and follow different time courses. Strength deficits develop prior to the onset of soreness and persist after soreness has remitted.<sup>62,204</sup> Thus, force production deficits appear to be the result of muscle damage, possibly myofibrillar damage at the Z bands,<sup>42,203</sup> which directly affects the structural integrity of the contractile units of muscle, rather than neuromuscular inhibition as the result of pain.<sup>203,204</sup>

**Prevention and treatment of DOMS.** Prevention and treatment of DOMS at the initiation of an exercise program have been either ineffective or, at best, marginally successful.

It is a commonly held opinion in clinical and fitness settings that the initial onset of DOMS can be prevented or at least kept to a minimum by progressing the intensity and volume of exercise *gradually*,<sup>46,72</sup> by performing low-intensity warm-up and cool-down activities,<sup>64,72,235</sup> or by gently stretching the exercised muscles before and after strenuous exercise.<sup>64,235</sup> Although these techniques are regularly advocated and employed, little to no evidence in the literature supports their efficacy in the prevention of DOMS.

There is some evidence to suggest that the use of repetitive concentric exercise prior to DOMS-inducing eccentric exercise does not entirely prevent but does reduce the severity of muscle soreness and other markers of muscle damage.<sup>206</sup> Paradoxically, a regular routine of eccentric exercise performed prior to the onset of DOMS or after an initial episode of DOMS has developed can minimize its effects.<sup>7,42,43,46</sup> This response is often referred to as the “repeated-bout effect,” whereby a bout of eccentric exercise protects the muscle from damage from subsequent bouts of eccentric exercise.<sup>187</sup> It may well be that with repeated bouts of the same level of eccentric exercise or activity that caused the initial episode of DOMS, the muscle adapts to the physical stress and prevents additional episodes of DOMS.<sup>7,42,169,187</sup>

To date, the efficacy of DOMS treatment has been mixed. Evidence shows that continuation of a training program that has induced DOMS does not worsen the muscle damage or slow the recovery process.<sup>42,207</sup> Light, high-speed isokinetic, concentric exercise has been reported to reduce muscle soreness and hasten the remediation of strength deficits associated with DOMS,<sup>120</sup> but other reports suggest no significant improvement in strength or relief of muscle soreness with light exercise.<sup>69,267</sup>

The effectiveness of therapeutic modalities and massage techniques is also questionable. Electrical stimulation to reduce soreness has been reported to be effective<sup>62,147</sup> and ineffective.<sup>267</sup> Although cryotherapy, specifically cold water immersion, after vigorous eccentric exercise reduces signs of muscle damage, little to no effect on the perpetuation of muscle tenderness or strength deficit is reported.<sup>81</sup> Also, there is no significant evidence that post-exercise massage, despite its widespread use in sports settings, reduces the signs and symptoms of DOMS.<sup>147,259,267</sup> Other treatments, such as hyperbaric oxygen therapy and nutritional supplements, also have limited benefits.<sup>46</sup> However, use of compression sleeves<sup>160,165</sup> and topical salicylate creams, which provide an analgesic effect, may reduce the severity of and hasten the recovery from DOMS-related symptoms.

### FOCUS ON EVIDENCE

In a prospective study<sup>160,165</sup> of DOMS that was induced by maximal eccentric exercise, the use of a compression sleeve over the exercised muscle group resulted in no increase in circumferential measurements of the upper arm, suggesting the prevention of soft tissue swelling. In participants wearing

a sleeve, there was also a more rapid reduction in the perception of muscle soreness and a more rapid amelioration of deficits in peak torque than in those who did not wear the compression sleeve.

In summary, although some interventions for the treatment of DOMS appear to have potential, a definitive treatment has yet to be determined.

## Pathological Fracture

When an individual has or is at high risk for osteoporosis or osteopenia, the risk of pathological fracture from participating in a resistance exercise program must be considered. *Osteoporosis*, which is discussed in greater detail in Chapter 11 and in Chapter 24, is a systemic skeletal disease characterized by reduced mineralized bone mass that is associated with an imbalance between bone resorption and bone formation, leading to fragility of bones. In addition to the loss of bone mass, there also is narrowing of the bone shaft and widening of the medullary canal.<sup>7,30,168</sup>

The changes associated with osteoporosis make the bone less able to withstand physical stress making them highly susceptible to pathological fracture. A *pathological fracture*, or fragility fracture, is the failure of bone already weakened by disease that results from minor stress to the skeletal system.<sup>30,110,201</sup> Pathological fractures most commonly occur in the vertebrae, femurs, wrists, and ribs.<sup>110,168</sup> Therefore, to design and implement a safe exercise program, a therapist needs to know if a patient has a history of osteoporosis and, as such, an increased risk of pathological fracture. If there is no known history of osteoporosis, the therapist must be able to recognize those factors that place a patient at risk for osteoporosis.<sup>30,51,168</sup> As noted in Chapter 11, postmenopausal women, for example, are at high risk for primary (type I) osteoporosis. Secondary (type II) osteoporosis is associated with prolonged immobilization or disuse, restricted weight bearing, or extended use of certain medications, such as systemic corticosteroids or immunosuppressants.

## Prevention of Pathological Fracture

Numerous studies have demonstrated that physical activity that includes resistance training has positive osteogenic effects. Consequently, in addition to aerobic exercises that involve weight-bearing, resistance exercises have become an essential element of rehabilitation and conditioning programs for individuals with or at risk for osteoporosis.<sup>6,7,218,228</sup> Therefore, individuals who are at risk for pathological fracture often engage in resistance training with a goal of increasing bone density.

Successful, safe resistance training must impose a great enough load to satisfy the overload principle and achieve the goals of the exercise program but not so heavy a load as to cause a pathological fracture. Guidelines and precautions during resistance training to reduce the risk of pathological fracture for individuals with or at risk for osteoporosis are summarized in Box 6.14.<sup>201,218,228</sup>

### BOX 6.14 Resistance Training Guidelines and Precautions to Reduce the Risk of Pathological Fracture

- *Intensity of exercise.* Avoid high-intensity, high-volume weight training. Depending on the severity of osteoporosis, begin weight training at a minimal intensity (40% to 60% of 1-RM) and progress to moderate-intensity (60% to <80% of 1-RM) only if indicated.
- *Repetitions and sets.* Initially, perform only one set of several exercises, using 8 to 12 repetitions of each exercise for the first 6 to 8 weeks.
  - Progress intensity and volume (repetitions) gradually; eventually work up to three or four sets of each exercise at moderate levels of intensity.
- *Frequency.* Perform resistance exercises two to three times per week.
- *Type of exercise.* Integrate weight-bearing activities into resistance training, but use the following precautions:
  - Avoid high-impact activities such as jumping or hopping. Perform most strengthening exercises in weight-bearing postures that involve low impact, such as lunges or step-ups/step-downs against additional resistance (handheld weights, a weighted vest, or elastic resistance).
  - Avoid high-velocity movements.
  - Avoid trunk flexion with rotation and end-range resisted flexion of the spine. Such combinations can place excessive loading on the anterior portion of the vertebrae, potentially resulting in anterior compression fracture, wedging of the vertebral body, and loss of height.
  - Avoid lower extremity weight-bearing activities that involve torsional movements of the hips, particularly if there is evidence of osteoporosis of the proximal femur.
  - To avoid loss of balance during lower extremity exercises while standing, have the patient hold onto a stable surface such as a countertop. If the patient is at high risk for falling or has a history of falls, perform exercises in a chair to provide weight bearing through the spine.
  - In group exercise classes, keep participant-instructor ratios low; for patients at high risk for falling or with a history of previous fracture, consider direct supervision on a one-to-one basis from another trained person.

## Contraindications to Resistance Exercise

There are only a few instances when resistance exercises are contraindicated. Resistance training is most often contraindicated during periods of acute inflammation and with some acute diseases and disorders. By carefully selecting the appropriate type (mode) of exercise (static versus dynamic; weight bearing versus nonweight bearing) and keeping the initial intensity of the exercise at a low to moderate level, adverse effects from resistance training can almost always be avoided.

## Pain

If a patient experiences severe joint or muscle pain during active movements against no external load, dynamic resistance exercises should not be initiated. During testing, if a patient experiences acute muscle pain during a resisted isometric contraction, resistance exercises should not be initiated. Lastly, if a patient experiences pain that cannot be eliminated by reducing the external resistance, the exercise should be stopped.

## Inflammation

Dynamic and static resistance training is absolutely contraindicated in the presence of inflammatory neuromuscular disease. For example, in patients with acute anterior horn cell disease (Guillain-Barré) or inflammatory muscle disease (polymyositis, dermatomyositis) resistance exercises may actually cause irreversible deterioration of strength through damage to muscle. *Dynamic* resistance exercises are contraindicated in the presence of acute inflammation of a joint. The use of dynamic resisted exercise can irritate the joint and cause more inflammation. Gentle setting exercises against negligible resistance are appropriate.

## Severe Cardiopulmonary Disease

Severe cardiac or respiratory diseases or disorders associated with acute symptoms contraindicate resistance training. For example, patients with severe coronary artery disease, carditis, cardiac myopathy, congestive heart failure, or uncontrolled hypertension or dysrhythmias should not participate in vigorous physical activities, including a resistance training program.<sup>6</sup>

After myocardial infarction or coronary artery bypass graft surgery, resistance training should be postponed for at least 5 weeks (that includes participation in 4 weeks of supervised cardiac rehabilitation endurance training) and until clearance from the patient's physician has been received.<sup>6</sup>

# Manual Resistance Exercise

## Definition and Use

*Manual resistance exercise* is a form of active resistive exercise in which the resistance force is applied to either a dynamic or a static muscular contraction by the therapist.

- When joint motion is permissible, resistance is usually applied throughout the available ROM.
- Resistance is applied during exercise carried out in anatomical planes of motion, in diagonal patterns associated with PNF techniques,<sup>159,265</sup> or in combined patterns of movement that simulate functional activities.
- A specific muscle may also be strengthened by resisting the action of that muscle, as described in manual muscle-testing procedures.<sup>132,152</sup>
- In rehabilitation programs, manual resistance exercise, which may be preceded by active-assisted and active exercise, is part

of the continuum of active exercises available to a therapist to improve or restore muscular performance.

There are many advantages to the use of manual resistance exercises, but there also are disadvantages and limitations to this form of resistance exercises. These issues are summarized in Box 6.15.

## Guidelines and Special Considerations

The general principles for the application of resistance exercises discussed in the preceding section of this chapter also apply to manual resistance exercise. In addition, there are some special considerations unique to manual resistance exercises that should be followed. The following guidelines apply to manual resistance exercise carried out in anatomical planes of motion and in diagonal patterns association with PNF.

### BOX 6.15 Manual Resistance Exercise: Advantages and Disadvantages

#### Advantages

- Most effective during the early stages of rehabilitation when muscles are weak (MMT of 4/5 or less).
- Effective form of exercise for transition from assisted to mechanically resisted movements.
- More finely graded resistance than mechanical resistance.
- Resistance is adjusted throughout the ROM as the therapist responds to the patient's efforts or a painful arc.
- Muscle works maximally at all portions of the ROM.
- The range of joint movement can be carefully controlled by the therapist to protect healing tissues or to prevent movement into an unstable portion of the range.
- Useful for dynamic or static strengthening.
- Direct manual stabilization prevents substitute motions.
- Can be performed in a variety of patient positions.
- Placement of resistance is easily adjusted.
- Gives the therapist an opportunity for direct interaction and continuous monitoring of the patient's performance.

#### Disadvantages

- Exercise load (amount of resistance) is subjective; it cannot be measured or quantitatively documented for purposes of establishing a baseline or exercise-induced improvements in muscle performance.
- Amount of resistance is limited to the strength of the therapist; therefore, resistance imposed is not adequate to strengthen already strong muscle groups.
- Speed of movement is slow to moderate, which may not carry over to most functional activities.
- Cannot be performed independently by the patient for most muscle groups.
- Not useful in home program unless caregiver assistance is available.
- Labor and time intensive for the therapist.
- Impractical for improving muscular endurance; too time-consuming.

## Body Mechanics of the Therapist

- Select a treatment table on which to position the patient that is a suitable height or adjust the height of the patient's bed, if possible, to enhance use of proper body mechanics.
- Assume a position close to the patient to avoid stresses on your low back and to maximize control of the patient's upper or lower extremity.
- Use a wide base of support to maintain stability while applying resistance; shift your weight to move as the patient moves his or her limb.

## Application of Manual Resistance and Stabilization

- Review the principles and guidelines for placement and direction of resistance and stabilization (see Figs. 6.12 and 6.13). Stabilize the proximal attachment of the contracting muscle with one hand, when necessary, while applying resistance distally to the moving segment. Use appropriate hand placements (manual contacts) to provide tactile and proprioceptive cues to help the patient better understand in which direction to move.<sup>251</sup>
- Grade and vary the amount of resistance to equal the abilities of the muscle throughout the available ROM.

### CLINICAL TIP

When applying manual resistance, the therapist must possess well-developed skills in order to provide enough resistance to challenge but not overpower the patient's efforts, especially when the patient has significant weakness.

- Gradually apply and release the resistance so movements are smooth, not unexpected or uncontrolled.
- Hold the patient's extremity close to your body so some of the force applied is from the weight of your body not just the strength of your upper extremities. This enables you to apply a greater amount of resistance, particularly as the patient's strength increases.
- When applying manual resistance to alternating isometric contractions of agonist and antagonist muscles to develop joint stability, maintain manual contacts at all times as the isometric contractions are repeated. As a transition is made from one muscle contraction to another, no abrupt relaxation phase or joint movements should occur between the opposing contractions.

## Verbal Commands

- Coordinate the timing of the verbal commands with the application of resistance to maintain control when the patient initiates a movement.
- Use simple, direct verbal commands.
- Use different verbal commands to facilitate isometric, concentric, or eccentric contractions. To resist an *isometric* contraction, tell the patient to "Hold," "Don't let me move you," or "Match my resistance." To resist a *concentric* contraction, tell the patient to "Push" or "Pull." To resist

an *eccentric* contraction, tell the patient to "Slowly let go as I push or pull you."

## Number of Repetitions and Sets/Rest Intervals

- As with all forms of resistance exercise, the number of repetitions is dependent on the response of the patient.
- For manual resistance exercise, the number of repetitions also is contingent on the strength and endurance of the therapist.
- Build in adequate rest intervals for the patient *and* the therapist; after 8 to 12 repetitions, both the patient and the therapist typically begin to experience some degree of muscular fatigue.

## Techniques: General Background

The manual resistance exercise techniques described in this section are for the upper and lower extremities, performed concentrically in anatomical planes of motion. The direction of limb movement would be the opposite if manual resistance were applied to an eccentric contraction. The exercises described are performed in nonweight-bearing positions and involve movements to isolate individual muscles or muscle groups.

Consistent with Chapter 3, most of the exercises described and illustrated in this section are performed with the patient in a *supine position*. Variations in the therapist's position and hand placements may be necessary, depending on the size and strength of the therapist and the patient. Alternative patient positions, such as prone or sitting, are described when appropriate or necessary. Ultimately, a therapist must be versatile and able to apply manual resistance with the patient in all positions to meet the needs of many patients with significant differences in abilities, limitations, and pathologies.

**NOTE:** In all illustrations in this section, the direction in which resistance (R) is applied is indicated with a solid arrow.

Reciprocal motions, such as flexion/extension and abduction/adduction, are often alternately resisted in an exercise program in which strength and balanced neuromuscular control in both agonists and antagonists are desired. Resistance to reciprocal movement patterns also enhances a patient's ability to reverse the direction of movement smoothly and quickly, a neuromuscular skill that is necessary in many functional activities. Reversal of direction requires muscular control of both prime movers and stabilizers and combines concentric and eccentric contractions to decrease momentum and make a controlled transition from one direction to the opposite direction of movement.

Manual resistance in diagonal patterns associated with PNF are described and illustrated in the next section of this chapter. Additional resistance exercises to increase strength, power, endurance, and neuromuscular control in the extremities can be found in Chapters 17 through 23. In these chapters many examples and illustrations of resisted eccentric exercises, exercises in weight-bearing positions, and exercises in functional movement patterns are featured. Resistance exercises for the cervical, thoracic, and lumbar spine are described and illustrated in Chapter 16.

## Upper Extremity

### Shoulder Flexion VIDEO 6.1

#### Hand Placement and Procedure

- Apply resistance to the anterior aspect of the distal arm or to the distal portion of the forearm if the elbow is stable and pain-free (Fig. 6.14).
- Stabilization of the scapula and trunk is provided by the treatment table.

FIGURE 6.14 Resisted shoulder flexion.

### Shoulder Extension

#### Hand Placement and Procedure

- Apply resistance to the posterior aspect of the distal arm or the distal portion of the forearm.
- Stabilization of the scapula is provided by the table.

### Shoulder Hyperextension

The patient assumes the supine position, close to the edge of the table, side-lying, or prone so hyperextension can occur.

#### Hand Placement and Procedure

- Apply resistance in the same manner as for extension of the shoulder.
- Stabilize the anterior aspect of the shoulder if the patient is supine.
- If the patient is side-lying, adequate stabilization must be given to the trunk and scapula. This usually can be done if the patient is positioned close to the edge of the table and the therapist uses their trunk to stabilize.
- If the patient is lying prone, manually stabilize the scapula.

### Shoulder Abduction and Adduction

#### Hand Placement and Procedure

- Apply resistance to the distal arm with the patient's elbow flexed to 90°. To resist abduction (Fig. 6.15), apply resistance

FIGURE 6.15 Resisted shoulder abduction.

to the lateral aspect of the arm. To resist adduction, apply resistance to the medial aspect of the arm.

- Stabilization (although not pictured in Fig. 6.15) is applied to the superior aspect of the shoulder, if necessary, to prevent the patient from *initiating* abduction by shrugging the shoulder (elevation of the scapula).

**PRECAUTION:** Allow the glenohumeral joint to externally rotate when resisting abduction above 90° to avoid impingement.

### Elevation of the Arm in the Plane of the Scapula

#### Hand Placement and Procedure

- Same as previously described for shoulder flexion.
- Apply resistance as the patient elevates the arm in the plane of the scapula (30° to 40° anterior to the frontal plane of the body).<sup>175,211</sup>

#### CLINICAL TIP

Although scapular plane elevation is not a motion of the shoulder that occurs in one of the anatomical planes of the body, resistance in the scapular plane is thought to have its merits. The evidence is inconclusive<sup>227,273</sup> as to whether the torque-producing capabilities of the key muscle groups of the glenohumeral joint are greater when the arm elevates in the plane of the scapula versus the frontal or sagittal planes. However, the glenohumeral joint is considered to be more stable with less risk of soft tissue impingement when strength training is performed in the scapular plane.<sup>183,211</sup> (See additional discussion in Chapter 17.)

### Shoulder Internal and External Rotation

#### Hand Placement and Procedure

- Flex the elbow to 90° and position the shoulder midway between full adduction and 90° abduction. A towel can be placed under the distal arm to approach the plane of the scapula.

- Apply resistance to the distal forearm during internal rotation and external rotation (Fig. 6.16A).
- Stabilize at the level of the clavicle during internal rotation; the back and scapula are stabilized by the table during external rotation.

#### Alternate Procedure

Alternate alignment of the humerus (Fig. 6.16 B). If the mobility and stability of the glenohumeral joint permit, the

**FIGURE 6.16** (A) Resisted external rotation of the shoulder with the shoulder positioned in flexion and abduction (approaching the plane of the scapula). (B) Resisted internal rotation of the shoulder with the shoulder in 90° of abduction.

shoulder can be positioned in 90° of abduction during resisted rotation.

### Shoulder Horizontal Abduction and Adduction

#### Hand Placement and Procedure

- Flex the shoulder and elbow to 90° and place the shoulder in neutral rotation.
- Apply resistance to the distal arm just above the elbow during horizontal adduction and abduction.
- Stabilize the anterior aspect of the shoulder during horizontal adduction. The table stabilizes the scapula and trunk during horizontal abduction.
- To resist horizontal abduction from 0° to 45°, the patient must be close to the edge of the table while supine or be placed side-lying or prone.

### Elevation and Depression of the Scapula

#### Video 6.2

#### Hand Placement and Procedure

- Have the patient assume a supine, side-lying, or sitting position.
- Apply resistance along the superior aspect of the shoulder girdle just above the clavicle during scapular elevation (Fig. 6.17).

**FIGURE 6.17** Elevation of the shoulders (scapulae), resisted bilaterally.

#### Alternate Procedures: Scapular Depression

To resist unilateral scapular depression in the supine position, have the patient attempt to reach down toward the foot and push the hand into the therapist's hand. When the patient has

adequate strength, the exercise can be performed to include weight bearing through the upper extremity by having the patient sit on the edge of a low table and lift the body weight with both hands.

## Protraction and Retraction of the Scapula

### Hand Placement and Procedure

- Apply resistance to the anterior portion of the shoulder at the head of the humerus to resist protraction and to the posterior aspect of the shoulder to resist retraction.
- Resistance may also be applied directly to the scapula if the patient sits or lies on the side, facing the therapist.
- Stabilize the trunk to prevent trunk rotation.

## Elbow Flexion and Extension VIDEO 6.3

### Hand Placement and Procedure

- To strengthen the elbow flexors, apply resistance to the anterior aspect of the distal forearm (Fig. 6.18).
- The forearm may be positioned in supination, pronation, and neutral to resist individual flexor muscles of the elbow.
- To strengthen the elbow extensors, place the patient prone (Fig. 6.19) or supine and apply resistance to the distal forearm.
- Stabilize the upper portion of the humerus during both motions.

FIGURE 6.18 Resisted elbow flexion with proximal stabilization.

FIGURE 6.19 Resisted elbow extension.

## Forearm Pronation and Supination VIDEO 6.4

### VIDEO 6.4

### Hand Placement and Procedure

- Apply resistance to the radius of the distal forearm with the patient's elbow flexed to 90° (Fig. 6.20) to prevent rotation of the humerus.

**PRECAUTION:** Do not apply resistance to the hand to avoid twisting forces at the wrist.

FIGURE 6.20 Resisted pronation of the forearm.

## Wrist Flexion and Extension VIDEO 6.5

### Hand Placement and Procedure

- Apply resistance to the volar and dorsal aspects of the hand at the level of the metacarpals to resist flexion and extension, respectively (Fig. 6.21).
- Stabilize the volar or dorsal aspect of the distal forearm.

**FIGURE 6.21** Resisted wrist flexion and stabilization of the forearm.

## Wrist Radial and Ulnar Deviation

### Hand Placement and Procedure

- Apply resistance to the second and fifth metacarpals alternately to resist radial and ulnar deviation.
- Stabilize the distal forearm.

## Motions of the Fingers and Thumb

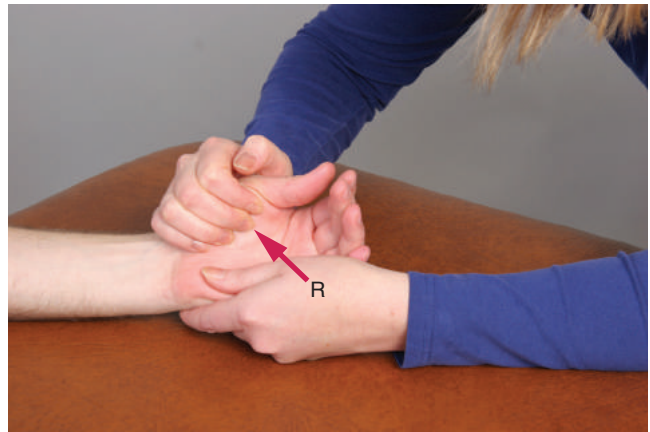

VIDEO 6.6

### Hand Placement and Procedure

- Apply resistance just distal to the joint that is moving. Resistance is applied to one joint motion at a time (Figs. 6.22 and 6.23).
- Stabilize the joints proximal and distal to the moving joint.

**FIGURE 6.22** Resisted flexion of the proximal interphalangeal (PIP) joint of the index finger with stabilization of the metacarpophalangeal (MCP) and distal interphalangeal (DIP) joints.

**FIGURE 6.23** Resisted opposition of the thumb.

## Lower Extremity

### Hip Flexion With Knee Flexion VIDEO 6.7

#### Hand Placement and Procedure

- Apply resistance to the anterior portion of the distal thigh (Fig. 6.24). Simultaneous resistance to knee flexion may be applied at the distal and posterior aspect of the lower leg, just above the ankle.
- Stabilization of the pelvis and lumbar spine is provided by adequate strength of the abdominal muscles.

**PRECAUTION:** If the pelvis rotates anteriorly and lumbar spine lordosis increases during resisted hip flexion, the patient can flex the contralateral hip and knee and plant the foot on the table to stabilize the pelvis and protect the low back region.

**FIGURE 6.24** Resisted flexion of the hip with the knee flexed.

## Hip Extension

#### Hand Placement and Procedure

- Apply resistance to the posterior aspect of the distal thigh with one hand and to the inferior and distal aspect of the heel with the other hand (Fig. 6.25).
- Stabilization of the pelvis and lumbar spine is provided by the table.

**FIGURE 6.25** Resisted hip and knee extension with the hand placed at the popliteal space to prevent hyperextension of the knee.

### Hip Hyperextension

*Patient position:* prone.

#### Hand Placement and Procedure

- With the patient in a prone position, apply resistance to the posterior aspect of the distal thigh (Fig. 6.26).
- Stabilize the posterior aspect of the pelvis to avoid motion of the lumbar spine.

**FIGURE 6.26** Resisted end-range hip extension with stabilization of the pelvis.

### Hip Abduction and Adduction

#### Hand Placement and Procedure

- Apply resistance to the lateral and the medial aspects of the distal thigh to resist abduction (Fig. 6.27) and adduction, respectively, or to the lateral and medial aspects of the distal leg just above the malleoli if the knee is stable and pain-free.
- Stabilization is applied to the pelvis to avoid hip-hiking from substitute action of the quadratus lumborum and to keep the thigh in neutral position to prevent external rotation of the femur and subsequent substitution by the iliopsoas.

**FIGURE 6.27** Resisted hip abduction.

### Hip Internal and External Rotation

*Patient position:* supine with the hip and knee extended.

#### Hand Placement and Procedure

- Apply resistance to the lateral aspect of the distal thigh to resist external rotation and to the medial aspect of the thigh to resist internal rotation.
- Stabilize the pelvis.

*Patient position:* supine with the hip and knee flexed (Fig. 6.28).

**FIGURE 6.28** Resisted external rotation of the hip with the patient lying supine.

### Hand Placement and Procedure

- Apply resistance to the medial aspect of the lower leg just above the malleolus during external rotation and to the lateral aspect of the lower leg during internal rotation.
- Stabilize the anterior aspect of the pelvis as the thigh is supported to keep the hip in 90° of flexion.

*Patient position:* prone, with the hip extended and the knee flexed (Fig. 6.29).

**FIGURE 6.29** Resisted internal rotation of the hip with the patient lying prone.

### Hand Placement and Procedure

- Apply resistance to the medial and lateral aspects of the lower leg.
- Stabilize the pelvis by applying pressure across the buttocks.

### Knee Flexion VIDEO 6.8

- Resistance to knee flexion may be combined with resistance to hip flexion, as described earlier with the patient supine.

*Alternate patient position:* prone with the hips extended (Fig. 6.30).

### Hand Placement and Procedure

- Apply resistance to the posterior aspect of the lower leg just above the heel.
- Stabilize the posterior pelvis across the buttocks.

*Additional patient position:* sitting at the edge of a table with the hips and knees flexed and the back supported and stabilized.

**FIGURE 6.30** Resisted knee flexion with stabilization of the hip.

### Knee Extension

#### Alternate Patient Positions

- If the patient is lying supine on a table, the hip must be abducted and the knee flexed so the lower leg is over the side of the table. This position should not be used if the rectus femoris or iliopsoas is tight because it causes an anterior tilt of the pelvis and places stress on the low back.
- If the patient is prone, place a rolled towel under the anterior aspect of the distal thigh; this allows the patella to glide normally during knee extension.
- If the patient is sitting, place a rolled towel under the posterior aspect of the distal thigh (Fig. 6.31).

**FIGURE 6.31** Resisted knee extension with the patient sitting and stabilizing the trunk with the upper extremities and the therapist stabilizing the thigh.

### Hand Placement and Procedure

- Apply resistance to the anterior aspect of the lower leg.
- Stabilize the femur, pelvis, or trunk as necessary.

### Ankle Dorsiflexion and Plantarflexion VIDEO 6.9

#### Hand Placement and Procedure

- Apply resistance to the dorsum of the foot just above the toes to resist dorsiflexion (Fig. 6.32 A) and to the plantar surface of the foot at the metatarsals to resist plantarflexion (Fig. 6.32 B).
- Stabilize the lower leg.

**FIGURE 6.32** (A) Resisted dorsiflexion. (B) Resisted plantarflexion of the ankle.

### Ankle Inversion and Eversion

#### Hand Placement and Procedure

- Apply resistance to the medial aspect of the first metatarsal to resist inversion and to the lateral aspect of the fifth metatarsal to resist eversion.
- Stabilize the lower leg.

### Flexion and Extension of the Toes

#### Hand Placement and Procedure

- Apply resistance to the plantar and dorsal surfaces of the toes as the patient flexes and extends the toes.
- Stabilize the joints above and below the joint that is moving.

## Proprioceptive Neuromuscular Facilitation: Principles and Techniques

PNF is an approach to therapeutic exercise that combines functionally based diagonal patterns of movement with techniques of neuromuscular facilitation to evoke motor responses and improve neuromuscular control and function. This widely used approach to exercise was developed during the 1940s and 1950s by the pioneering work of Kabat, Knott, and Voss.<sup>159</sup> Their work integrated the analysis of movement during functional activities with then current theories of motor development, control, and learning and principles of neurophysiology as the foundations of their approach to exercise and rehabilitation. Long associated with neurorehabilitation, PNF techniques also have widespread application for rehabilitation of patients with musculoskeletal conditions that result in altered neuromuscular control of the extremities, neck, and trunk.<sup>127,251,263</sup>

PNF techniques can be used to develop muscular strength and endurance; to facilitate stability, mobility, neuromuscular control, and coordinated movements; and to lay a foundation for the restoration of function. PNF techniques are useful throughout the continuum of rehabilitation from the early phase of tissue healing when isometric techniques are appropriate to the final phase of rehabilitation when high-velocity, diagonal movements can be performed against maximum resistance.

Hallmarks of this approach to therapeutic exercise are the use of diagonal patterns and the application of sensory cues—specifically proprioceptive, cutaneous, visual, and auditory stimuli—to elicit or augment motor responses. Embedded in this philosophy and approach to exercise is that the stronger muscle groups of a diagonal pattern facilitate the responsiveness of the weaker muscle groups. The focus of discussion of PNF in this chapter deals with the use of PNF patterns and techniques as an important form of resistance exercise for the

development of strength, muscular endurance, and dynamic stability.

Although PNF patterns for the extremities can be performed unilaterally or bilaterally and in a variety of weight-bearing and nonweight-bearing positions, only unilateral patterns with the patient in a supine position are described and illustrated. In Chapter 4 of this text the use of several PNF stretching techniques are described. As noted in Chapter 3, diagonal patterns can also be used for passive and active ROM. Additional application of diagonal patterns for the extremities and trunk, some using resistance equipment, are described in the regional chapters later in this text.

## Diagonal Patterns

PNF patterns are composed of *multijoint, multiplanar, diagonal*, and *rotational* movements of the extremities, trunk, and neck. Multiple muscle groups contract simultaneously during the execution of these patterned motions. There are two pairs of diagonal patterns that can be used for the upper and lower extremities: diagonal 1 ( $D_1$ ) and diagonal 2 ( $D_2$ ). Each diagonal pattern can be performed when moving in either a flexion or extension direction. Hence, the terminology used is  $D_1$ Flexion or  $D_1$ Extension and  $D_2$ Flexion or  $D_2$ Extension of the upper or lower extremities. The patterns encompass motion at each joint of the extremity but are identified by the

motions that occur at the most proximal joints—the shoulder or the hip. In other words, a pattern is named by *the position of the shoulder or hip when the diagonal pattern has been completed*. Within each pattern, flexion or extension is coupled with abduction or adduction as well as external or internal rotation. Table 6.9 summarizes the component motions of each of the diagonal patterns.

As mentioned, the diagonal patterns can be carried out unilaterally or bilaterally. Bilateral patterns can be done *symmetrically* (e.g.,  $D_1$ Flexion of both extremities), *asymmetrically* ( $D_1$ Flexion of one extremity coupled with  $D_2$ Flexion of the other extremity), or *reciprocally* ( $D_1$ Flexion of one extremity and  $D_1$ Extension of the opposite extremity). Furthermore, there are patterns specifically for the scapula or pelvis and techniques that integrate diagonal movements into functional activities, such as rolling, crawling, and walking. There are several in-depth resources that describe and illustrate the many variations and applications of PNF techniques.<sup>212,251,265</sup>

## Basic Procedures With PNF Patterns

A number of basic procedures that involve the application of multiple types of sensory cues are superimposed on the diagonal patterns to elicit the best possible neuromuscular responses.<sup>212,251,265</sup> Although the diagonal patterns can be

**TABLE 6.9** Component Motions of PNF Patterns: Upper and Lower Extremities

Joints or Segments	Diagonal 1: Flexion ( $D_1$ Flx)	Diagonal 1: Extension ( $D_1$ Ext)	Diagonal 2: Flexion ( $D_2$ Flx)	Diagonal 2: Extension ( $D_2$ Ext)
<b>Upper Extremity Component Motions</b>				
Shoulder	Flexion-adduction-external rotation	Extension-abduction-internal rotation	Flexion-abduction-external rotation	Extension-adduction-internal rotation
Scapula	Elevation, abduction, upward rotation	Depression, adduction, downward rotation	Elevation, abduction, upward rotation	Depression, adduction, downward rotation
Elbow	Flexion or extension	Flexion or extension	Flexion or extension	Flexion or extension
Forearm	Supination	Pronation	Supination	Pronation

Ankle	Dorsiflexion, inversion	Plantarflexion, eversion	Dorsiflexion, eversion	Plantarflexion, inversion
Toes	Extension	Flexion	Extension	Flexion

used with various forms of mechanical resistance (e.g., free weights, simple weight-pulley systems, elastic resistance, or even an isokinetic unit), the interaction between the patient and therapist, a prominent feature of PNF, provides the greatest amount and variety of sensory input, particularly in the early phases of re-establishing neuromuscular control.

### Manual Contacts

The term *manual contact* refers to how and where the therapist's hands are placed on the patient. Whenever possible, manual contacts are placed over the agonist muscle groups or their tendinous insertions. These contacts allow the therapist to apply resistance to the appropriate muscle groups and cue the patient as to the desired direction of movement. For example, if wrist and finger extension is to be resisted, manual contact is on the dorsal surface of the hand and wrist. In the extremity patterns, one manual contact is placed distally and the other manual contact can be placed more proximally. Placement of manual contacts is adjusted based on the patient's response and their skill at performing and controlling the pattern.

### Maximal Resistance

The amount of resistance applied during dynamic concentric muscle contractions is the greatest amount possible that still allows the patient to move smoothly and without pain through the available ROM. Resistance should be adjusted throughout the pattern to accommodate strong and weak components of the pattern.

### Position and Movement of the Therapist

The therapist remains positioned and aligned along the diagonal planes of movement with shoulders and trunk facing in the direction of the moving limb. Use of effective body mechanics is essential. Resistance should be applied through body weight, not only through the upper extremities. The therapist must use a wide base of support, move with the patient, and pivot over the base of support to allow rotation to occur in the diagonal pattern.

### Stretch

**Stretch stimulus.** The stretch stimulus is the act of physically placing the patient's body segments in positions that lengthen the muscles that will contract during the diagonal movement pattern. For example, prior to initiating D<sub>1</sub>Flexion of the lower extremity, the lower limb is placed in D<sub>1</sub>Extension to lengthen the flexors.

Considerable importance is placed on rotation during the stretch stimulus. It is believed that the rotational component elongates the muscle fibers and spindles of the agonist muscles for a given pattern, increasing the excitability and responsiveness of those muscles. The stretch stimulus is sometimes described as "winding up the part" or "taking up the slack."

**Stretch reflex.** The stretch reflex is facilitated by a rapid stretch or overpressure just past the point of tension to an

agonist muscle that is positioned for a stretch stimulus. The stretch reflex is usually directed to a distal muscle group to elicit a phasic muscle contraction that initiates a given diagonal movement pattern. The quick stretch is followed by sustained manual resistance to the agonist muscles to maintain their tension. For example, to initiate D<sub>1</sub>Flexion of the upper extremity, a quick stretch is applied to the already elongated wrist and finger flexors followed by application of resistance. A quick stretch also can be applied to any agonist muscle group at any point during the execution of a diagonal pattern to further stimulate an agonist muscle contraction or direct a patient's attention to a weak component of a pattern. (See additional discussion of the use of *repeated contractions* in the next section, which describes special PNF techniques.)

**PRECAUTION:** Use of a stretch reflex, even prior to resisted isometric muscle contractions, is not advisable during the early stages of soft tissue healing after injury or surgery. It is also inappropriate with acute or active arthritic conditions.

### Normal Timing

A sequence of distal to proximal coordinated muscle contractions and joint motions occurs during the diagonal patterns. The distal component motions of the pattern should be completed halfway through the full pattern. Correct sequencing of movements promotes neuromuscular control and coordinated movement.

### Traction

Traction is the slight separation of joint surfaces, theoretically, to inhibit pain and facilitate movement during execution of the movement patterns.<sup>212,251,265</sup> Traction is most often applied manually during flexion patterns.

### Approximation

The gentle compression of joint surfaces by means of manual compression or weight bearing during the movement patterns stimulates co-contraction of agonists and antagonists to enhance dynamic stability and postural control via joint and muscle mechanoreceptors.<sup>212,251,265</sup>

### Verbal Commands

Auditory commands and cues are given to enhance motor output. The tone and volume of the verbal commands are varied to help maintain the patient's attention. A sharp verbal command is given simultaneously with the application of the stretch reflex to synchronize the phasic, reflexive motor response with a sustained volitional effort by the patient. Verbal cues then direct the patient throughout the movement patterns. As the patient learns the sequence of movements, verbal cues can be more succinct.

### Visual Cues

The patient is asked to follow the movement of a limb with both head and eye motion to further enhance correct movement throughout the full ROM.

## Upper Extremity Diagonal Patterns

**NOTE:** All descriptions for manual contacts are for the patient's right (R) upper extremity. During each pattern tell the patient to watch their moving hand. Be sure that rotation shifts *gradually* from full internal to full external rotation (or vice versa) throughout the ROM. By midrange, the arm should be in neutral rotation. Manual contacts may be altered from the suggested placements as long as contact remains on the appropriate surfaces. The therapist should manually resist all patterns through the full, available ROM.

### D<sub>1</sub>Flexion VIDEO 6.10

#### Starting Position (Fig. 6.33 A)

Position the upper extremity in shoulder extension, abduction, and internal rotation; elbow extension; forearm pronation; and wrist and finger extension with the hand about 8 to 12 inches from the hip.

FIGURE 6.33 (A) Starting position and

#### Hand Placement

Place the index and middle fingers of your (R) hand in the palm of the patient's hand and your left (L) hand on the volar surface of the distal forearm or at the cubital fossa of the elbow.

#### Verbal Commands

Apply a quick stretch to the wrist and finger flexors and tell the patient to "Squeeze my fingers; turn your palm up; pull your arm up and across your face," as you resist the pattern.

#### Ending Position (Fig. 6.33 B)

Complete the pattern with the arm across the face in shoulder flexion, adduction, external rotation; partial elbow flexion; forearm supination; and wrist and finger flexion.

FIGURE 6.33 (B) ending position for D<sub>1</sub> flexion of the upper extremity.

### D<sub>1</sub>Extension

#### Starting Position (Fig. 6.34 A)

Begin as described for completion of D<sub>1</sub>Flexion.

FIGURE 6.34 (A) Starting position and

#### Hand Placements

Grasp the dorsal surface of the patient's hand and fingers with your (R) hand using a *lumbrical grip*. Place your (L) hand on the extensor surface of the arm just proximal to the elbow.

#### Verbal Commands

As you apply a quick stretch to the wrist and finger extensors, tell the patient, "Open your hand" (or "Wrist and fingers up"); then "Push your arm down and out."

**Ending Position (Fig. 6.34 B)**

Finish the pattern in shoulder extension, abduction, internal rotation; elbow extension; forearm pronation; and wrist and finger extension.

**FIGURE 6.34—cont'd (B)** ending position for D<sub>1</sub> extension of the upper extremity.

**D<sub>2</sub>Flexion** VIDEO 6.11**Starting Position (Fig. 6.35 A)**

Position the upper extremity in shoulder extension, adduction, and internal rotation; elbow extension; forearm pronation; and wrist and finger flexion. The forearm should lie across the umbilicus.

**Hand Placement**

Grasp the dorsum of the patient's hand with your (L) hand using a lumbrical grip. Grasp the dorsal surface of the patient's forearm close to the elbow with your (R) hand.

**FIGURE 6.35 (A)** Starting position and

**Verbal Commands**

As you apply a quick stretch to the wrist and finger extensors, tell the patient, "Open your hand and turn it to your face;" "Lift your arm up and out;" "Point your thumb out."

**Ending Position (Fig. 6.35 B)**

Finish the pattern in shoulder flexion, abduction, and external rotation; elbow extension; forearm supination; and wrist and finger extension. The arm should be 8 to 10 inches from the ear; the thumb should be pointing to the floor.

**FIGURE 6.35 (B)** ending position for D<sub>2</sub> flexion of the upper extremity.

**D<sub>2</sub>Extension****Starting Position (Fig. 6.36 A)**

Begin as described for completion of D<sub>2</sub>Flexion.

**FIGURE 6.36 (A)** Starting position and

### Hand Placement

Place the index and middle fingers of your (R) hand in the palm of the patient's hand and your (L) hand on the volar surface of the forearm or distal humerus.

### Verbal Commands

As you apply a quick stretch to the wrist and finger flexors, tell the patient, "Squeeze my fingers and pull down and across your chest."

### Ending Position (Fig. 6.36 B)

Complete the pattern in shoulder extension, adduction, and internal rotation; elbow extension; forearm pronation; and wrist and finger flexion. The forearm should cross the umbilicus.

**FIGURE 6.36—cont'd (B)** ending position for  $D_2$  extension of the upper extremity.

## Lower Extremity Diagonal Patterns

**NOTE:** Follow the same guidelines with regard to rotation and resistance as previously described for the upper extremity. All descriptions of manual contacts are for the patient's (R) lower extremity.

### $D_1$ Flexion [VIDEO 6.12](#)

#### Starting Position (Fig. 6.37 A)

Position the lower extremity in hip extension, abduction, and internal rotation; knee extension; plantar flexion and eversion of the ankle; and toe flexion.

**NOTE:** This pattern may also be initiated with the knee flexed and the lower leg over the edge of the table.

### Hand Placement

Place your (R) hand on the dorsal and medial surface of the foot and toes and your (L) hand on the anteromedial aspect of the thigh just proximal to the knee.

**FIGURE 6.37 (A)** Starting position and

### Verbal Commands

As you apply a quick stretch to the ankle dorsiflexors and invertors and toe extensors, tell the patient, "Foot and toes up and in; bend your knee; pull your leg over and across."

### Ending Position (Fig. 6.37 b)

Complete the pattern in hip flexion, adduction, and external rotation; knee flexion (or extension); ankle dorsiflexion and inversion; toe extension. The hip should be adducted across the midline, creating lower trunk rotation to the patient's (L) side.

**FIGURE 6.37 (B)** ending position for  $D_1$  flexion of the lower extremity.

### $D_1$ Extension

#### Starting Position (Fig. 6.38 A)

Begin as described for completion of  $D_1$  Flexion.

**FIGURE 6.38 (A)** Starting position and

### Hand Placement

Place your (R) hand on the plantar and lateral surface of the foot at the base of the toes. Place your (L) hand (palm up) at the posterior aspect of the knee at the popliteal fossa.

### Verbal Commands

As you apply a quick stretch to the plantarflexors of the ankle and toes, tell the patient, “Curl (point) your toes; push down and out.”

### Ending Position (Fig. 6.38 B)

Finish the pattern in hip extension, abduction, and internal rotation; knee extension or flexion; ankle plantarflexion and eversion; and toe flexion.

**FIGURE 6.38 (B)** ending position for  $D_1$  extension of the lower extremity.

## D<sub>2</sub>Flexion VIDEO 6.13

### Starting Position (Fig. 6.39 A)

Place the lower extremity in hip extension, adduction, and external rotation; knee extension; ankle plantarflexion and inversion; and toe flexion.

**FIGURE 6.39 (A)** Starting position and

### Hand Placement

Place your (R) hand along the dorsal and lateral surfaces of the foot and your (L) hand on the anterolateral aspect of the thigh just proximal to the knee. The fingers of your (L) hand should point distally.

### Verbal Commands

As you apply a quick stretch to the ankle dorsiflexors and evertors and toe extensors, tell the patient, “Foot and toes up and out; lift your leg up and out.”

### Ending Position (Fig. 6.39 B)

Complete the pattern in hip flexion, abduction, and internal rotation; knee flexion (or extension); ankle dorsiflexion and eversion; and toe extension.

**FIGURE 6.39 (B)** ending position for  $D_2$  flexion of the lower extremity.

## D<sub>2</sub>Extension

### Starting Position (Fig. 6.40 A)

Begin as described for the completion of  $D_2$ Flexion.

**FIGURE 6.40 (A)** Starting position and

### Hand Placement

Place your (R) hand on the plantar and medial surface of the foot at the base of the toes and your (L) hand at the postero-medial aspect of the thigh, just proximal to the knee.

### Verbal Commands

As you apply a quick stretch to the plantarflexors and invertors of the ankle and toe flexors, tell the patient, “Curl (point) your toes down and in; push your leg down and in.”

### Ending Position (Fig. 6.40 B)

Complete the pattern in hip extension, adduction, and external rotation; knee extension; ankle plantarflexion and inversion; and toe flexion.

**FIGURE 6.40 (B)** ending position for D<sub>2</sub> extension of the lower extremity.

## Specific Techniques With PNF

There are a number of specific additional techniques that may be used during the execution of a PNF pattern to further stimulate weak muscles and enhance movement or stability.

These techniques are implemented selectively by the therapist to evoke the best possible response from the patient and to focus on specific treatment goals.

### Rhythmic Initiation

Rhythmic initiation is used to promote the ability to initiate a movement pattern. After the patient voluntarily relaxes, the therapist moves the patient's limb passively through the available range of the desired movement pattern several times so the patient becomes familiar with the sequence of movements within the pattern. Rhythmic initiation also helps the patient understand the rate at which movement is to occur. Practicing assisted or active movements (without resistance) also helps the patient learn a movement pattern.

### Repeated Contractions

Repeated, dynamic contractions, initiated with repeated quick stretches followed by resistance, are applied at any point in the ROM to strengthen a weak agonist component of a diagonal pattern.

### Reversal of Antagonists

Many functional activities involve quick reversals of the direction of movement. This is evident in diverse activities such as sawing or chopping wood, dancing, playing tennis, or grasping and releasing objects. The reversal of antagonists technique involves stimulation of a weak agonist pattern by first resisting static or dynamic contractions of the antagonist pattern. The reversals of a movement pattern are instituted just before the previous pattern has been fully completed.

There are two categories of reversal techniques available to strengthen weak muscle groups.

**Slow reversal.** Slow reversal involves dynamic concentric contraction of a stronger agonist pattern immediately followed by dynamic concentric contraction of the weaker antagonist pattern. There is no voluntary relaxation between patterns. This promotes rapid, reciprocal action of agonists and antagonists.

**Slow reversal hold.** Slow reversal hold adds an *isometric* contraction at the end of the range of a pattern to enhance end-range holding of a weakened muscle. With no period of relaxation, the direction of movement is then rapidly reversed by means of *dynamic* contraction of the agonist muscle groups quickly followed by isometric contraction of those same muscles. This is one of several techniques used to enhance dynamic stability, particularly in proximal muscle groups.

### Alternating Isometrics VIDEO 6.14

Another technique to improve isometric strength and stability of the postural muscles of the trunk or proximal stabilizing muscles of the shoulder girdle or hip is alternating isometrics. Manual resistance is applied in a single plane on one side of a body segment and then on the other. The patient is

instructed to “hold” his or her position as resistance is alternated from one direction to the opposite direction. No joint movement should occur. This procedure isometrically strengthens agonists and antagonists, and it can be applied to one extremity, to both extremities simultaneously, or to the trunk. Alternating isometrics can be applied with the extremities in weight-bearing or nonweight-bearing positions.

For example, if a patient assumes a side-lying position, manual contacts are alternately placed on the anterior aspect of the trunk and then on the posterior aspect of the trunk. The patient is told to maintain (hold) the side-lying position as the therapist first attempts to push the trunk in a posterior and then anterior direction (Fig. 6.41 A). Manual contacts are maintained on the patient as the therapist’s hands are moved alternately from the anterior to posterior surfaces. Resistance is gradually applied and released. The same can be done unilaterally or bilaterally in the extremities (Fig. 6.41 B).

**FIGURE 6.41 (A)** Use of alternating isometrics to improve static strength of the proximal musculature by alternately placing both hands and applying resistance to the anterior aspect of the body and then to the posterior aspect of the body. **(B)** Use of alternating isometrics in the upper extremities.

### Rhythmic Stabilization

Rhythmic stabilization is used as a progression of alternating isometrics and is designed to promote stability through co-contraction of the proximal stabilizing musculature of the trunk as well as the shoulder and pelvic girdle regions of the body. Rhythmic stabilization typically is performed in weight-bearing positions to incorporate joint approximation into the procedure, hence further facilitating co-contraction. The therapist applies multidirectional, rather than unidirectional, resistance by placing manual contacts on opposite sides of the body and applying resistance simultaneously in opposite directions as the patient holds the selected position. Multiple muscle groups around joints—most importantly the rotators—must contract to hold the position.

For example, the patient is told to hold the exercise position as the therapist pushes against the posterior aspect of the body with one hand and simultaneously pushes against the anterior aspect of the body with the other hand (Fig. 6.42). Manual contacts are then shifted to the opposite surfaces and isometric holding against resistance is repeated. There is no voluntary relaxation between contractions.

Use of these special techniques, as well as others associated with PNF, gives the therapist a significant variety of methods for increasing muscle strength and promoting dynamic stability and controlled mobility.

**FIGURE 6.42** Use of rhythmic stabilization to improve stability of the trunk by simultaneously applying resistance in opposite directions to the anterior and posterior surfaces of the trunk, emphasizing isometric contractions of the trunk rotators.

## Mechanical Resistance Exercise

*Mechanical resistance exercise* is any form of exercise in which external resistance is applied by means of some type of exercise equipment. Frequently used terms that denote the use of mechanical resistance are *resistance training*, *weight training*, and *strength training*.<sup>5-8,16,35</sup>

Mechanical resistance exercise is an integral component of rehabilitation and fitness/conditioning programs for individuals of all ages. The advantages and disadvantages of using mechanical resistance in an exercise program are noted in Box 6.16.

## Application in Rehabilitation Programs

Mechanical resistance exercise is commonly implemented in rehabilitation programs to eliminate or reduce deficits in muscular performance caused by an array of pathological

conditions and to restore or improve functional abilities. Guidelines for integration of mechanical resistance exercises into an individualized rehabilitation program for patients with specific conditions are detailed in Chapters 16 through 23.

## Application in Fitness and Conditioning Programs

There is general consensus that training with weights or other forms of mechanical resistance is an important component of comprehensive health and fitness programs. As in rehabilitation programs, resistance training complements aerobic training and flexibility exercises in conditioning and fitness programs. Guidelines for a balanced resistance training program for the healthy but untrained adult (less than 50 to 60 years of age) recommended by the ACSM<sup>6,8</sup> and the CDC<sup>35</sup> are summarized in Box 6.17.

**NOTE:** Special considerations for resistance exercises in the older adult population are presented in Chapter 24.

### BOX 6.16 Mechanical Resistance Exercise: Advantages and Disadvantages

#### Advantages

- Establishes a quantitative baseline measurement of muscle performance against which improvement can be judged.
- Most appropriate during intermediate and advanced phases of rehabilitation when muscle strength is 4/5 or greater or when the strength of the patient exceeds the therapist's strength.
- Provides exercise loads far beyond that which can be applied manually by a therapist to induce a training effect for already strong muscle groups.
- Provides quantitative documentation of incremental increases in the amount of resistance.
  - Quantitative improvement is an effective source of motivation for the patient.
- Useful for improving dynamic or static muscular strength.
- Adds variety to a resistance training program.
- Practical for high-repetition training to improve muscular endurance.
- Some equipment provides variable resistance through the ROM.
- High-velocity resistance training is possible and safe with some forms of mechanical resistance (hydraulic and pneumatic variable resistance machines, isokinetic units, and elastic resistance).
  - Potentially better carryover to functional activities than relatively slow-velocity manual resistance exercises.
  - Appropriate for independent exercise in a home program after careful patient education and a period of supervision.

#### Disadvantages

- Not appropriate when muscles are very weak or soft tissues are in the very early stages of healing, with the exception of some equipment that provides assistance, support, or control against gravity.
- Equipment that provides constant external resistance maximally loads the muscle at only one point in the ROM.
- No accommodation for a painful arc (except with hydraulic, pneumatic, or isokinetic equipment).
- Expense for purchase and maintenance of equipment.
- With free weights and weight machines, gradation in resistance is dependent on the manufacturer's increments of resistance.

### BOX 6.17 Summary of Guidelines for Resistance Training in Conditioning Programs for Healthy Adults (<50–60 years old)

- Prior to resistance training, perform warm-up activities followed by flexibility exercises.
- Perform dynamic exercises through the full, available, and pain-free ROM and target the major muscle groups of the body (approximately 8–10 muscle groups of the upper and lower extremities and trunk) for total body muscular fitness.
- Balance flexion-dominant (pulling) exercises with extension-dominant (pushing) exercises.
- Include both concentric (lifting) and eccentric (lowering) muscle contractions.
- *Intensity:* Perform moderate-intensity (60% to 80% of 1-RM) exercises that allow 8 to 12 repetitions of each exercise per set.
  - Increase intensity gradually (increments of approximately 5% of 1-RM) to progress the program as strength and muscular endurance improve.
- *Sets:* Two sets, progressing to four sets of each exercise.
- *Rest intervals:* 2 to 3 minutes between sets. While resting one muscle group, exercise a different muscle group.
- *Frequency:* Two to three times per week.
- Use slow to moderate speeds of movement.
- Use rhythmic, controlled, non-ballistic movements.
- Exercises should not interfere with normal breathing.
- Whenever possible, train with a partner for feedback and assistance.
- Cool-down after completion of exercises.
- Reduce the resistance and volume when reinitiating weight training after a layoff of more than 1 to 2 weeks.

## Special Considerations for Children and Adolescents

### Resistance Training

There is growing evidence that children and adolescents can achieve health-related benefits from resistance training and can safely engage in weight-training programs if designed appropriately and closely supervised.<sup>6,36,114,119,253</sup> Use of body weight as a source of resistance and equipment specifically designed to fit children and adolescents will contribute to program safety (Fig. 6.43).

Training-induced strength, power, and performance gains in children and adolescents have been documented,<sup>83,85,119,281</sup> but sport-related injury prevention remains questionable.<sup>83,281</sup> As with adults, information on the impact of strength training on the enhancement of functional motor skills is limited.

**FIGURE 6.43** Youth resistance training on Kids-N-Motion® equipment (Triceps-Dip), specifically designed and sized for a child's use. (Courtesy of Youth Fitness International, Moncks Corner, SC; [www.youthfit.com/](http://www.youthfit.com/).)

### FOCUS ON EVIDENCE

Research has shown that some acute and chronic responses to exercise in children are similar to those of adults, while other responses are quite different. For example, because of an immature thermo-regulation system, children dissipate body heat less easily, fatigue more quickly, and therefore need longer rest periods than young adults to recover from exercise.<sup>73,281</sup> Such differences in response to resistance exercise must be considered when designing and implementing strength training programs for children.

The American Academy of Pediatrics,<sup>5</sup> ACSM,<sup>6</sup> the Canadian Society for Exercise Physiology,<sup>20</sup> and the CDC<sup>36</sup> support youth involvement in resistance training—but only if a number of special guidelines and precautions are consistently followed. Although the risk of injury from resistance training is quite low if performed at an appropriate intensity and volume,<sup>86,253</sup> exercise-induced soft tissue or growth plate injuries have been noted if guidelines and precautions are not followed. Guidelines and special considerations for resistance training in children as a component of regular physical activity are summarized in Box 6.18.<sup>5,6,36,83,84,114,253</sup> Consistent with adult guidelines, a balanced program of dynamic exercise for major muscle groups includes warm-up and cool-down periods.

## Specific Resistance Training Regimens

As resistance training gained acceptance, many specific systems of exercise were developed to improve muscle strength, power, and endurance. All of these systems are based on the overload principle, and most use some form of mechanical resistance to load the muscle. The driving force behind the development of these regimens seems to be to design the “optimal”—that is, the most effective and efficient—method to improve muscular performance and functional abilities.

Several frequently used regimens of resistance training for rehabilitation and for fitness and conditioning programs—PRE, circuit weight training, and velocity spectrum isokinetic training—are presented in this section. Some approaches to advanced training, such as plyometric exercises (stretch-shortening drills) to develop muscle power, are presented in Chapter 23.

### Progressive Resistance Exercise

PRE is a system of dynamic resistance training in which a constant external load is applied to the contracting muscle by some mechanical means and incrementally increased. The RM is used as the basis for determining and progressing the amount of resistance used during training.

### FOCUS ON EVIDENCE

The results of countless studies have demonstrated that PRE improves the force-generating capacity of muscle and may improve physical performance. It is important to note that the participants in many of these studies were young, healthy adults rather than patients with impairments associated with injury and disease.

However, a systematic literature review<sup>254</sup> indicated that PRE was also beneficial for patients with a variety of pathological

**BOX 6.18 Resistance Training for Children: Guidelines and Special Considerations**

- No formal resistance training for children younger than 6 to 7 years of age; age-appropriate physical activity through organized and free play is recommended.
- At age 6 to 7, introduce the *concept* of an exercise session; encourage 60 or more minutes of moderate-intensity physical activity daily;<sup>36</sup> focus on aerobic activities (active exercises without weights).
  - Include weight-bearing exercises, such as push-ups and jumping activities for bone strengthening 3 days per week.
  - Emphasize a variety of short-duration, play-oriented exercises to prevent boredom, overheating, and muscle fatigue.
  - As a small portion of daily physical activity, perform muscle-strengthening exercises against the resistance of body weight (sit-ups, chin-ups). Postpone including exercises with light weights added for several years.
- When introducing weight-training in the prepubescent years:
  - Maintain *close* and *continuous supervision* by trained personnel or a parent who has received instruction.
  - Always perform warm-up activities for at least 5 to 10 minutes before initiating resistance exercises.
  - Focus on proper form, exercise technique, and safety (alignment, stabilization, and controlled/nonballistic movements).
- Emphasize low-intensity exercise throughout childhood to avoid potential injury to a child's growing skeletal system and to joints and supportive soft tissues.
- Emphasize adequate hydration.
- **Intensity:** Select low exercise loads that allow 8 to 15<sup>7,83</sup> repetitions.
  - Progress gradually to moderate-intensity (60% to 80% of an estimated 1-RM) exercise loads.
  - Do not use near-maximal or maximal exercise loads or participate in power lifting or body building until physical and skeletal maturity has been reached.
- **Sets and rest intervals:** Initially perform only one set, progressing to two to three sets of each exercise; rest at least 3 minutes between sets of exercises.
- **Frequency:** Limit the frequency of resistance training to no more than two sessions per week.
- Emphasize multi-joint, combined movements.
- Avoid or limit the use of eccentric resistance exercises.
- Initially progress resistance training by increasing repetitions, not resistance, or by increasing the total number of exercises. Later, increase weight by no more than 5% at a time.<sup>6,83</sup>
- Use properly fitting equipment that is designed or can be adapted for a child's size. Many weight machines cannot be adequately adjusted to fit a child's stature.

conditions including musculoskeletal injuries, osteoarthritis, osteoporosis, hypertension, adult-onset (type II) diabetes, and chronic obstructive pulmonary disease. Specific findings of some of the studies identified in this systematic review are presented in later chapters of this textbook.

### DeLorme and Oxford Regimens

The concept of PRE was introduced by DeLorme,<sup>60,61</sup> who originally used the term *heavy resistance training*<sup>60</sup> and later *load-resisting exercise*<sup>61</sup> to describe a new system of strength training. DeLorme proposed and studied the use of three sets of resistance training with progressive loading during each set, using a percentage of a 10-RM. Other investigators<sup>288</sup> developed a modified regimen, the Oxford technique, with regressive loading in each set (Table 6.10).

The DeLorme technique builds a warm-up period into the protocol, whereas the Oxford technique decreases the resistance

as the muscle fatigues within a session. Both regimens incorporate a rest interval between sets, both increase the resistance incrementally over time to apply progressive overload, and both have been shown to result in training-induced strength gains.

### FOCUS ON EVIDENCE

In a randomized study comparing the DeLorme and Oxford regimens, no significant difference was found in adaptive quadriceps muscle group strength gains in older adults after a 9-week exercise program.<sup>91</sup>

Many variations of PRE protocols have been proposed and studied since the DeLorme and Oxford systems were introduced, most aiming to determine the optimal intensity, number of repetitions and sets, frequency, and progression of loading. In reality, an ideal combination of these variables does not exist. Extensive research has shown that many combinations of exercise load, repetitions and sets, frequency, and rest intervals significantly improve strength.<sup>16,95,163</sup> The typical PRE program produces training-induced strength gains using 2 to 3 sets of 6 to 12 repetitions of a 6- to 12-RM.<sup>8,16,95,162,163</sup> This gives a therapist wide latitude when designing an effective resistance training program.

### DAPRE Regimen

Knowing when and by how much to increase the resistance in a PRE program is often imprecise and arbitrary. A common guideline is to increase the weight by 5% to 10% when all

**TABLE 6.10** Comparison of Two PRE Regimens

DeLorme Regimen	Oxford Regimen
Determination of a 10-RM	Determination of a 10
10 reps @ 50% of the 10-RM	10 reps @ 100% of the 10
10 reps @ 75% of the 10-RM	10 reps @ 75% of the 10
10 reps @ 100% of the 10-RM	10 reps @ 50% of the 10

prescribed repetitions and sets can be completed easily without significant fatigue. The Daily Adjustable Progressive Resistive Exercise (DAPRE) technique<sup>157,158</sup> is a more systematic and objective system that takes into account the different rates at which individuals progress during rehabilitation or conditioning programs. The system is based on a 6-RM working weight (Table 6.11). The adjusted working weight, which is based on the maximum number of repetitions possible using the working weight in Set #3 of the regimen, determines the working weight for the next exercise session (Table 6.12).

**NOTE:** It should be pointed out that the recommended increases or decrease in the adjusted working weight are based on progressive loading of the quadriceps muscle group.

## Circuit Weight Training

Another system of mechanical resistance training that has been developed is *circuit weight training*.<sup>19,32,163</sup> A pre-established sequence or circuit of exercises targeting major muscle groups is performed in succession at individual exercise stations. Typically, minimal rest is provided between the 8 to 12 individual circuit stations, which add cardiovascular system conditioning to the strengthening program. An example of a circuit weight training sequence is shown in Box 6.19.

**TABLE 6.11** DAPRE Technique

Sets	Repetitions	Amount of Resistance
1	10	50% 6-RM*
2	6	75% 6-RM
3	Maximum possible	100% 6-RM
4	Maximum possible	100% adjusted working weight**

\*6-RM = working weight

\*\*See Table 6.13 for calculation of the adjusted working weight.

**TABLE 6.12** Calculation of the Adjusted Working Weight for the DAPRE Regimen

Adjustment of Working Weight		
Repetitions in Set 3	Set 4	Next exercise session 3
0–2	↓ 5–10 lb	↓ 5–10 lb
3–4	↓ 0–5 lb	Same weight
5–6	Keep same weight	↑ 5–10 lb
7–10	↑ 5–10 lb	↑ 5–15 lb
11 or more	↑ 10–15 lb	↑ 10–20 lb

### BOX 6.19 Example of a Resistance Training Circuit

Station #1: Bench press → #2: Leg press or squats → #3: Sit-ups → #4: Upright rowing → #5: Hamstring curls → #6: Prone trunk extension → #7: Shoulder press → #8: Heel raises → #9: Push-ups → #10: Leg lifts or lowering

Each resistance exercise is performed at an exercise station for a specified number of repetitions and sets. Typically, intensity (resistance) is lower and repetitions are higher than in other forms of weight training. For example, two to three sets of 8 to 12 repetitions at 90% to 100% 10-RM or 10 to 20 repetitions at 40% to 50% 1-RM are performed,<sup>9,184</sup> with a minimum amount of rest (15 to 20 seconds) between sets and stations. The program is progressed by increasing the number of sets or repetitions, the resistance, the number of exercise stations, and the number of circuit revolutions.

*Exercise order* is an important consideration when setting up a weight training circuit.<sup>15,32,162</sup> Exercises with free weights or weight machines should alternate among upper extremity, lower extremity, and trunk musculature and between muscle groups involved in pushing or pulling actions. This enables one muscle group to rest and recover from exercise while exercising another group so that muscle fatigue is minimized. Ideally, larger muscle groups should be exercised before smaller muscle groups. Multijoint exercises that recruit multiple muscle groups should be performed before exercises that recruit an isolated muscle group to minimize the risk of injury from fatigue.

## Isokinetic Regimens

It is well established that isokinetic training improves muscle performance, but its effectiveness in carryover to functional tasks is less clear. Studies support<sup>78,193</sup> and refute<sup>121,221</sup> that isokinetic training improves function. Ideally, when isokinetic training is implemented in a rehabilitation program, it should be performed at velocities that closely match or at least approach the expected velocities of movement of specific functional tasks to have the most positive impact on function. Because many functional movements occur at a variety of medium to fast speeds, isokinetic training typically is performed at medium and fast velocities.<sup>4,53,58,76</sup>

Current isokinetic technology makes it possible to align training speeds to the movement velocities of some lower extremity functions such as walking.<sup>53,283</sup> This is less possible in the upper extremities where some functional movements occur at velocities that far exceed the capabilities of isokinetic dynamometers.<sup>76</sup> For example, overhead throwing velocities are well beyond 1000° per second.

It is also widely accepted that isokinetic training is relatively speed specific, with only limited transfer of training.<sup>142,260</sup>

Therefore, *speed-specific isokinetic training* matched to the velocity of a specific functional task is advocated.<sup>4,55,76</sup>

### Velocity Spectrum Rehabilitation

To deal with the problem of limited physiological overflow of training effects from one training velocity to another, a regimen called *velocity spectrum rehabilitation* (VSR) has been advocated.<sup>53,76,95</sup> With this system of training, isokinetic exercises are performed across a range of angular velocities.<sup>240</sup>

**NOTE:** The guidelines for VSR that follow are for *concentric* isokinetic training. General guidelines for eccentric isokinetics are identified at the conclusion of this section.

**Selection of training velocities.** Typically, medium (60° to 90° to 180° per second) and fast (180° to 360° per second) angular velocities are selected for VSR. Although isokinetic units are designed for velocities faster than 360° per second, they are not used for VSR training because the limb must accelerate to the preset speed before encountering resistance from the torque arm of the dynamometer. At very high speeds, this acceleration phase consumes most of the arc of motion so that resistance is met in only a small portion of the ROM, limiting the potential for benefit.

It is proposed that the effects of isokinetic training only carry over to movements that are within 15° to 30° per second of the training velocity.<sup>53,142</sup> Therefore, some protocols use 30° per second increments for VSR training. Of course, if a patient trains at medium and fast velocities (from 60° or 90° to 360° per second) in one exercise session, this strategy necessitates nine different training velocities for one agonist/antagonist muscle pair, giving rise to a time-consuming exercise session. For this reason, a more common protocol is to use as few as three training velocities.<sup>4,76,240</sup>

**Repetitions, sets, and rest.** A typical VSR protocol might have the patient perform 1 or 2 sets of 8 to 10 repetitions of agonist/antagonist muscle groups (reciprocal training) at multiple velocities.<sup>4,53,76</sup> For example, at medium velocities training could occur at 90°, 120°, 150°, and 180° per second. A second series would then be performed at decreasing velocities—180°, 150°, 120°, and 90° per second. Because many combinations of repetitions, sets, and different training velocities lead to improvement in muscle performance, the therapist has many options when designing a VSR program. A 15- to 20-second rest between sets and a 60-second rest between exercise velocities is recommended.<sup>245</sup> The suggested frequency for VSR is a maximum of three times per week.<sup>4</sup>

**Intensity.** Submaximal effort exercise on the dynamometer can be used for a brief warm-up period. However, this is not a replacement for a more general form of upper or lower body warm-up exercises, such as cycling or upper-extremity ergometry. When training to improve endurance, exercises are carried out at a submaximal intensity (effort) but to improve strength or power, maximal intensity exercise is used.

During the early stages of isokinetic training, it is useful to begin with submaximal intensity exercise at medium and slow velocities so the patient gets the “feel” of the device while protecting the muscle. As the training program progresses, it is usually safe for the patient to exert maximum effort at medium speeds. Slow-velocity training is eliminated when the patient begins to exert maximum effort. During the advanced phase of rehabilitation, training with maximum-effort at fast velocities is emphasized as long as exercises are pain-free.<sup>58</sup> Additional aspects to a progression of isokinetic training regimens include short-arc to full-arc exercises and concentric to eccentric movements.<sup>58</sup>

**PRECAUTION:** Training with maximum effort at slow velocities is rarely indicated because of the excessive shear forces produced across joint surfaces.<sup>53,76</sup>

### Eccentric Isokinetic Training: Special Considerations

Because eccentric isokinetic training became available more gradually as technology evolved, there is less guidance on exercise parameters and minimal evidence supporting its efficacy. Most current guidelines are based on clinical opinion or anecdotal evidence. Key differences in eccentric versus concentric isokinetic guidelines are listed in Box 6.20. Several resources describe pathology-specific guidelines for eccentric isokinetic training based on clinical experience.<sup>4,53,76,115,116</sup>

**PRECAUTION:** Eccentric isokinetic training is appropriate only during the final phase of a rehabilitation program, when additional challenge to individual muscle groups is needed due to persistent strength and power deficits. Because eccentric isokinetic training may not accurately match the functional

#### BOX 6.20 Key Differences in Eccentric Versus Concentric Isokinetic Training

Eccentric isokinetic exercise is:

- Introduced only *after maximal* effort concentric isokinetic exercise can be performed without pain at several velocities
- Implemented only after functional ROM has been restored
- Performed at slower velocities across a narrower velocity spectrum than concentric isokinetic exercise—usually between 60° and 120°/sec per second for the general population and up to 180°/sec for athletes
- Carried out at submaximal levels for a longer time frame to avoid extensive torque production and lessen the risk of DOMS
- Most commonly performed in a continuous concentric-eccentric pattern for a muscle group during training, whereas concentric isokinetics involves reciprocal training of agonist/antagonist muscle groups

way in which eccentric contractions occur, medium training velocities are considered safer than fast velocities. Sudden, rapid, motor-driven movements of the dynamometer's torque arm against a limb could injure healing tissue.

## Equipment for Resistance Training

There is a large variety of resistance training exercise equipment available on the market. The equipment ranges from simple to complex, compact to space-consuming, and inexpensive to expensive. An assortment of simple but versatile handheld and cuff weights or elastic resistance products is useful in clinical and home settings, whereas multiple pieces of variable resistance equipment may be useful for advanced-level resistance training. The literature distributed by manufacturers, product demonstrations at professional meetings, and studies of these products reported in the research literature are the main sources of information about new products on the market.

Although most equipment is *load resisting* (augments the resistance of gravity), a few pieces of equipment can be adapted to be *load assisting* (eliminates or diminishes the

resistance of gravity) to improve the strength of weak muscles. Equipment can be used for static or dynamic, concentric or eccentric, and open-chain or closed-chain exercises to improve muscular strength, power, or endurance, neuromuscular stability or control, as well as cardiopulmonary fitness.

Ultimately, the right equipment choice depends on the needs, abilities, and goals of the person using the equipment. Other factors that influence equipment choice are the *availability*, the *cost* of purchase and/or maintenance, the *ease of use*, the *versatility*, and the *space requirements*. Once the appropriate equipment has been selected, its safe and effective use is the highest priority. General principles for equipment use are listed in Box 6.21.

## Free Weights and Simple Weight-Pulley Systems

### Types of Free Weights

Free weights are incremental weights that are held in the hand or secured to an extremity or the trunk. They include commercially available dumbbells, barbells, weighted balls (Fig. 6.44), cuff weights, weighted vests, and even sandbags. Free weights can even be fashioned from readily available materials and objects for use in a home exercise program.

### BOX 6.21 General Principles for the Selection and Use of Equipment

- Base the selection of equipment on a comprehensive examination and evaluation of the patient.
- Determine when in the exercise program the use of equipment should be introduced and when it should be altered or discontinued.
- Determine if the equipment can or should be set up and used independently by a patient.
- Teach appropriate exercise form and technique with the equipment before adding resistance.
- Teach and supervise the application and use of the equipment before allowing a patient to use the equipment independently.
- Adhere to all safety precautions when applying and using equipment.
  - Be sure all attachments, cuffs, collars, and straps are secured and that the equipment is appropriately adjusted to the individual patient prior to the exercise.
  - Apply padding for comfort, if necessary, especially over bony prominences. Stabilize or support appropriate structures to prevent unwanted movement and undue stress on body parts.
  - If exercise machines are used independently, be certain that set-up and safety instructions are clearly illustrated and affixed directly to the equipment.
- Use available range-limiting attachments when ROM must be restricted to protect healing tissues or unstable structures.
- Give explicit instructions on how, when, and to what extent to change or adapt the equipment to provide a progressive overload when the patient is using the equipment in a home program.
- When transitioning from one type of resistance equipment to another, be certain that the newly selected equipment and method of set-up provides a similar level of torque production to the prior equipment to avoid insufficient or excessive loads.
- When the exercise has been completed:
  - Disengage the equipment and leave it in proper condition for future use.
  - Never leave broken or potentially hazardous equipment available for future use.
- Set up a regular routine of maintenance, replacement, or safety checks for all equipment.

**FIGURE 6.44 (A & B)** Holding a weighted ball while performing combined patterns of movement provides resistance to upper extremity and trunk muscles and augments the resistance of body weight to lower extremity muscle groups during weight-bearing activities.

### Simple Weight-Pulley Systems

Free-standing or wall-mounted simple weight-pulley systems are commonly used for resisted upper and lower extremity or trunk exercises (Fig. 6.45). Permanent or interchangeable weights are available. Permanent systems typically have stacks

**FIGURE 6.45** Multi-Exercise Pulley Unit can be used to strengthen a variety of muscle groups. (Courtesy of N-K Products Company, Inc., Soquel, CA.)

of individual weight plates in 5- to 10-lb increments. The amount of resistance used for exercise can be easily adjusted by selecting a certain number of stacked plates with the placement of a single weight key or pin.

**NOTE:** The simple weight-pulley systems described here are those that impose a relatively constant (fixed) load. Variable resistance weight machines, some of which incorporate pulleys into their designs, are discussed later in this section.

### Characteristics of Free Weights and Simple Weight-Pulley Systems

Free weights and weight-pulley systems impose a constant load. In these systems the external resistance maximally challenges the contacting muscle at only one portion of the ROM, which depends on the patient's positioning. The weight that is selected for exercise cannot be greater than what the muscle can control at this particular point in the ROM. In addition, there is no accommodation for a painful arc if the patient needs to reduce their internal effort at some point in the ROM.

When using free weights, it is possible to vary the point in the ROM at which the maximum exercise load is experienced by changing the patient's position with respect to gravity or the direction of the resistance load. For example, shoulder flexion may be resisted with the patient standing or supine and holding a weight in the hand.

- *Patient position:* standing (Fig. 6.46)—Maximum resistance is experienced and maximum external torque is produced

**FIGURE 6.46** When the patient is standing and lifting a weight: **(A)** Zero torque is produced in the shoulder flexors when the shoulder is at  $0^\circ$  of flexion; **(B)** maximum torque is produced when the shoulder is at  $90^\circ$  of flexion; and **(C)** torque again decreases as the arm moves from  $90^\circ$  to  $180^\circ$  of shoulder flexion.

when the shoulder is at  $90^\circ$  of flexion. No torque is produced by the weight when the shoulder is at  $0^\circ$  of flexion. External torque progressively decreases as the patient lifts the weight from  $90^\circ$  to  $180^\circ$  of flexion. In addition, when the weight is at the side (in the  $0^\circ$  position of the shoulder), it causes traction force on the extremity; when overhead, it causes compression force through the upper extremity joints.

- **Patient position:** supine (Fig. 6.47)—Maximum resistance is experienced and maximum external torque is produced when the shoulder is at  $0^\circ$  of flexion. No torque is produced

**FIGURE 6.47** When the patient is supine and lifting a weight: **(A)** Maximum torque is produced at  $0^\circ$  of shoulder flexion; **(B)** zero torque is produced at  $90^\circ$  of shoulder flexion; and **(C)** the shoulder extensors are active and contract eccentrically against resistance from  $90^\circ$  to  $180^\circ$  of shoulder flexion.

by the weight at  $90^\circ$  of shoulder flexion. In this position the load creates a compression force on the extremity. The shoulder flexors are not active between  $90^\circ$  and  $180^\circ$  of shoulder flexion. Instead, the shoulder extensors contract eccentrically to control the descent of the arm and weight.

The therapist must determine at which portion of the patient's ROM maximum strength is needed and then choose the optimum position in which the exercise should be performed to gain maximum benefit from the exercise.

Simple weight-pulley systems provide maximum resistance when the angle of the pulley is at right angles to the moving bone. As the angle of the pulley becomes more acute, the load creates more compression through the moving bones and joints and offers less effective resistance.

Unlike many weight machines, neither free weights nor pulleys provide external stabilization. When a patient lifts or lowers a weight to and from an overhead position, muscles of the scapula and shoulder abductors, adductors, and rotators must synergistically contract to stabilize the arm and keep it aligned in the correct plane of motion. The need for concurrent contraction of adjacent stabilizing muscle groups can be viewed as an advantage or a disadvantage. Because muscular stabilization is necessary to control the plane or pattern of movement, less external resistance can be controlled with free weights than can be managed with a weight machine that offers stabilization.

### Advantages and Disadvantages of Free Weights and Simple Weight-Pulley Systems

- Exercises can be performed in many positions, including supine, side-lying, prone, sitting, or standing. Many muscle groups in the extremities and trunk can be strengthened by simply repositioning the patient.
- Free weights and simple weight-pulley systems are typically used for dynamic, nonweight-bearing exercises but also can be set up for isometric exercise and resisted weight-bearing activities.
- Stabilizing muscle groups are recruited; however, because there is no external source of stabilization and movements must be controlled entirely by the patient, it may take more time for the patient to learn correct alignment and movement patterns.
- Many movement patterns are possible, incorporating single plane or multiplanar motions. An exercise can be highly specific to one muscle or generalized to several muscle groups. Movement patterns that replicate functional activities can be resisted.
- If a large enough assortment of graduated free weights is available, resistance can be increased by very small increments. The weight plates of pulley systems have larger increments of resistance, usually a minimum of 5 pounds per plate.
- Most exercises with free weights and weight-pulley systems must be performed slowly to minimize acceleration and momentum and prevent uncontrolled, end-range movements that could compromise patient safety. It is thought

that exclusively performing slow movements during strengthening activities has less carryover to many daily living activities compared with incorporating both slow- and fast-velocity exercises.

- Dumbbells and barbells that allow adjustable resistance through interchangeable plates are versatile and can be used for patients with many different levels of strength, but they require patient or personnel time for proper assembly.
- Bilateral lifting exercises with barbell weights often require the assistance of a spotter to ensure patient safety, thus increasing personnel time.

## Variable Resistance Units

Variable resistance exercise equipment falls into two broad categories: specially designed weight-cable (weight-pulley) machines and hydraulic and pneumatic units. Both categories of equipment impose a variable load on the contracting muscles consistent with the changing torque-producing capabilities of the muscles throughout the available ROM.

### Variable Resistance Weight-Cable Systems

Variable resistance weight-cable machines (Fig. 6.48) use a cam (an elliptical or kidney-shaped disk) in their design. The cam is designed to vary the load (torque) applied to the contracting muscle even though the weight remains constant. In theory, the cam is configured to match the torque output of the contracting muscle. This system varies the external load imposed on the contracting muscle based on the physical dimensions of the “average” individual. How effectively this design provides truly accommodating resistance throughout the full ROM is debatable.

During each repetition of an exercise, the same muscle group contracts both concentrically and eccentrically to manage the external resistance. As with simple weight-pulley systems and free weights, exercises must be performed at

**FIGURE 6.48** Variable resistance by means of a cam mechanism in the weight-pulley system is applied to concentric and eccentric contractions of the hamstrings as the knees flex and extend.

relatively slow velocities, thus compromising carryover to many functional activities.

### Hydraulic and Pneumatic Resistance Devices

Other variable resistance units employ hydraulic or pressurized pneumatic resistance to vary the resistance throughout the ROM. Fluid or air contained in a cylinder is forced through a small opening by a piston. The faster the piston is pushed, the greater the resistance encountered.

These devices allow concentric, reciprocal muscle work to agonist and antagonist muscle groups and, in some machines, provide concentric resistance followed by controlled eccentric return through the ROM. Patients can exercise safely at medium and, to some extent, fast velocities. These units also allow a patient to accommodate for a painful arc in the ROM.

### Advantages and Disadvantages of Variable Resistance Machines

- The obvious advantage of these machines is that the resistance is adjusted in an attempt to match a muscle's torque-generating capabilities throughout the ROM. The contracting muscle is subjected to near maximal loads at multiple points in the ROM rather than just through one small portion of the range.
- Most pieces of equipment are designed to isolate and exercise specific muscle groups. For example, resisted squats are performed on one machine and hamstring curls on another. Consequently, numerous units are needed to exercise all major muscles groups.
- Unlike functional movement, most machines allow only single-plane movements, although some newer units now offer a dual-axis design allowing multiplanar motions that strengthen multiple muscle groups and more closely resemble functional movement patterns.
- The equipment is adjustable to allow individuals of varying heights to perform each exercise in a well-aligned position.
- Each unit provides substantial external stabilization to guide or limit movements. This makes it easier for the patient to learn how to perform the exercise correctly and safely and helps maintain appropriate alignment without assistance or supervision.
- One of the main disadvantages of weight machines is the initial expense and ongoing maintenance costs. Multiple machines, usually 8 to 10 or more, must be purchased to target multiple major muscle groups. Multiple machines also require a large amount of space in a facility.

### Elastic Resistance Devices

Elastic resistance products are widely used in rehabilitation and have been shown to be an effective method of providing sufficient resistance to improve muscle strength.<sup>139</sup> Resistance training with elastic products is also a feasible alternative to training with weight machines<sup>44</sup> and free weights,<sup>11</sup> generating comparably high levels of muscle activation during exercises.

Quantitative analysis of the resistance supplied by elastic products or the level of muscle activation during their use suggests that their effectiveness requires not only the application of biomechanical principles, but also an understanding of the physical properties of elastic resistance material.<sup>130,131,140,145,214,216,232,257</sup>

### Types of Elastic Resistance

Elastic resistance products, specifically designed for use during exercise, fall into two broad categories: elastic bands and elastic tubing. Elastic bands and tubing are produced by several manufacturers under different product names, the most familiar of which is Thera-Band® Elastic Resistance Bands and Tubing (Hygenic Corp., Akron, OH). Both types of products are available in an assortment of thicknesses or diameters that provide progressive levels of resistance. Color-coding denotes the thickness of the product and grades of resistance.

### Properties of Elastic Resistance: Implications for Exercise

A number of studies describing the physical characteristics of elastic resistance have provided quantitative information about its material properties. Knowledge of this information enables a therapist to use elastic resistance more effectively for therapeutic exercise programs.

**Effect of elongation of elastic material.** Elastic resistance provides a form of variable resistance because the force generated changes as the material is elongated. Specifically, as it is stretched, the amount of resistance (force) produced by an elastic band or tubing increases depending on the *relative change* in the length of the material (*percentage of elongation/deformation*) from the start to the end of elongation. There is a relatively predictable and *linear* relationship between the percentage of elongation and the tensile force of the material.<sup>131,140,145,216,232</sup>

To determine the percentage of elongation, the stretched length must be compared with the resting length of the elastic material. The *resting length* of a band or tubing is its length when it is laid out flat and there is no stretch applied. The actual length of the material before it is stretched has no effect on the force imparted. Rather, it is the percentage of elongation that affects the tensile forces.<sup>216</sup>

The formula for calculating the percentage of elongation/deformation is:<sup>139,232</sup>

$$\text{Percent of elongation} = (\text{stretched length} - \text{resting length}) \div \text{resting length} \times 100$$

Using this formula, if a 2-ft length of red tubing, for example, is stretched to 4 feet, the percentage of elongation is 100%. With this in mind, it is understandable why a 1-ft length stretched to 2 feet (100% elongation) generates the same force as a 2-ft length of the same color tubing stretched to 4 feet.<sup>214,215</sup>

Furthermore, the *rate* at which elastic material is stretched does not seem to have a significant effect on the amount of

resistance encountered.<sup>216</sup> Consequently, when a patient is performing a particular exercise, so long as the percentage of elongation of the tubing or band is the same from one repetition to the next, the resistance encountered is the same regardless of whether the exercise is performed at slow or fast velocity.

**Determination and quantification of resistance.** To help clinicians make decisions about the grade (color) of elastic material to select for a patient's exercise program, a number of studies have quantified the resistance imparted by elastic bands or tubing.<sup>131,140,145,216,232,257</sup> These studies measured and compared the tensile forces generated by various grades of elastic bands or tubing in relation to the percentage of elongation of the material. The forces expected at specific percentages of elongation of each grade of bands or tubing can be calculated by means of linear regression equations. Detailed specifications about the material properties of one brand of elastic resistance products, Thera-Band®, are available at [www.thera-bandacademy.com/](http://www.thera-bandacademy.com/).

During exercise, the percentage of deformation and resulting resistance (force) from the material is not the only factor that must be considered. The amount of torque (force × distance) imposed by the elastic material on the bony lever is also an important consideration. Just because the tension produced by an elastic band or tubing increases as it is stretched, it does not mean that the imposed torque necessarily increases from the beginning to the end of an exercise. In addition to the resistance (force) imposed by the elastic material as it is stretched, the length of the external moment arm will change as the angle of the elastic resistance vector with respect to the moving limb will modify the torque generated by the elastic material.<sup>140</sup> Studies have indicated that bell-shaped torque curves occur during exercises with elastic material, with the peak torque near midrange.<sup>140,215</sup> As in all forms of dynamic resistance exercise, the length-tension relationship of the contracting muscle also affects its ability to respond to the changing external load.

**Fatigue characteristics.** Elastic resistance products tend to fatigue over time, which causes the material to lose some of its force-generating property.<sup>139</sup> The extent of this *material fatigue* is dependent on the number of times the elastic band or tubing has been stretched (number of stretch cycles) and the percentage of deformation with each stretch.<sup>232</sup>

Studies have shown that the decrease in tensile force is significant but small, with much of the decrease occurring within the first 20<sup>216</sup> or 50<sup>139</sup> stretch cycles. However, in the former study, investigators found that after this small, initial decrease in tensile force occurred, there was no appreciable decrease in the force-generating potential of the tubing after more than 5,000 cycles of stretch. This translates to performing 10 repetitions each of 4 different exercises, 3 times a day, every day for 6 weeks with the same piece of tubing before it needs replacing.

Elastic materials also display a property called *viscoelastic creep*. If a constant load is placed on elastic material, in time it becomes brittle and eventually ruptures. Environmental

conditions, such as heat and humidity, also affect the force-generating potential of elastic bands and tubing.<sup>139</sup>

## Application of Elastic Resistance

**Selecting the appropriate grade of material.** The thickness (stiffness) of the material affects the level of resistance. Heavier grades of elastic generate greater tension when stretched and, therefore, impart greater levels of resistance.<sup>131,139,232</sup> As already noted, corresponding levels of resistance have been published for the different grades of bands and tubing. Therapists and patients should be aware that color-coding schemes and their corresponding levels of resistance might not be consistent across manufacturers.

### FOCUS ON EVIDENCE

In a study<sup>257</sup> comparing similar colors and lengths of Thera-Band® and Cando tubing (Cando Fabrication Enterprises, White Plains, NY), investigators measured (by means of a strain gauge) the forces generated under similar conditions. They found no appreciable differences between the two products except for the thinnest (yellow) and thickest (silver/grey) grades. In those two grades the Cando tubing produced approximately 30% to 35% higher levels of force than the Thera-Band® product. Despite these small differences, investigators suggested that it is prudent to use the same product with the same patient.

**Selecting the appropriate length.** Elastic bands or tubing come in large rolls and can be cut to length for the specific exercise to be performed and the height of a patient or the length of the extremities. The length of the elastic material should be sufficient to attach it *securely* at both ends. It should be taut but not stretched (*resting length*) at the beginning position of an exercise.

Because the percentage of elongation of the material affects the tension produced, it is essential that the same length of elastic material is used each time a particular exercise is performed. Otherwise, the imposed load may vary between exercise sessions even though the same grade of elastic is used.

**Securing bands or tubing.** One end of the material is often tied or attached to a fixed object such as a doorknob, table leg, or D-ring or can be secured by having the patient stand on it. The other end is then grasped or fastened to a nylon loop, which is then placed around a limb segment. The elastic material can also be secured to a harness on a patient's trunk for resisted walking activities. The material can also be held in both hands or looped under both feet for bilateral exercise. Figure 6.49 A, B, and C depicts upper or lower extremity and trunk strengthening activities using elastic resistance.

**Setting up an exercise.** With elastic resistance, the maximum external resistance torque occurs when the material is on a stretch and angled 90° to the lever arm (moving bone). The therapist should determine the limb position at which maximum resistance is desired during the exercise and then

**FIGURE 6.49** Use of elastic resistance to strengthen (A) upper or (B) lower extremity or (C) trunk musculature.

secure the elastic material so that a right angle is formed between the material and limb at that position. When the material is at an acute angle to the moving bone, there is less resistance but greater joint compressive force.

It is important to position the patient and elastic material in the same manner from one exercise session to the next. Each

time a patient performs a specific exercise, in addition to using the same length of elastic material, the relationship between the patient and the attachment site of the material should be consistent. A resource by Page and Ellenbecker<sup>214</sup> describes setups for numerous exercises using elastic resistance.

**Progressing exercises.** Exercises can be progressed by increasing the number of repetitions performed with the same grade of resistance or by using the next higher grade of elastic band or tubing.

## Advantages and Disadvantages of Exercise With Elastic Resistance

### Advantages

- Elastic resistance products are portable and relatively inexpensive, making them an ideal choice for home exercise programs.
- Because elastic resistance is not significantly gravity dependent, elastic bands and tubing are extremely *versatile*, allowing many combinations of limb and trunk movement patterns and patient positions.<sup>139,140,215</sup>
- It is safe to exercise at moderate to fast velocities with elastic resistance because the patient does not have to overcome the inertia of a rapidly moving weight. As such, it is appropriate for plyometric training (see Chapter 23).

### Disadvantages

- One of the most significant drawbacks to the use of elastic resistance is the need to refer to a table of figures for quantitative information about the level of resistance for each color-coded grade of material. This makes it difficult to know which grade to select initially and to what extent changing the grade of the band or tubing changes the level of resistance.
- As with free weights, there is no source of stabilization or control of extraneous movements when an elastic band or tubing is used for resistance. The patient must use muscular stabilization to ensure that the correct movement pattern occurs.
- Although the effects of material fatigue are small with typical clinical use, elastic bands and tubing should be replaced on a routine basis to ensure patient safety.<sup>139,232</sup> When many individuals use the same precut lengths of bands or tubing, it may be difficult to determine how much use has occurred and when replacement is necessary.
- Some elastic products contain latex, which is a fairly common allergen, thus eliminating use by some individuals. However, there are latex-free products on the market at a relatively comparable cost.

## Equipment for Dynamic Stabilization Training

### BodyBlade®

The BodyBlade® (Fig. 6.50) is a dynamic, reactive device that produces oscillatory resistance proportional to an oscillatory force generated by the patient.<sup>33,177</sup> During exercise, agonist

**FIGURE 6.50** Dynamic stabilization exercises of the upper extremity and trunk using the BodyBlade®.

and antagonist muscle groups rapidly contract in an attempt to control the instability created by oscillations of the blade. The greater the amplitude or flex of the blade, the greater the resistance. This provides progressive resistance that the patient controls.

Initially, the oscillating blade is maintained in single positions in space, particularly those positions in which dynamic stability is required for functional activities. The patient can progress the exercises by moving the upper extremity through various planes of motion (from sagittal to frontal and ultimately to transverse) while maintaining oscillations of the blade. The goal of this type of resistance is to develop proximal joint stability as a foundation of controlled mobility.

### FOCUS ON EVIDENCE

Lister and colleagues<sup>177</sup> conducted a within-subject trial to determine the extent of activation of the scapula stabilizing muscles during upper extremity exercise with three forms of resistance (a cuff weight, elastic resistance, and a BodyBlade®). Healthy college athletes ( $n = 30$ ) performed shoulder flexion and abduction with each type of equipment as activity in the upper trapezius, lower trapezius, and serratus anterior muscles was quantified with EMG. The study demonstrated that significantly greater muscle activity occurred in each of the three scapular stabilizers during exercises with the blade than with either the cuff weight or elastic resistance. The investigators recommended use of a blade in shoulder rehabilitation to develop scapular stability during arm movements.

### Swiss Balls (Stability Balls)

Heavy-duty vinyl balls, usually 20 to 30 inches in diameter, are used for a variety of trunk and extremity stabilization exercises. Using elastic resistance or free weights while on the ball increases the difficulty of exercises. Refer to Chapters 16 and 23 for descriptions of a number of dynamic stabilization exercises using stability balls.

### Equipment for Closed-Chain Training

Many closed-chain exercises are performed in weight-bearing positions to develop strength, endurance, and stability across multiple joints. Typically, these exercises use partial or full body weight as the source of resistance. Examples in the lower extremities include squats, lunges, and step-ups or step-downs, and in the upper extremities examples include push-ups, press-ups, and pull-ups. These exercises are progressed by adding resistance with handheld weights, a weighted belt or vest, or elastic resistance. Changing from bilateral to unilateral weight bearing (when feasible) also progresses the exercise. The following equipment is designed specifically for closed-chain training to improve muscle performance across multiple joints.

#### Body Weight Resistance: Multipurpose Exercise Systems

The Total Gym® system uses a glide board, which can be set at 10 incline angles, enabling a patient to perform bilateral or unilateral closed-chain strengthening and endurance exercises in positions that range from partially reclining to standing (Fig. 6.51 A and B). The level of resistance on the Total Gym apparatus is increased or decreased by adjusting the angle of the glide board on the incline.

Performing squatting exercises in a semi-reclining position allows the patient to begin closed-chain training in a partially loaded (partial weight-bearing) condition early in the rehabilitation program. Later, the patient can progress to forward lunges (where the foot slides forward on the glide board) while in a standing position.

**FIGURE 6.51** Closed-chain training in the (A) semi-reclining position and

**FIGURE 6.51 (B)** standing position using the Total Gym® system. (Courtesy of Total Gym®, San Diego, CA.)

#### CLINICAL TIP

The Total Gym® system also can be set up for trunk exercises and open-chain exercises for the upper or lower extremities.

#### Slide Boards

The ProFitter® (Fig. 6.52) consists of a moving platform that slides side to side across an elliptical surface against adjustable resistance. While it is most often used with the patient standing for lower extremity rehabilitation, it can also be used for

**FIGURE 6.52** Pro Fitter provides closed-chain resistance to lower extremity musculature in preparation for functional activities.

upper extremity and trunk stability exercises. Medial-lateral or anterior-posterior movements are possible.

### Balance Equipment

A balance board (wobble board) or BOSU® (in the shape of a half sphere with a flat and round side) is used primarily for stabilization, proprioceptive, and perturbation training. Bilateral or unilateral weight bearing through the upper or lower extremities can be performed on this equipment to develop strength and stability. Some balance boards, such as the BAPS (Biomechanical Ankle Platform System) board, have interchangeable half spheres in several sizes that progressively increase the difficulty of the balance activity. Refer to Chapters 8 and 23 for examples of balance activities using various types of equipment.

### Mini-Trampolines (Rebounders)

Mini-trampolines enable the patient to begin gentle, bilateral or unilateral bouncing activities on a resilient surface to decrease the impact on joints. A patient can jog, jump, or hop in place. “Mini-tramps” that have a waist-height bar attached to their frame for the patient to hold onto during exercise provide additional safety.

### Reciprocal Exercise Equipment

Similar to other types of equipment that can be used for closed-chain training, reciprocal exercise devices strengthen multiple muscle groups across multiple joints. They also are appropriate for low-intensity, high-repetition resistance training to improve muscular endurance, reciprocal coordination of the upper or lower extremities, and cardiopulmonary fitness. They are often used for warm-up or cool-down exercises prior to or following more intense resistance training. Resistance is imparted by an adjustable friction device or by a hydraulic or pneumatic mechanism.

### Stationary Exercise Cycles

Upright or recumbent stationary exercise cycles are used to increase lower extremity strength and endurance. An upright cycle requires greater patient trunk control and balance than does a recumbent cycle. A few exercise cycles provide resistance to the upper extremities as well. Resistance can be graded to progressively challenge the patient. Distance, speed, or duration of exercise can be monitored.

Exercise cycles provide resistance to muscles during repetitive, nonimpact, and reciprocal extremity movements. Passive cycles resist only concentric muscle activity as the patient performs pushing or pulling movements. Motor-driven exercise cycles can be adjusted to provide eccentric as well as concentric resistance. Adjusting the seat placement alters the ROM that occurs in the lower extremity joints.

### Portable Resistive Reciprocal Exercise Units

A number of portable resistive exercisers are effective alternatives to an exercise cycle for repetitive, reciprocal exercise. One such product, the Chattanooga Group Exerciser® (Fig. 6.53), can be used for lower extremity exercise by placing the unit on the floor in front of a chair or wheelchair. This is particularly appropriate

**FIGURE 6.53** Resisted reciprocal exercise using the Chattanooga Exerciser® (Courtesy of Chattanooga Group, Inc., Hixson, TN.)

for a patient who is unable to get on and off an exercise cycle. In addition, it can be placed on a table for upper extremity exercise. Resistance can be adjusted to meet the abilities of individual patients and to progress the exercise when appropriate.

### Stair-Stepping Machines

The StairMaster® (Fig. 6.54) and the Climb Max 2000® are examples of stepping machines that allow the patient to perform reciprocal pushing movements against adjustable resistance

**FIGURE 6.54** A stepping machine provides resistance during alternating lower extremity-pushing movements that simulate stair-climbing.

to make the weight-bearing activity more difficult. Stepping machines provide nonimpact, closed-chain strengthening as an alternative to walking or jogging on a treadmill. A patient can also kneel next to the unit and place both hands on the foot plates to use this equipment for upper extremity closed-chain exercises.

### Elliptical Trainers and Cross-Country Ski Machines

Elliptical trainers and cross-country ski machines also provide nonimpact, reciprocal resistance to the lower extremities in an upright, weight-bearing position. Variable incline adjustments of these units expand the resistance options. Both types of equipment also incorporate reciprocal resistance to the upper extremities into their designs.

### Upper Extremity Ergometers

Upper extremity ergometers provide resistance primarily to the upper extremities to increase strength and muscular endurance (Fig. 6.55). Forward and reverse cycling at varying speeds is possible. As with stationary cycles, upper extremity ergometers also are used to improve cardiopulmonary fitness. Typically the patient is seated, but some ergometers can be used in a standing position to minimize the arm elevation necessary with each revolution. This is particularly helpful for patients with impingement syndromes of the shoulder.

**FIGURE 6.55** An upper extremity ergometer is used for upper body strength and endurance training and cardiopulmonary fitness.

## Isokinetic Testing and Training Equipment

Isokinetic dynamometers (rate-limiting devices that control the velocity of motion) provide accommodating resistance during dynamic exercises of the extremities or trunk (see Fig. 6.9). The equipment supplies resistance proportional to the force generated by the person using the machine. The preset rate of movement (degrees per second) cannot be exceeded no matter how vigorously the person pushes against the force arm. Therefore, the muscle contracts to its fullest capacity at all points in the ROM.

### Features of Isokinetic Dynamometers

Features include computerized testing capabilities; passive and active modes that permit open-chain, concentric and eccentric testing and training; and velocity settings from 0° per second for isometric exercise, up to 500° per second for the concentric mode, and up to 250° per second for the eccentric mode. Computer programming can limit limb movement to a specified range. Single-joint, uniplanar, open-chain movements are most common, but adaptations are available that permit a limited number of multiplanar movement patterns and multijoint, closed-chain exercises. Reciprocal training of agonist and antagonist and concentric/eccentric training of the same muscle group are possible.

### Advantages and Disadvantages of Isokinetic Equipment

The characteristics of isokinetic exercise and equipment have already been presented in an earlier section of this chapter. The advantages and disadvantages of isokinetic dynamometers include the following.

#### Advantages

- If the patient puts forth a maximum effort, isokinetic equipment provides maximum resistance through the entire ROM.
- Both high- and low-velocity training can be done safely and effectively.
- The equipment accommodates for a painful arc of motion.
- As a patient fatigues, exercise can still continue.
- Isolated strengthening of muscle groups is possible to correct strength deficits in specific muscle groups.
- External stabilization keeps the patient and moving segment well aligned.
- Concentric and eccentric contractions of the same muscle group can be performed repeatedly, or reciprocal exercise of opposite muscle groups can be performed, allowing one muscle group to rest while its antagonist contracts; the latter method minimizes muscle ischemia.
- Computer-based visual or auditory cues provide feedback to the patient so submaximal to maximal work can be carried out more consistently.

### Disadvantages

- The equipment is large and expensive to purchase and maintain.
  - Setup time and assistance from personnel are necessary if a patient is to exercise multiple muscle groups.
  - Most units allow only open-chain (nonweight-bearing) movement patterns, which do not translate to many lower extremity and some upper extremity functions.
  - Although functional movements typically occur in combined patterns and at varying velocities, most exercises are performed in a single plane and at a constant velocity.
- Although the range of concentric training velocities (up to 500° per second) is comparable to some lower extremity limb speeds during functional activities, even the upper limits of this range of velocities cannot begin to approximate the rapid limb speeds that are necessary during many sports-related motions, such as throwing. In addition, the eccentric velocities available, at best, only begin to approach medium-range speeds, far slower than the velocity of movement associated with quick changes of direction and deceleration. Both of these limitations in the range of training velocities compromise carryover to functional goals.

## Independent Learning Activities

### Critical Thinking and Discussion

1. What physical findings from an examination and evaluation of a patient would lead you to determine that resistance exercises were an appropriate intervention?
2. What are the benefits and limitations of isometric, dynamic, and isokinetic exercises?
3. Compare and contrast constant resistance and variable resistance.
4. What are the key changes that occur in muscle strength and endurance throughout the life span?
5. You have been asked to design a resistance exercise program as part of a total fitness program for a group of 7- to 9-year-old soccer players (boys and girls).
  - a. Indicate the exercises you would include, the equipment you need, and the guidelines for intensity, volume, frequency, and rest.
  - b. What special precautions during resistance training should be taken with children and why?
6. Analyze five daily living tasks or recreational activities that you currently perform or would like to be able to perform effectively and efficiently. Identify the aspects of muscle performance (strength, power, and endurance) that are involved in each task. Propose two exercises for each task that would help to improve the muscle performance aspects you identified.
7. Develop an instructional presentation that deals with the appropriate and effective use of elastic resistance products.
8. You have been asked to help design a circuit weight training sequence at a soon-to-open fitness facility at the outpatient treatment center where you work. Select equipment to meet the needs of beginning and advanced individuals. Establish general guidelines for intensity, repetitions and sets, order of exercise, rest intervals, and frequency.

### Laboratory Practice

1. Perform manual resistance exercise to all muscle groups of the upper and lower extremities in the following positions: supine, prone, side-lying, and sitting. What are the major limitations to effective, full-range strengthening in each of these positions?
2. Apply manual resistance exercises to each of the muscles of the wrist, fingers, and thumb.
3. Practice upper extremity and lower extremity D<sub>1</sub> and D<sub>2</sub> PNF exercises on your laboratory partner's right *and* left extremities.
4. Determine a 1-RM and 10-RM for the following muscle groups: shoulder flexors, shoulder abductors, shoulder external rotators, elbow flexors and extensors, hip abductors, hip flexors, knee flexors, and extensors. Select one upper and one lower extremity muscle group. Determine a 1-RM or 10-RM with free weights in two positions. Determine where in the ROM maximum resistance is encountered. Then determine a 1-RM or 10-RM with a pulley system. Compare your results.
5. Set up and safely apply exercises with elastic bands or tubing to strengthen the major muscle groups of the upper and lower extremities. Identify the point in each exercise where the external resistance is greatest and consider how this will impact effectiveness. Include a dynamic open-chain, a dynamic closed-chain, and an isometric exercise for each muscle group.
6. Demonstrate a series of simulated functional activities that could be used in the final stages of rehabilitation to continue to improve muscle performance as a transition into independent functional activities for a mail carrier, a nurse's aide who works in a skilled nursing facility, a ski instructor, a package delivery truck driver, and a day-care worker.

 Young Adults 261  
 Older Adults 261

## Independent Learning Activities 262

There are numerous sources from which to obtain information on training for endurance in athletes and healthy young people and for individuals with chronic diseases such as coronary heart disease, diabetes, and others.<sup>2-4</sup> Using the most recent research, the American College of Sports Medicine (ACSM) published basic guidelines for many of the more common chronic conditions.<sup>2-4</sup> This chapter uses information from these well-known sources to demonstrate that the physical therapist can use aerobic-type activity when working with either healthy individuals or patients with a variety of conditions. In addition, some fundamental information about cardiovascular and respiratory parameters in children and the elderly, as well as the young or middle-aged adult, is presented so the physical therapist can be prepared to treat individuals of all ages.

## Key Terms and Concepts

### Physical Activity

*Physical activity* as defined by ACSM<sup>2</sup> and the Centers for Disease Control and Prevention (CDC)<sup>6</sup> is “any bodily movement produced by the contraction of skeletal muscles that result in a substantial increase over resting energy expenditure.”

### Exercise

*Exercise* is any planned and structured physical activity designed to improve or maintain physical fitness.

## Physical Fitness

*Fitness* is a general term used to describe the ability to perform physical work. Performing physical work requires cardiorespiratory functioning, muscular strength and endurance, and musculoskeletal flexibility. Optimum body composition is also included when describing fitness.

To become physically fit, individuals must participate regularly in some form of physical activity that uses large muscle groups and challenges the cardiorespiratory system. Individuals of all ages can improve their general fitness status by participating in activities that include walking, biking, running, swimming, stair climbing, cross-country skiing, and/or training with weights.

Fitness levels can be described on a continuum from poor to superior based on energy expenditure during a bout of physical work.<sup>11,12</sup> These ratings are often based on direct or indirect measurement of the body's maximum oxygen consumption. Oxygen consumption is influenced by age, gender, heredity, inactivity, and disease.

## Maximum Oxygen Consumption

*Maximum oxygen consumption* ( $\text{VO}_{2\text{ max}}$ ) is a measure of the body's capacity to use oxygen.<sup>2,4,11,12</sup> It is usually measured when performing an exercise that uses many large muscle groups such as swimming, walking, and running. It is the maximum amount of oxygen consumed per minute when the individual has reached maximum effort. It is usually expressed relative to body weight, as milliliters of oxygen per kilogram of body weight per minute (mL/kg per minute). It is dependent on the transport of oxygen, the oxygen-binding capacity of the blood, cardiac function, oxygen extraction capabilities, and muscular oxidative potential.

## Endurance

*Endurance* (a measure of fitness) is the ability to work for prolonged periods of time and the ability to resist fatigue.<sup>11,12</sup> It includes muscular endurance and cardiovascular endurance. Muscular endurance refers to the ability of an isolated muscle group to perform repeated contractions over a period of time, whereas cardiovascular endurance refers to the ability to perform large muscle dynamic exercise, such as walking, swimming, and/or biking for long periods of time.

## Aerobic Exercise Training (Cardiorespiratory Endurance)

*Aerobic exercise training*, or cardiorespiratory endurance training, is augmentation of the energy utilization of the muscle by means of an exercise program.<sup>2,11,12</sup> The improvement of the muscle's ability to use energy is a direct result of increased levels of oxidative enzymes in the muscles, increased

mitochondrial density and size, and an increased muscle fiber capillary supply.

- Training is dependent on exercise of sufficient frequency, intensity, and time.
- Training produces cardiovascular and/or muscular adaptation and is reflected in an individual's endurance.
- Training for a particular sport or event is dependent on the *specificity principle*<sup>11,12</sup>—that is, the individual improves in the exercise task used for training and may not improve in other tasks. For example, swimming may enhance one's performance in swimming events but may not improve one's performance in treadmill running.

## Adaptation

The cardiovascular system and the muscles used *adapt* to the training stimulus over time.<sup>11,12</sup> Significant changes can be measured in as little as 10 to 12 weeks.

*Adaptation* results in increased efficiency of the cardiovascular system and the active muscles. Adaptation represents a variety of neurological, physical, and biochemical changes in the cardiovascular and muscular systems. Performance improves in that the same amount of work can be performed after training but at a lower physiological cost.

Adaptation is dependent on the ability of the organism to change and the training stimulus threshold (the stimulus that elicits a training response). The person with a low level of fitness has more potential to improve than the one who has a high level of fitness.

Training stimulus thresholds are variable. The higher the initial level of fitness, the greater the intensity of exercise needed to elicit a significant change.

## Myocardial Oxygen Consumption

*Myocardial oxygen consumption* is a measure of the oxygen consumed by the myocardial muscle.<sup>2,4,11,12</sup> The need or demand for oxygen is determined by the heart rate (HR), systemic blood pressure, myocardial contractility, and afterload. Afterload is determined by the left ventricular wall tension and central aortic pressure. It is the ventricular force required to open the aortic valve at the beginning of systole. Left ventricular wall tension is primarily determined by ventricular size and wall thickness.

The ability to supply the myocardium with oxygen is dependent on the arterial oxygen content (blood substrate), hemoglobin oxygen dissociation, and coronary blood flow, which is determined by aortic diastolic pressure, duration of diastole, coronary artery resistance, and collateral circulation. In a healthy individual, a balance between myocardial oxygen supply and demand is maintained during maximum exercise. When the demand for oxygen is greater than the supply, myocardial ischemia results.

Because the myocardial muscle extracts 70% to 80% of the oxygen from the blood during rest, its main source of supply

during exercise is through an increase in coronary blood flow. The clinical relevance is described in Box 7.1.

## Deconditioning

*Deconditioning* occurs with prolonged bed rest, and its effects are frequently seen in the patient who has had an extended, acute illness or long-term chronic condition. Decreases in  $\text{VO}_{2 \text{ max}}$ , cardiac output (stroke volume), and muscular strength occur rapidly. These effects are also seen, although possibly to a lesser degree, in the individual who has spent a period of time on bed rest without any accompanying disease process and in the individual who is sedentary because of lifestyle and increasing age. Deconditioning effects associated with bed rest are summarized in Box 7.2.

### FOCUS ON EVIDENCE

In a meta-analysis by Biswas et al,<sup>5</sup> increased time spent in sedentary activities, particularly sitting during the activities, was associated with an increased risk of all-cause mortality including cardiovascular disease incidence and mortality, cancer incidence and mortality, and type II diabetes

#### BOX 7.1 Clinical Relevance—Exertional Angina

Persons who have coronary occlusion may not present with any type of chest pain/symptoms (angina) until they need to exert themselves. This is because when the body works harder the heart rate increases, diastolic filling time decreases, and increased coronary blood flow is sacrificed by the reduced time for filling the coronary arteries. Without an adequate blood supply, the underlying cardiac tissue no longer receives the oxygen needed for metabolic activity, resulting in anginal pain/symptoms.

#### BOX 7.2 Deconditioning Effects Associated With Bed Rest<sup>8,10</sup>

- ↓ Muscle mass
- ↓ Strength
- ↓ Cardiovascular function
- ↓ Total blood volume
- ↓ Plasma volume
- ↓ Heart volume
- ↓ Orthostatic tolerance
- ↓ Exercise tolerance
- ↓ Bone mineral density

incidence. When addressing the combined effect of sedentary time and physical activity with the noted risks, those with high levels of physical activity had a 30% lower risk of all-cause mortality.

Davis et al<sup>7</sup> assessed the amount of time spent in sedentary activities, the frequency of breaks in sedentary time, and the level of physical activity in 217 older adults (age  $\geq 70$  years) with lower extremity function. Less time spent in sedentary activities and more frequent breaks during sedentary time was associated with higher lower extremity function scores as measured by the Short Physical Performance Battery. An increase of 0.58 points in lower extremity function was reported with each additional break in sedentary time per hour.

## Energy Systems, Energy Expenditure, and Efficiency

### Energy Systems

Energy systems are metabolic systems involving a series of biochemical reactions resulting in the formation of adenosine triphosphate (ATP), carbon dioxide, and water.<sup>11,12</sup> The cell uses the energy produced from the conversion of ATP to adenosine diphosphate (ADP) and phosphate (P) to perform metabolic activities. Muscle cells use this energy for actin-myosin cross-bridge formation when contracting. There are three major energy systems. The intensity and duration of activity determine when and to what extent each metabolic system contributes.

#### Phosphagen, or ATP-PC, System

The adenosine triphosphate–phosphocreatine (ATP-PC) system has the following characteristics:

- PC and ATP are stored in the muscle cell.
- PC is the chemical fuel source.
- No oxygen is required (anaerobic).
- When muscle is rested, the supply of ATP-PC is replenished.
- The maximum capacity of the system is small (0.7 mol ATP).
- The maximum power of the system is great (3.7 mol ATP/min).
- The system provides energy for short, quick bursts of activity.
- It is the major source of energy during the first 30 seconds of intense exercise.

#### Anaerobic Glycolytic System

The anaerobic glycolytic system has the following characteristics:

- Glycogen (glucose) is the fuel source (glycolysis).
- No oxygen is required (anaerobic).
- ATP is resynthesized in the muscle cell.
- Lactic acid is produced (by-product of anaerobic glycolysis).
- The maximum capacity of the system is intermediate (1.2 mol ATP).

- The maximum power of the system is intermediate (1.6 mol ATP/min).
- The systems provide energy for activity of moderate intensity and short duration.
- It is the major source of energy from the 30th to 90th second of exercise.

### Aerobic System

The aerobic system has the following characteristics:

- Glycogen, fats, and proteins are fuel sources and are utilized relative to their availability and the intensity of the exercise.
- Oxygen is required (aerobic).
- ATP is resynthesized in the mitochondria of the muscle cell. The ability to metabolize oxygen and other substrates is related to the number and concentration of the mitochondria and cells.
- The maximum capacity of the system is great (90.0 mol ATP).
- The maximum power of the system is small (1.0 mol ATP/min).
- The system predominates over the other energy systems after the second minute of exercise.

### Recruitment of Motor Units

Recruitment of motor units is dependent on the rate of work. Fibers are recruited selectively during exercise.<sup>11,12</sup>

- *Slow-twitch fibers (type I)* are characterized by a slow contractile response, are rich in myoglobin and mitochondria, have a high oxidative capacity and a low anaerobic capacity, and are recruited for activities demanding endurance. These fibers are supplied by small neurons with a low threshold of activation and are used preferentially in low-intensity exercise.
- *Fast-twitch fibers (type IIB)* are characterized by a fast contractile response, have a low myoglobin content and few mitochondria, have a high glycolytic capacity, and are recruited for activities requiring power.
- *Fast-twitch fibers (type IIA)* have characteristics of both type I and type IIB fibers and are recruited for both anaerobic and aerobic activities.

### Functional Implications

- *Bursts of intense activity* lasting only seconds develop muscle strength and stronger tendons and ligaments. ATP is supplied by the phosphagen system.
- *Intense activity* lasting 1 to 2 minutes repeated after 4 minutes of rest or mild exercise enhances anaerobic power. ATP is supplied by the phosphagen and anaerobic glycolytic system.
- Activity with *large muscles*, which is less than maximum intensity for 3 to 5 minutes repeated after rest or mild exercise of similar duration, may develop aerobic power and endurance capabilities. ATP is supplied by the phosphagen, anaerobic glycolytic, and aerobic systems.
- Activity of *submaximum intensity* lasting 20 to 30 minutes or more taxes a high percentage of the aerobic system and develops endurance.

## Energy Expenditure

Energy is expended by individuals engaging in physical activity and is often expressed in kilocalories. Activities can be categorized as light, moderate, or heavy by determining the energy cost. The energy cost of any activity is affected by mechanical efficiency and body mass. Factors that affect both walking and running are terrain, stride length, and air resistance.<sup>11,12</sup>

### Quantification of Energy Expenditure

Energy expended is computed from the amount of oxygen consumed. Units used to quantify energy expenditure are METs and kilocalories.

- A *MET* is defined as the oxygen consumed (milliliters) per kilogram of body weight per minute (mL/kg). It is equal to approximately 3.5 mL/kg per minute.<sup>2,11,12</sup>
- A *kilocalorie* is a measure expressing the energy value of food. It is the amount of heat necessary to raise 1 kilogram (kg) of water 1°C. A kilocalorie (kcal) can be expressed in oxygen equivalents. Five kilocalories equal approximately 1 liter of oxygen consumed (5 kcal = 1 liter O<sub>2</sub>).<sup>2,11,12</sup>
- To convert METs to kcal per minute, use the following formula: [(METs × 3.5 mL/kg per minute × body weight in kg) ÷ 1000] × 5.<sup>2</sup>

### Classification of Activities

Activities are classified as light, moderate, or vigorous according to the energy expended or the oxygen consumed while accomplishing them.<sup>2</sup>

- *Light activity* is 2.0 to 2.9 METs or 3.5 to 10.15 mL/kg per minute.
- *Moderate activity* is 3.0 to 5.9 METs or 10.5 to 10.65 mL/kg per minute.
- *Vigorous activity* is 6 to 8.8 METs or 21 to 30.8 mL/kg per minute.

The energy expenditure necessary for most industrial jobs requires more than three times the energy expenditure at rest. Energy expenditure of certain physical activities can vary, depending on factors such as skill, pace, and fitness level (Box 7.3).

#### BOX 7.3 Energy Expenditure of Daily Tasks

MET	Type of Physical Activity
1.0–2.9	Sitting, standing, self-care, making the bed, food shopping, walking less than 2.5 mph
3.0–5.9	Walking downstairs, walking 2.5 mph to less than 3.5 mph, mowing the lawn (walking) with a power mower, playing golf
6.0–8.8	Walking faster than 3.5 mph, swimming laps (moderate effort), jogging, running at 5.0 mph, shoveling snow

## Efficiency

Efficiency is usually expressed as a percentage:<sup>11,12</sup>

$$\text{Percent efficiency} = \frac{\text{useful work output}}{\text{energy expended or work input}} \times 100$$

*Work output* equals force times distance ( $W = F \times D$ ). It can be expressed in power units or work per unit of time ( $P = w/t$ ). On a treadmill, work equals the weight of the subject times the vertical distance the subject is raised walking up the incline of the treadmill. On a bicycle ergometer, work equals the distance (which is the circumference of the flywheel times the number of revolutions) times the bicycle resistance.

*Work input* equals energy expenditure and is expressed as the net oxygen consumption per unit of time. With aerobic exercise, the resting volume of oxygen used per unit of time ( $VO_2$  value) is subtracted from the oxygen consumed during 1 minute of the steady-state period.

- Steady state is reached within 3 to 4 minutes after exercise has started if the load or resistance is kept constant.
- In the steady-state period,  $VO_2$  remains at a constant (steady) value.

Total net oxygen cost is multiplied by the total time in minutes the exercise is performed. The higher the net oxygen cost, the lower the efficiency in performing the activity. Efficiency of large muscle activities is usually 20% to 25%.

## Physiological Response to Aerobic Exercise

The rapid increase in energy requirements during exercise requires equally rapid circulatory adjustments to meet the increased need for oxygen and nutrients to remove the end-products of metabolism, such as carbon dioxide, water, and lactic acid, and to dissipate excess heat. The shift in body metabolism occurs through a coordinated activity of all the systems of the body: neuromuscular, respiratory, cardiovascular, metabolic, and hormonal (Box 7.4). Oxygen transport and its utilization by the mitochondria of the contracting muscle are dependent on adequate blood flow in conjunction with cellular respiration.<sup>11,12</sup>

### BOX 7.4 Factors Affecting the Response to Acute Exercise

Ambient temperature, humidity, and altitude can affect the physiological responses to acute exercise. Diurnal fluctuations as well as changes associated with a female subject's menstrual cycle can affect these responses as well. Therefore, researchers control these factors as much as possible when evaluating the response to exercise.

## Cardiovascular Response to Exercise

### Exercise Pressor Response

Stimulation of small myelinated and unmyelinated fibers in skeletal muscle involves a sympathetic nervous system (SNS) response. The central pathways are not known.<sup>2,4, 11,12</sup>

- The SNS response includes generalized peripheral vasoconstriction in nonexercising muscles and increased myocardial contractility, an increased HR, and an increased systolic blood pressure. This results in a marked increase and redistribution of the cardiac output.
- The degree of the response equals the muscle mass involved and the intensity of the exercise.

### Cardiac Effects

- The frequency of sinoatrial node depolarization increases, as does the HR.
- There is a decrease in vagal stimuli as well as an increase in SNS stimulation.
- There is an increase in the force development of the cardiac myofibers. A direct inotropic response of the SNS increases myocardial contractility.

### Peripheral Effects

**Net reduction in total peripheral resistance.** Generalized vasoconstriction occurs that allows blood to be shunted from the nonworking muscles, kidneys, liver, spleen, and splanchnic area to the working muscles. A locally mediated reduction in resistance in the working muscle arterial vascular bed, independent of the autonomic nervous system, is produced by metabolites such as  $Mg^{2+}$ ,  $Ca^{2+}$ , ADP, and  $PCO_2$ . The veins of the working and nonworking muscles remain constricted.

**Increased cardiac output.** The cardiac output increases because of the increase in myocardial contractility, with a resultant increase in stroke volume, HR, blood flow through the working muscle, and an increase in the constriction of the capacitance vessels on the venous side of the circulation in both the working and nonworking muscles, raising the peripheral venous pressure.

**Increase in systolic blood pressure.** The increase in systolic blood pressure is the result of the augmented cardiac output.

## Respiratory Response to Exercise

- Respiratory changes occur rapidly, even before the initiation of exercise.<sup>11,12</sup> Gas exchange ( $O_2$ ,  $CO_2$ ) increases across the alveolar-capillary membrane by the first or second breath. Increased muscle metabolism during exercise results in more  $O_2$  extracted from arterial blood, resulting in an increase in venous  $PCO_2$  and  $H^+$ , an increase in body temperature, increased epinephrine, and increased stimulation of receptors of the joints and muscles. Any of these factors alone or in combination may stimulate the respiratory system. Baroreceptor reflexes, protective reflexes, pain,

emotion, and voluntary control of respiration may also contribute to the increase in respiration.

- Minute ventilation increases as respiratory frequency and tidal volume increase.
- Alveolar ventilation, occurring with the diffusion of gases across the capillary-alveolar membrane, increases 10- to 20-fold during heavy exercise to supply the additional oxygen needed and excrete the excess CO<sub>2</sub> produced.

## Responses Providing Additional Oxygen to Muscle

### Increased Blood Flow

The increased blood flow to the working muscle previously discussed provides additional oxygen.

### Increased Oxygen Extraction

There is also extraction of more oxygen from each liter of blood. There are several changes that allow for this.

- A decrease of the local tissue PO<sub>2</sub> occurs because of the use of more oxygen by the working muscle. As the partial pressure of oxygen decreases, the unloading of oxygen from hemoglobin is facilitated.
- The production of more CO<sub>2</sub> causes the tissue to become acidotic (the hydrogen ion concentration increases) and the temperature of the tissue to increase. Both situations increase the amount of oxygen released from hemoglobin at any given partial pressure.
- The increase of red blood cell 2,3-diphosphoglycerate (DPG) produced by glycolysis during exercise also contributes to the enhanced release of oxygen.

### Oxygen Consumption

Factors determining how much of the oxygen is consumed are:

- Vascularity of the muscles.
- Fiber distribution.
- Number of mitochondria.
- Oxidative mitochondrial enzymes present in the fibers. The oxidative capacity of the muscle is reflected in the arteriovenous oxygen difference (a-vO<sub>2</sub> difference), which is the difference between the oxygen content of arterial and venous blood.

## Testing as a Basis for Exercise Programs

Testing for physical fitness of healthy individuals should be distinct from graded exercise testing of convalescing patients, individuals with symptoms of coronary heart disease, or individuals who are 35 years or older but asymptomatic.<sup>2-4</sup> Regardless of the type of testing, the level of performance is based on the submaximum oxygen uptake, the VO<sub>2 max</sub>, or the symptom-limited oxygen uptake. The capacity of the

individual to transport and utilize oxygen is reflected in the oxygen uptake. Readers are referred to publications by the ACSM<sup>2-4</sup> for additional information.

## Fitness Testing of Healthy Subjects

Field tests for determining cardiovascular fitness include the time to run 1.5 miles or the distance run in 12 minutes. These measures correlate well with VO<sub>2 max</sub>, but their use is limited to young persons or middle-aged individuals who have been carefully screened and have been jogging or running for some time.<sup>2,4</sup> Other field tests include the 1-mile walk test, 6-minute walk test, and step tests. These tests are more suitable for individuals who are not as physically active.

Multistage testing can provide a direct measurement of VO<sub>2 max</sub> by analyzing samples of expired air.<sup>2,4</sup> Testing is usually completed in four to six treadmill stages, which progressively increase in speed and or grade. Each stage is 3 to 6 minutes long. Electrocardiographic (ECG) monitoring is performed during the testing. Maximum oxygen uptake can be determined when the oxygen utilization plateaus despite an increase in workload.

## Stress Testing for Convalescing Individuals and Individuals at Risk

Individuals undergoing stress testing should have a physical examination; be monitored by the ECG; and be closely observed at rest, during exercise, and during recovery (Fig. 7.1).

**FIGURE 7.1** Treadmill stress test with electrocardiogram monitoring. (From Porcari, J, Bryant, C, and Comana, F: Exercise Physiology. Philadelphia: F.A. Davis, 2015, p. 762, with permission.)

### Principles of Stress Testing

The principles of stress testing include:<sup>2,4</sup>

- Changing the workload by increasing the speed and/or grade of the treadmill or the resistance on the bicycle ergometer
- An initial workload that is low in terms of the individual's anticipated aerobic threshold

- Maintaining each workload for 1 minute or longer
- Terminating the test at the onset of symptoms or a definable abnormality of the ECG
- When available, measuring the individual's  $\text{VO}_2 \text{max}$

### Purpose of Stress Testing

In addition to serving as a basis for determining exercise levels or the exercise prescription, the stress test:

- Helps establish a diagnosis of overt or latent heart disease.
- Evaluates cardiovascular functional capacity as a means of clearing individuals for strenuous work or exercise programs.
- Determines the physical work capacity in kilogram-meters per minute (kg-m/min) or the functional capacity in METs.
- Evaluates responses to exercise training and/or preventive programs.
- Assists in the selection and evaluation of appropriate modes of treatment for heart disease.
- Increases individual motivation for entering and adhering to exercise programs.
- Is used clinically to evaluate patients with chest sensations or a history of chest pain to establish the probability that such patients have coronary disease. It can also evaluate the functional capacity of patients with chronic disease.

### Preparation for Stress Testing

All individuals who are taking a stress test should:

- Have had a physical examination
- Be monitored by ECG and closely observed at rest, during exercise, and during recovery
- Sign a consent form

**PRECAUTIONS:** Precautions to be taken are summarized in Box 7.5. They are applicable for both stress testing and the exercise program.<sup>2,4</sup>

### Termination of Stress Testing

Endpoints requiring termination of the test period are<sup>2</sup>:

- Onset and/or progressive angina
- A significant drop ( $\geq 10$  mm Hg) in systolic pressure in response to an increasing workload
- Lightheadedness, confusion, pallor, cyanosis, nausea, peripheral circulatory insufficiency, shortness of breath, wheezing, or leg cramps
- Excessive rise in blood pressure
- No increase in HR with an increase in exercise intensity
- Onset or change in heart rhythm
- Subject wishes to stop
- Observed or reported symptoms of severe fatigue

### Multistage Testing

Each of the four to six stages lasts approximately 1 to 6 minutes. Differences in protocols involve the number of stages, magnitude of the exercise (intensity), equipment used (bicycle, treadmill), duration of stages, endpoints, position of body, muscle groups exercised, and types of effort.<sup>2,4</sup>

### BOX 7.5 Precautions for Stress Testing and Exercise Program

Cardiopulmonary changes occur with stress testing and exercises. Monitor and recognize the following:

- Heart rate increases with exercise approximately 8–12 beats per minute per MET of physical activity. Monitor for abnormal increases in heart rate.
- Blood pressure increases with exercise approximately 8 to 12 millimeters (mm) of mercury (Hg) per MET of physical activity.
  - Systolic pressure should not exceed 250 mm Hg.
  - Diastolic pressure should not exceed 115 mm Hg.
- Rate and depth of respiration increase with exercise.
  - Respiration should not be labored.
  - The individual should have no perception of shortness of breath.
- The increase in blood flow while exercising, which regulates core temperature and meets the demands of the working muscles, results in changes in the skin of the cheeks, nose, and earlobes. They become pink, moist, and warm to the touch.

Protocols have been developed for multistage testing. The most popular treadmill protocol is the Bruce protocol. Treadmill speed and grade are changed every 3 minutes. Speed increases from 1.7 mph up to 5 mph, and the initial grade of 10% increases up to 18% during the five stages. A sample result of a stress test and referral for cardiac rehabilitation is available on the FA Davis website associated with this text.

## Determinants of an Exercise Program

Just as testing for fitness should be distinct from stress testing for patients or individuals at high risk, training programs for healthy individuals are distinct from the exercise prescription for individuals with cardiopulmonary disease.

Effective endurance training for any population must produce a conditioning or cardiovascular response. Elicitation of the cardiovascular response is dependent on several critical elements of exercise. A recommendation by ACSM<sup>2</sup> and others<sup>9,11,12</sup> is to use the FITT-VP method: *F*requency, *I*ntensity, *T*ime (duration), and *T*ype of exercise, plus *V*olume (amount) and *P*rogression.

### Frequency

While there is no clear-cut information provided on the most effective frequency of exercise for adaptation to occur, optimal frequency of training is generally three to four times a week. Frequency varies, dependent on the health and age of the individual, and may be a less important factor than intensity or

duration in exercise training. If training is at a low intensity, greater frequency may be beneficial. A frequency of two times a week does not generally evoke cardiovascular changes, although older individuals and convalescing patients may benefit from a program of that frequency.

## Intensity

Determination of the appropriate intensity of exercise to use is based on the overload principle and the specificity principle and is the most important component for successful changes to aerobic fitness.<sup>2,4,11,12</sup>

### Overload Principle

Overload is stress on an organism that is greater than that regularly encountered during everyday life. To improve cardiovascular and muscular endurance, an overload must be applied to these systems. The exercise load (overload) must be above the training stimulus threshold (the stimulus that elicits a training or conditioning response) for adaptation to occur.

Once adaptation to a given load has taken place, the training intensity (exercise load) must be increased for the individual to achieve further improvement. Training stimulus thresholds are variable, depending on the individual's level of health, level of activity, age, and gender. The higher the initial level of fitness, the greater the intensity of exercise needed to elicit a change.

A conditioning response occurs generally at 60% to 90% maximum heart rate ( $HR_{max}$ ; 50% to 85%  $VO_{2max}$ ) depending on the individual and the initial level of fitness.

- Seventy percent  $HR_{max}$  is a minimal-level stimulus for eliciting a conditioning response in healthy young individuals.
- Sedentary or “deconditioned” individuals respond to a low exercise intensity, 40% to 50% of  $VO_{2max}$ .
- The exercise does not have to be exhaustive to achieve a training response.
- Determining the  $HR_{max}$  and the *exercise HR* for training programs provides the basis for the initial intensity of the exercise (Box 7.6).
- When the individual is young and healthy, the  $HR_{max}$  can be determined directly from a maximum performance

#### BOX 7.6 Methods to Determine Maximum Heart Rate and Exercise Heart Rate

##### Determine Maximum Heart Rate (HR)

- From multistage test (for young and healthy)
- HR achieved in predetermined submaximum test
- 220 minus age (less accurate)

##### Determine Exercise HR

- Percentage of maximum HR (dependent on level of fitness)
- Karvonen's formula (HRR)

$$\text{Exercise HR} = HR_{rest} + 60\% - 70\% (HR_{max} - HR_{rest})$$

multistage test; extrapolated from the HR achieved on a predetermined submaximum test; or, less accurately, calculated as 220 minus age.

- The *exercise HR* is determined in one of two ways: (1) as a percentage of the  $HR_{max}$  (the percentage used is dependent on the level of fitness of the individual) or (2) using the HR reserve (HRR; Karvonen's formula). Karvonen's formula is based on the HRR, which is the difference between the resting HR ( $HR_{rest}$ ) and the  $HR_{max}$ . The exercise HR is determined as a percentage (usually 60% to 70%) of the HRR plus the  $HR_{rest}$  (see Box 7.6).
- When using Karvonen's formula, the exercise HR is higher than when using the  $HR_{max}$  alone.

### Individuals at Risk

$HR_{max}$  and exercise HR used for the exercise prescription for individuals at risk for coronary artery disease, individuals with coronary artery disease or other chronic disease, and individuals who are elderly are ideally identified based on their performance on the stress test. The  $HR_{max}$  cannot be determined in the same manner as for the young and healthy.

- Assuming that an individual has an average  $HR_{max}$ , using the formula 220 minus age produces substantial errors in prescribing the exercise intensity for these individuals.
- $HR_{max}$ , which may be symptom limited, is considered maximum. At no time should the exercise HR exceed the symptom-limited HR achieved on the exercise test.
- Individuals with cardiopulmonary disease may start exercise programs, depending on their diagnosis, as low as 40% to 60% of their  $HR_{max}$ .

### Variables

Exercising at a high-intensity for a shorter period of time appears to elicit a greater improvement in  $VO_{2max}$  than exercising at a moderate intensity for a longer period of time. However, as exercise approaches the maximum limit, there is an increase in the relative risk of cardiovascular complications and the risk of musculoskeletal injury.

- The higher the intensity and the longer the exercise intervals, the faster the training effect.
- $VO_{2max}$  is the best measure of exercise intensity. Aerobic capacity and HR are linearly related; therefore, the  $HR_{max}$  is a function of intensity.

### Specificity Principle

The specificity principle as related to the specificity of training refers to adaptations in metabolic and physiological systems depending on the demand imposed. There is no overlap when training for strength-power activities and training for endurance activities. Workload and work-rest periods are selected so training results in:

- Muscle strength without a significant increase in total oxygen consumption.
- Aerobic or endurance training without training the anaerobic systems.

- Anaerobic training without training the aerobic systems.
- Aerobic training specific to the type of activity. When training for swimming events, the individual may not demonstrate an improvement in  $\text{VO}_{2\text{max}}$  when running.

## Time (Duration)

The optimal duration of exercise for cardiovascular conditioning is dependent on the total work performed, exercise intensity and frequency, and fitness level. Generally speaking, the greater the intensity of the exercise, the shorter the duration needed for adaptation, and the lower the intensity of exercise, the longer the duration needed.

A 20- to 30-minute session is generally optimal at 70%  $\text{HR}_{\text{max}}$ . When the intensity is below the HR threshold, a 45-minute continuous exercise period may provide the appropriate overload. With high-intensity exercise, 10- to 15-minute exercise periods are adequate; three 5-minute daily periods are effective in some deconditioned patients.

## Type (Mode)

Many types of activity provide the stimulus for improving cardiorespiratory fitness. The important factor is that the exercise involves *large muscle groups* that are activated in a *rhythmic, aerobic* nature. However, the magnitude of the changes may be determined by the mode used.

For specific aerobic activities, such as cycling and running, the overload must use the muscles required by the activity and stress the cardiorespiratory system (specificity principle). If endurance of the upper extremities is needed to perform activities on the job, the upper extremity muscles must be targeted in the exercise program. The muscles trained develop a greater oxidative capacity with an increase in blood flow to the area. The increase in blood flow is due to increased microcirculation and more effective distribution of the cardiac output.

Training benefits are optimized when programs are planned to meet the individual needs and capacities of the participants. The skill of the individual, variations among individuals in competitiveness and aggressiveness, and variation in environmental conditions must be considered.

## Volume

The volume or quantity of exercise completed weekly is the product of frequency, intensity, and time. Examples include MET-minute per week and kcal per week. The recommended volume of moderate intensity exercise needed for reaching health and fitness goals and to decrease the risk of cardiovascular disease for adults is  $\geq 500$  to 1,000 MET-min per week (approximately 1,000 kcal per week).<sup>2,9</sup>

## Progression

How to progress the aerobic exercise prescription is dependent on an individual's overall health at the start of the program and what their fitness and health goals are. Generally,

the time should be increased first, and then the frequency, with the intensity increased last.

## Reversibility Principle

The beneficial effects of exercise training are transient and reversible.

- Detraining occurs rapidly when a person stops exercising. After only 2 weeks of detraining, significant reductions in work capacity can be measured, and improvements can be lost within several months. A similar phenomenon occurs with individuals who are confined to bed with illness or disability: the individual becomes severely deconditioned, with loss of the ability to carry out normal daily activities as a result of inactivity.
- The frequency or duration of physical activity required to maintain a certain level of aerobic fitness is less than that required to improve it.

## CLINICAL TIP

The ACSM,<sup>2,9</sup> the American Heart Association, and the CDC and Surgeon General<sup>6</sup> have specified the amount of aerobic physical activity for children, adults, and older adults. The following are the general recommendations:

- **Children age 6 to 17:** 60 minutes of moderate to vigorous aerobic physical activity per day.
- **Adults age 18 to 65:** 30 minutes of moderate intensity activity (3–5.9 MET level) 5 days/week or 20 minutes of vigorous intensity activity ( $\geq 6$  METs) 3 days/week, or a combination of moderate and vigorous intensity. The 30-minute total of moderate intensity can be accumulated in small bouts of continuous activity of at least 10 minutes. A volume of 500 to 1,000 MET-minutes per week or 1,000 kcal per week.
- **Older adults age 65 or older (or adults 50 to 65 with chronic health conditions):** 30 minutes of moderate intensity activity 5 days/week or 20 minutes of vigorous intensity activity 3 days/week, or a combination of moderate and vigorous intensity. The 30-minute total of moderate intensity can be accumulated in small bouts of continuous activity of at least 10 minutes. A volume of 500 to 1,000 MET-minutes per week or 1,000 kcal per week.

The adult criteria are based on MET level. The older adult criteria for moderate or vigorous intensity are based on a 10- point scale, where 0 is sitting and 10 is working as hard as you can. Moderate intensity activity would be a 5 to 6 and vigorous activity would be 7 to 8.

**NOTE:** Doing more than the minimum described above for adults and older adults is recommended for achieving additional health benefits.

## Exercise Program

A carefully planned exercise program can result in higher levels of fitness for the healthy individual, slow the decrease in functional capacity of the elderly, and recondition those who have been ill or have chronic disease. There are three components of the exercise program: (1) a warm-up period; (2) the aerobic exercise period; and (3) a cool-down period. General guidelines for an aerobic training are summarized in Box 7.7.

### Warm-Up Period

Physiologically, a time lag exists between the onset of activity and the bodily adjustments needed to meet the physical requirements of the body. The purpose of the warm-up period is to enhance the numerous adjustments that must take place before physical activity.

#### BOX 7.7 General Guidelines for an Aerobic Training Program

- Establish the target heart rate and maximum heart rate.
- Warm-up gradually for 5 to 10 minutes. Include stretching and repetitive motions at slow speeds, gradually increasing the effort.
- Increase the pace of the activity so the target heart rate can be maintained for 20 to 30 minutes. Examples include fast walking, running, bicycling, swimming, cross-country skiing, and aerobic dancing.
- Cool-down for 5 to 10 minutes with slow, total body repetitive motions and stretching activities.
- The aerobic activity should be undertaken three to five times per week.
- To avoid injuries from stress, use appropriate equipment, such as correct footwear, for proper biomechanical support. Avoid running, jogging, or aerobic dancing on hard surfaces such as asphalt and concrete.
- To avoid overuse syndromes in structures of the musculoskeletal system, proper warm-up and stretching of muscles to be used should be performed. Progression of activities should be within the tolerance of the individual. Overuse commonly occurs when there is an increase in time or effort without adequate rest (recovery) time between sessions. Increase the repetitions or the time by no more than 10% per week. If pain begins while exercising or lasts longer than 2 hours after exercising, heed the warning and reduce the stress.
- Individualize the program of exercise. All people are not at the same fitness level and therefore cannot perform the same exercises. Any one exercise has the potential to be detrimental if attempted by someone not able to execute it properly. During recovery following an injury or surgery, choose an exercise that does not stress the vulnerable tissue. Begin at a safe level for the individual and progress as the individual meets the desired goals.

### Physiological Responses

During this period there is:

- An increase in muscle temperature. The higher temperature increases the efficiency of muscular contraction by reducing muscle viscosity and increasing the rate of nerve conduction.
- An increased need for oxygen to meet the energy demands for the muscle. Extraction from hemoglobin is greater at higher muscle temperatures, facilitating the oxidative processes at work.
- Dilatation of the previously constricted capillaries with increases in the circulation, augmenting oxygen delivery to the active muscles and minimizing the oxygen deficit and the formation of lactic acid.
- Adaptation in sensitivity of the neural respiratory center to various exercise stimulants.
- An increase in venous return. This occurs as blood flow is shifted centrally from the periphery.

### Purposes

In addition to the physiological responses, the warm-up also prevents or decreases the susceptibility of the musculoskeletal system to injury and the occurrence of ischemic ECG changes and arrhythmias.

### Guidelines

The warm-up should be gradual and sufficient to increase muscle and core temperature without causing fatigue or reducing energy stores. Characteristics of the period include:

- A 10-minute period of total body movement exercises, such as calisthenics and walking slowly
- Attaining a HR that is within 20 beats/min of the target HR

### Aerobic Exercise Period

The aerobic exercise period is the training part of the exercise program. Attention to the determinants of frequency, intensity, time, and type of the program, as previously discussed, has an impact on the effectiveness of the program. The main consideration when choosing a specific method of training is that the intensity be great enough to stimulate an increase in stroke volume and cardiac output and to enhance local circulation and aerobic metabolism in the appropriate muscle groups. The exercise period must be within the person's tolerance, above the threshold level for adaptation to occur, and below the level of exercise that evokes clinical symptoms.

In aerobic exercise, submaximal, rhythmic, repetitive, dynamic exercise of large muscle groups is emphasized.

There are four methods of training that challenge the aerobic system: continuous, interval (work relief), circuit, and circuit interval.

### Continuous Training

- A submaximum energy requirement, sustained throughout the training period, is imposed.

- Once the steady state is achieved, the muscle obtains energy by means of aerobic metabolism. Stress is placed primarily on the slow-twitch fibers.
- The activity can be prolonged for 20 to 60 minutes without exhausting the oxygen transport system.
- The work rate is increased progressively as training improvements are achieved. Overload can be accomplished by increasing the exercise duration.

### Interval Training

With this type of training, the work or exercise is followed by a properly prescribed relief or rest interval. Interval training is perceived to be less demanding than continuous training.

- The relief interval is either a rest relief (passive recovery) or a work relief (active recovery), and its duration ranges from a few seconds to several minutes. Work recovery involves continuing the exercise but at a reduced level from the work period. During the relief period, a portion of the muscular stores of ATP and the oxygen associated with myoglobin that were depleted during the work period are replenished by the aerobic system; an increase in  $VO_{2\max}$  occurs.
- The longer the work interval, the more the aerobic system is stressed. With a short work interval, the duration of the rest interval is critical if the aerobic system is to be stressed (a work/recovery ratio of one to one to one to five is appropriate). A rest interval equal to one and a half times the work interval allows the succeeding exercise interval to begin before recovery is complete and stresses the aerobic system. With a longer work interval, the duration of the rest is not as important.
- A significant amount of high-intensity work can be achieved with interval or intermittent work if there is appropriate spacing of the work-relief intervals. The total amount of work that can be completed with intermittent work is greater than the amount of work that can be completed with continuous training.

### Circuit Training

Circuit training employs a series of exercise activities. At the end of the last activity, the individual starts from the beginning and again moves through the series. The series of activities is repeated several times.

- Several exercise modes can be used involving large and small muscle groups and a mix of static or dynamic effort.
- Use of circuit training can improve strength and endurance by stressing both the aerobic and anaerobic systems.

### Circuit-Interval Training

- Combining circuit and interval training is effective because of the interaction of aerobic and anaerobic production of ATP.
- In addition to the aerobic and anaerobic systems being stressed by the various activities, with the relief interval, there is a delay in the need for glycolysis and the production of lactic acid prior to the availability of oxygen supplying the ATP.

## Cool-Down Period

The cool-down period is similar to the warm-up period in that it should last 5 to 10 minutes and consist of total-body movements and static stretching.

The purpose of the cool-down period is to:

- Prevent pooling of the blood in the extremities by continuing to use the muscles to maintain venous return
- Prevent fainting by increasing the return of blood to the heart and brain as cardiac output and venous return decreases
- Enhance the recovery period with the oxidation of metabolic waste and replacement of the energy store
- Prevent myocardial ischemia, arrhythmias, or other cardiovascular complications

## Physiological Changes That Occur With Training

Changes in the cardiovascular and respiratory systems as well as changes in muscle metabolism occur following endurance training. These changes are reflected both at rest and with exercise. It is important to note that all of the following training effects cannot result from one training program.

### Cardiovascular Changes

#### Changes at Rest

- *A reduction in the resting pulse rate* occurs in some individuals because of a decrease in sympathetic drive, with decreasing levels of norepinephrine and epinephrine; a decrease in atrial rate secondary to biochemical changes in the muscles and levels of acetylcholine, norepinephrine, and epinephrine in the atria; and an apparent increase in parasympathetic (vagal) tone secondary to decreased sympathetic tone.
- *A decrease in blood pressure* occurs in some individuals with a decrease in peripheral vascular resistance. The largest decrease is in systolic blood pressure and is most apparent in hypertensive individuals.
- *An increase in blood volume and hemoglobin* may occur. This facilitates the oxygen delivery capacity of the system.

#### Changes During Exercise

- A reduction in the pulse rate occurs in some individuals because of the mechanisms listed earlier in this section.
- *Increased stroke volume* may occur because of an increase in myocardial contractility and an increase in ventricular volume.
- *Increased cardiac output* may occur as a result of the increased stroke volume that occurs with maximum exercise but not with submaximum exercise. The magnitude of the change is directly related to the increase in stroke volume and the magnitude of the reduced HR.
- *Increased extraction of oxygen by the working muscle* occurs in some individuals because of enzymatic and biochemical changes in the muscle, as well as increased  $VO_{2\max}$ . Greater

$\text{VO}_{2\text{max}}$  results in a greater work capacity. The increased cardiac output increases the delivery of oxygen to the working muscles. The increased ability of the muscle to extract oxygen from the blood increases the utilization of the available oxygen.

- *Decreased blood flow per kilogram of the working muscle* may occur even though increasing amounts of blood are shunted to the exercising muscle. The increase in extraction of oxygen from the blood compensates for this change.
- *Decreased myocardial oxygen consumption (pulse rate times systolic blood pressure) for any given intensity of exercise* may occur as a result of a decreased pulse rate with or without a modest decrease in blood pressure. The product can be decreased significantly in the healthy subject without any loss of efficiency at a specific workload.

## Respiratory Changes

### Changes at Rest

- *Larger lung volumes* develop because of improved pulmonary function, with no change in tidal volume.
- *Larger diffusion capacities* develop because of larger lung volumes and greater alveolar-capillary surface area.

### Changes During Exercise

- Larger diffusion capacities occur for the same reasons as those listed previously; the maximum capacity of ventilation is unchanged.
- A smaller amount of air is ventilated at the same oxygen consumption rate; maximum diffusion capacity is unchanged.
- The maximal minute ventilation is increased.
- Ventilatory efficiency is increased.

## Metabolic Changes

### Changes at Rest

- Muscle hypertrophy and increased capillary density occurs.
- The number and size of mitochondria are increased, increasing the capacity to generate ATP aerobically.
- The muscle myoglobin concentration increases, increasing the rate of oxygen transport and possibly the rate of oxygen diffusion to the mitochondria.

### Changes During Exercise

- A decreased rate of depletion of muscle glycogen at submaximum work levels may occur. Another term for this phenomenon is glycogen sparing. It is due to an increased capacity to mobilize and oxidize fat and increased fat-mobilizing and fat-metabolizing enzymes.
- Lower blood lactate levels at submaximal work may occur. The mechanism for this is unclear; it does not appear to be related to decreased hypoxia of the muscles.
- Less reliance on PC and ATP in skeletal muscle and an increased capability to oxidize carbohydrate may result because of an increased oxidative potential of the mitochondria and an increased glycogen storage in the muscle.

**NOTE:** Ill health may influence metabolic adaptations to exercise.

## Other System Changes

Changes in other systems that occur with training include:

- Decrease in body fat
- Decrease in blood cholesterol and triglyceride levels
- Increased heat acclimatization
- Increase in the breaking strength of bones and ligaments and the tensile strength of tendons

## Application of Principles of an Aerobic Training Program for the Patient With Coronary Disease

Employing the principles of aerobic training, in addition to secondary prevention and risk factor modification, is a dominant part of cardiac rehabilitation for individuals following a coronary event such as myocardial infarction (MI), revascularization, valve replacement, coronary artery bypass surgery, heart transplant, or heart failure.<sup>8,10</sup>

## Inpatient Cardiac Rehabilitation<sup>1</sup>

The inpatient phase of the program occurs in the hospital following stabilization of the patient's cardiovascular status, such as MI, valve replacement, or coronary bypass surgery, and generally lasts 3 to 5 days.

### Purpose

The purpose of the early portion of cardiac rehabilitation is to:

- Initiate risk factor education and address future modification of certain behaviors, such as eating habits and smoking.
- Initiate self-care activities and progress from sitting to standing to minimize deconditioning (1 to 3 days post event).
- Provide an orthostatic challenge to the cardiovascular system (3 to 5 days post event). This is usually accomplished by supervised ambulation. Ambulation is usually monitored electrocardiographically, as well as manually monitoring the HR, ventilation rate, and blood pressure. The intensity level of activity starts at 1 to 2 MET and is progressed to 3 to 4 MET by discharge if tolerated.
- Prepare patients and family for continued rehabilitation and for life at home after a cardiac event.

## Outpatient Cardiac Rehabilitation: Early Exercise Program

The early outpatient exercise program is initiated within 1 to 3 weeks of discharge from the hospital and lasts up to 36 sessions. Participants are monitored via telemetry to determine

HR and rhythm responses; blood pressure is recorded at rest and during exercise, and ventilation responses are noted. A description of a cardiac rehabilitation referral is available on the FA Davis website associated with this text.

## Purpose

The purpose of the program is to:

- Increase the person's exercise capacity in a safe, progressive manner so adaptive cardiovascular and muscular changes occur. The early part of the program might be considered by some as "low-level" exercise training.
- Enhance cardiac functions and reduce the cardiac cost of work. This may help eliminate or delay symptoms such as angina and ST-segment changes in the patient with coronary heart disease.
- Produce favorable metabolic changes.
- Determine the effect of medications on increasing levels of activity.
- Relieve anxiety and depression.
- Progress the patient to an independent exercise program.

## Guidelines<sup>2</sup>

**Frequency.** Participants often attend sessions offered three times per week.

**Intensity.** Multiple methods may be used to determine the intensity of the aerobic activity. The training intensity may be prescribed using the exercise capacity of HRR and may range from 40% to 80%. Another method is using the Rate of Perceived Exertion scale and should be between 11 and 16 on the 6-20 scale (see Box 25.4 in Chapter 25). The starting intensity is dictated by the severity of the diagnosis in concert with the individual's age and prior fitness level. The intensity is progressed as the individual responds to the training program.

**Time.** The duration of the exercise session may be limited to 10 to 15 minutes at the start, progressing to 20 to 60 minutes as the patient's status improves. Each session usually includes 5 to 10-minute warm-up and cool-down periods.

**Type.** The mode of exercise is usually continuous, using large muscle groups, such as stationary bike, rower, stepper, elliptical, or treadmill walking.

**Volume.** As noted previously the volume of exercise is the product of frequency, intensity, and time.

**Progression.** The progression of aerobic training is dependent on the patients' response to the activities and their goals for treatment.

## Maintenance Program<sup>1</sup>

The outpatient phase of cardiac rehabilitation includes a supervised exercise conditioning program, which is often continued in a hospital or community setting. HR and rhythm are no

longer monitored via telemetry. Participants are reminded to monitor their own pulse rate, and a supervisory person is available to monitor blood pressure.

## Purpose

The purpose of the program is to continue to improve or maintain fitness levels achieved during early outpatient cardiac rehabilitation and to continue secondary prevention activities to assist with behavior change and risk factor modification.

### CLINICAL TIP<sup>1</sup>

The number of visits completed in early outpatient cardiac rehabilitation and whether a patient is monitored with ECG (and for how long) depends on the risk for participating in aerobic training. Low-risk patients participate in 6 to 18 sessions which start with continuous ECG monitoring and then decrease its use within 6 to 12 visits. Moderate-risk patients participate in 12 to 24 sessions which start with continuous ECG monitoring decreasing to intermittent or no monitoring within 12 to 18 sessions if appropriate based on ECG results during exercise. High-risk patients participate in 28 to 36 sessions and start with continuous ECG monitoring and decreasing to intermittent if appropriate.

## Special Considerations

There are special considerations related to types of exercise and patient needs that must be recognized when developing conditioning programs for patients with coronary disease. Arm exercises elicit different responses than leg exercises.

- Mechanical efficiency based on the ratio between output of external work and caloric expenditure is lower than with leg exercises.
- Oxygen uptake at a given external workload is significantly higher for arm exercises than for leg exercises.
- Myocardial efficiency is lower with leg exercises than with arm exercises.
- Myocardial oxygen consumption ( $HR \times$  systolic blood pressure) is higher with arm exercises than with leg exercises.

**PRECAUTION:** Patients with coronary disease complete 35% less work with arm exercises than with leg exercises before symptoms occur.

## Adaptive Changes

Adaptive changes following training of individuals with cardiac disease include:

- Increased myocardial aerobic work capacity.
- Increased maximum aerobic or functional capacity by predominantly widening the  $a-vO_2$  difference.

- Increased stroke volume following high-intensity training 6 to 12 months into the training program.
- Decreased myocardial demand for oxygen.
- Increased myocardial supply by the decreased HR and prolongation of diastole.
- Increased tolerance to a given physical workload before angina occurs.
- Significantly lower HR at each submaximum workload and, therefore, a greater HRR. When muscles are used that are not directly involved in the activity, the reduction in HR is not as great.
- Improved psychological orientation and, over time, an impact on depression scores, scores for hysteria, hypochondriasis, and psychoasthenia on the Minnesota Multiphasic Personality Inventory.

## Applications of Aerobic Training for the Deconditioned Individual and the Patient With Chronic Illness

Deconditioned individuals, including those with chronic illness and the elderly, may have major limitations in pulmonary and cardiovascular reserves that severely curtail their daily activities.

### Deconditioning

Implications of the changes due to deconditioning brought on by inactivity resulting from any illness or chronic disease are important to remember.<sup>8,10,11</sup>

- There is decreased work capacity, which is a result of decreased maximum oxygen uptake and decreased ability to use oxygen and perform work. There is also decreased cardiac output, which is the major limiting factor.
- There is decreased circulating blood volume that can be as much as 700 to 800 mL. For some individuals, this results in tachycardia along with orthostatic hypotension, dizziness, and episodes of syncope when initially attempting to stand.
- There is a decrease in plasma and red blood cells, which increases the likelihood of life-threatening embolothrombotic episodes and prolongation of the convalescent period.
- There is a decrease in lean body mass, which results in decreased muscle size and decreased muscle strength and ability to perform activities requiring large muscle groups. For example, the individual may have difficulty walking with crutches or climbing stairs.
- There is increased excretion of urinary calcium, which results from a decrease in the weight-bearing stimulus critical

in maintaining bone integrity, in bone loss or osteoporosis, and in an increased likelihood of fractures upon falling because of osteoporosis.

### Reversal of Deconditioning

Through an exercise program, the negative cardiovascular, neuromuscular, and metabolic functions can be reversed. This results in:

- A decrease in the HR<sub>rest</sub>, the HR with any given exercise load, and urinary excretion of calcium
- An increase in stroke volume at rest, stroke volume with exercise, cardiac output with exercise, total heart volume, lung volume (ventilatory volume), vital capacity, maximum oxygen uptake, circulating blood volume, plasma volume and red blood cells, and lean body mass
- A reversal of the negative nitrogen and protein balance
- An increase in levels of mitochondrial enzymes and energy stores
- Less use of the anaerobic systems during activity

### Adaptations for Those With Activity Limitations and Participation Restrictions

Individuals who have participation or activity restrictions should not be excluded from a training program that can increase their fitness level. This includes individuals in wheelchairs or persons who have problems ambulating, such as those with paraplegia, hemiplegia, or amputation, and those with an orthopedic problem, such as arthrodesis.

- Adaptations must be made when testing the physically disabled using a wheelchair treadmill or, more frequently, using the upper extremity ergometer.
- Exercise protocols may emphasize upper extremities and manipulation of the wheelchair.
- It is important to remember that energy expenditure is increased when the gait is altered, and wheelchair use is less efficient than walking without impairment.

### Impairments, Goals, and Plan of Care

The goals of an aerobic exercise program are dependent on the initial level of fitness of the individual and on his or her specific clinical needs. The general goals are to decrease the deconditioning effects of disease and chronic illness and to improve the individual's cardiovascular and muscular fitness.

#### Common Impairments

- Increased susceptibility to thromboembolic episodes, pneumonia, atelectasis, and the likelihood of fractures
- Tachycardia, dizziness, and orthostatic hypotension when moving from sitting to standing

- A decrease in general muscle strength, with difficulty and shortness of breath in climbing stairs
- A decrease in work capacity that limits distances walked and activities tolerated
- Increased HR and blood pressure responses (rate-pressure product) to various activities
- A decrease in the maximum rate-pressure product tolerated with angina or other ischemic symptoms appearing at low levels of exercise

### Goals

- Prevent thromboembolic episodes, pneumonia, atelectasis, and fractures
- Decrease the magnitude of the orthostatic hypotensive response
- Improve ability to climb stairs safely and without shortness of breath
- Develop tolerance for walking longer measured distances and completing activities without fatigue or symptoms
- Decrease HR and blood pressure (rate-pressure product) at a given level of activity
- Increase the maximum rate-pressure product tolerated without ischemic symptoms

### Outcomes

- Improved pulmonary, cardiovascular, and metabolic response to various levels of exercise
- Improved ability to complete selected activities with appropriate HR and blood responses to exercise

### Guidelines

Guidelines for establishing a safe program of intervention for the deconditioned individual and the convalescent patient with chronic illness are summarized in Boxes 7.8 and 7.9.

#### BOX 7.8 Guidelines for Initiating an Aerobic Exercise Program for the Deconditioned Individual and the Patient With Chronic Illness

- Determine the exercise heart rate response that can be safely reached using the Karvonen formula as a guide, accounting for medical conditions, medications, and the individual's perceived exertion.
- Initiate a program of activities for the patient that does not elicit a cardiovascular response over the exercise heart rate (e.g., walking, repetitive activities, easy calisthenics).
- Provide patients with clearly written instructions about any activity they perform on their own.
- Initiate an educational program that provides the patient with information about effort symptoms and exercise precautions, monitoring the heart rate, and making modifications when indicated.

#### BOX 7.9 Guidelines for Progression of an Aerobic Training Program

- Determine the maximum heart rate or symptom-limited heart rate by multistage testing with ECG monitoring.
- Decide on the threshold stimulus (percentage of maximum or symptom-limited heart rate) that elicits a conditioning response for the individual tested and that can be used as the exercise heart rate.
- Determine the frequency, intensity, and time of exercise that results in attaining the exercise heart rate and a training response.
- Determine the type of exercise to be used based on the individual's physical capabilities and interest.
- Initiate an exercise program with the patient and provide clearly written instructions regarding the details of the program.
- Discuss how to progress the activity: increase time first, then increase frequency, and then increase the intensity.
- Educate the patient about:
  - Effort symptoms and the need to cease or modify exercise when these symptoms appear and to communicate with the physical therapist and/or physician about these problems.
  - Monitoring heart rate at rest as well as during and following exercise.
  - The importance of exercising within the guidelines provided by the physical therapist.
  - The importance of consistent long-term follow-up with the exercise program so it can be progressed within safe limits.
  - The importance of modifying risk factors related to cardiac problems.

## Age Differences

Differences in endurance and physical work capacity among children, young adults, and middle-aged or elderly individuals are evident. Some comparisons are made between maximum oxygen uptake and the factors influencing it and among blood pressure, respiratory rate, vital capacity, and maximum voluntary ventilation in the different age categories. It is important when developing aerobic conditioning programs that these age-related differences are taken into consideration.

### Children

Between the ages of 5 and 15, there is a three-fold increase in body weight, lung volume, heart volume, and maximum oxygen uptake.

**Heart rate.**  $HR_{rest}$  is on the average above 125 (126 in girls and 135 in boys) at infancy.  $HR_{rest}$  drops to adult levels at puberty.  $HR_{max}$  is age related (220 minus age).

**Stroke volume.** Stroke volume is closely related to size. Children 5 to 16 years of age have a stroke volume of 30 to 40 mL.

**Cardiac output.** Cardiac output is related to size. Cardiac output increases with increasing stroke volume. The increase in cardiac output for a given increase in oxygen consumption is a constant throughout life: it is the same in the child as in the adult.

**Arteriovenous oxygen difference.** Children tolerate a larger arteriovenous oxygen difference ( $a\text{-VO}_2$ ) than adults. The larger  $a\text{-VO}_2$  difference makes up for the smaller stroke volume.

**Maximum oxygen uptake.** The  $\text{VO}_{2\text{max}}$  increases with age up to 20 years (expressed as liters per minute). Before puberty, girls and boys show no significant difference in maximum aerobic capacity. Cardiac output in children is the same as in the adult for any given oxygen consumption. Endurance times increase with age until 17 to 18 years.

**Blood pressure.** Systolic blood pressure increases from 40 mm Hg at birth to 80 mm Hg at age 1 month to 100 mm Hg several years before puberty. Adult levels are observed at puberty. Diastolic blood pressure increases from 55 to 70 mm Hg from 4 to 14 years of age, with little change during adolescence.

**Respiration.** Respiratory rate decreases from 30 breaths per minute at infancy to 16 breaths per minute at 17 to 18 years of age. Vital capacity and maximum voluntary ventilation are correlated with height, although the greater increase in boys than girls at puberty may be due to an increase in lung tissue.

**Muscle mass and strength.** Muscle mass increases through adolescence, primarily owing to muscle fiber hypertrophy and the development of sarcomeres. Sarcomeres are added at the musculotendinous junction to compensate for the required increase in length. Girls develop peak muscle mass between 16 and 20 years, whereas boys develop peak muscle mass between 18 and 25 years. Strength gains are associated with increased muscle mass in conjunction with neural maturation.

**Anaerobic ability.** Children generally demonstrate a limited anaerobic capacity. They produce less lactic acid which may be due to a limited glycolytic capacity.

## Young Adults

There are more data on the physiological parameters of fitness for the young and middle-aged adult than for children or the elderly.

**Heart rate.**  $\text{HR}_{\text{rest}}$  reaches 60 to 65 beats per minute at 17 to 18 years of age (75 beats per minute in a sitting, sedentary young man).  $\text{HR}_{\text{max}}$  is age related (190 beats per minute in the same sedentary young man).

**Stroke volume.** The adult values for stroke volume are 60 to 80 mL (75 mL in a sitting, sedentary young man). With maximum exercise, stroke volume is 100 mL in that same sedentary young man.

**Cardiac output for the sedentary young man at rest.** Cardiac output at rest is 75 beats per minute  $\times$  75 mL, or 5.6 liters

per minute. With maximum exercise, cardiac output is 190 beats per minute  $\times$  100 mL, or 19 liters per minute.

**Arteriovenous oxygen difference.** Approximately 25% to 30% of the oxygen is extracted from blood as it runs through the muscles or other tissues at rest. In a normal, sedentary young man, it increases three-fold (5.2 to 15.8 mL/dL blood) with exercise.

**Maximum oxygen uptake.** The difference in  $\text{VO}_{2\text{max}}$  between males and females is greatest in the adult. Differences in  $\text{VO}_{2\text{max}}$  between the sexes is minimal when  $\text{VO}_{2\text{max}}$  is expressed relative to lean body weight. In the sedentary young man, maximum oxygen uptake equals 3,000 mL/min (oxygen uptake at rest equals 300 mL/min).

**Blood pressure.** Systolic blood pressure is 120 mm Hg (average). At peak effort during exercise, values may range from as low as 190 mm Hg to as high as 240 mm Hg. Diastolic blood pressure is 80 mm Hg (average). Diastolic pressure does not change markedly with exercise.

**Respiration.** Respiratory rate is 12 to 15 breaths per minute. Vital capacity is 4,800 mL in a man 20 to 30 years of age. Maximum voluntary ventilation varies considerably from laboratory to laboratory and is dependent on age and the surface area of the body.

**Muscle mass and strength.** Muscle mass increases with training as a result of hypertrophy. This hypertrophy can be the result of an increased number of myofibrils or increased actin and myosin, sarcoplasm, and/or connective tissue. As the nervous system matures, increased recruitment of motor units or decreased autogenic inhibition by Golgi tendon organs appears also to dictate strength gains.

**Anaerobic ability.** Anaerobic training increases the activity of several controlling enzymes in the glycolytic pathway and enhances stored quantities of ATP and PC. Anaerobic training increases the muscle's ability to buffer the hydrogen ions released when lactic acid is produced. Increased buffering allows the muscle to work anaerobically for longer periods of time.

## Older Adults

(See Chapter 24 for additional information on exercise in the older adult population.)

**Heart rate.**  $\text{HR}_{\text{rest}}$  is not influenced by age.  $\text{HR}_{\text{max}}$  is age related and decreases with age (in very general terms, 220 minus age). The average  $\text{HR}_{\text{max}}$  for men 20 to 29 years of age is 190 beats/min. For men 60 to 69 years of age, it is 164 beats/min. The amount that the HR increases in response to static and maximum dynamic exercise (hand grip) decreases in the elderly.

**Stroke volume.** Stroke volume decreases in the aged and results in decreased cardiac output.

**Cardiac output.** Cardiac output decreases with age as the result of a decrease in stroke volume and other age-related health changes which affect preload and afterload.

**Arteriovenous difference.** Arteriovenous oxygen difference decreases as a result of decreased lean body mass and low oxygen-carrying capacity.

**Maximum oxygen uptake.** According to cardiorespiratory fitness classification, if men 60 to 69 years of age of average fitness level are compared with men 20 to 29 years of age of the same fitness level, the maximum oxygen uptake for the older man is lower (20 to 29 years is 31 to 37 mL/kg per minute; 60 to 69 years is 18 to 23 mL/kg per minute). Aerobic capacity decreases about 10% per decade when evaluating sedentary men.  $\text{VO}_{2\text{max}}$  decreases on an average from 47.7 mL/kg per minute at age 25 years to 25.5 mL/kg per minute at age 75 years. This decrease is not directly the result of age; athletes who continue exercising have significantly less decrease in  $\text{VO}_{2\text{max}}$  when evaluated over a 10-year period.

**Blood pressure.** Blood pressure increases because of increased peripheral vascular resistance (average systolic blood

pressure of the aged is 150 mm Hg; average diastolic blood pressure is 90 mm Hg).

**Respiration.** Respiratory rate increases with age. Vital capacity decreases with age. There is a 25% decrease in the vital capacity of the 50- to 60-year-old man compared with the 20- to 30-year-old man with the same surface area. Maximum voluntary ventilation decreases with age.

**Muscle mass and strength.** Generally, the strength decline with age is associated with a decrease in muscle mass and physical activity. The decrease in muscle mass is primarily due to a decrease in protein synthesis, in concert with a decline in the number of fast-twitch muscle fibers. Aging may also affect strength by slowing the nervous system's response time. This may alter the ability to recruit motor units effectively. Continued training as one ages appears to reduce the effects of aging on the muscular system.

## Independent Learning Activities

### Critical Thinking and Discussion

- The clinic in which you work has developed an outpatient program to help overweight young adults lose weight and improve their cardiorespiratory fitness. Your first client is a 13-year-old male who is 5 feet, 3 inches tall and weighs 250 pounds.
  - Describe several methods of assessing this individual's current aerobic fitness level.
  - Outline an aerobic training program using the FITT-VP model. Be specific as to the type of aerobic exercise this client will do.
  - What precautions will you take working with this client?
- You are an invited speaker at a senior citizen center for a lunchtime discussion of lifetime fitness and establishing an appropriate exercise program for individuals in this age category.
  - Discuss the definition of physical activity, fitness, and endurance.
  - Discuss the benefits of aerobic training and the effect of training on HR, blood pressure, stroke volume, and cardiac output.
  - Discuss the deleterious effects of sitting too much and what an older adult could do to decrease these effects.
- Describe the necessary precautions when dealing with the older population (both the older athlete and the untrained individual).
- Explain the concepts of energy expenditure, oxygen consumption, and efficiency with regard to ambulating with an assistive device in the following weight bearing scenarios: nonweight bearing, partial weight bearing, and weight bearing as tolerated. Consider the use of a walker and crutches. How would energy expenditure change ambulating upstairs with crutches?
- Design an exercise program for the local firefighters. Utilize the concepts of the aerobic energy systems, anaerobic energy system, and strength training. What type of training activities would you prescribe keeping in mind the specificity principle?
- You have been invited to speak to a group of parents about the importance of aerobic exercise for children. Explain the basic physiological differences between children and adults at rest with regard to HR, respiratory rate, and metabolism and their response to exercise.

Loss of balance and falling are problems that affect individuals with a wide range of diagnoses. Physical therapists commonly evaluate balance and use balance training/exercises as either primary or secondary interventions for patients undergoing many types of rehabilitation programs. The purpose of this chapter is to present an overview of key background terms and concepts related to balance, how balance control is normally achieved in humans for a variety of conditions, possible causes of balance impairments, and evidence-based assessments and interventions for enhancing all aspects of an individual's balance control.

## Background and Concepts

### Balance: Key Terms and Definitions

*Balance*, or *postural stability*, is a generic term used to describe the dynamic process by which the body's position is maintained in equilibrium. Equilibrium means that the body is either at rest (static equilibrium) or in steady-state motion (dynamic equilibrium). Balance is greatest when the body's center of mass (COM) or center of gravity (COG) is maintained over its base of support (BOS).

**Center of mass.** The COM is a point that corresponds to the center of the total body mass and is the point at which the body is in perfect equilibrium. It is determined by finding the weighted average of the COM of each body segment.<sup>15</sup>

**Center of gravity.** The COG refers to the vertical projection of the COM to the ground. In the anatomical position, the COG of most adult humans is located slightly anterior to the second sacral vertebra,<sup>15</sup> or approximately 55% of a person's height.<sup>63</sup>

**Momentum.** Momentum is the product of mass times velocity. Linear momentum relates to the velocity of the body along a straight path, for example, in the sagittal or transverse planes. Angular momentum relates to the rotational velocity of the body.

**Base of support.** The BOS is defined as the perimeter of the contact area between the body and its support surface; foot placement alters the BOS and changes a person's postural stability.<sup>118</sup> A wide stance, such as is seen with many elderly individuals, increases stability, whereas a narrow BOS, such as tandem stance or walking, reduces it. As long as a person maintains the COG within the limits of the BOS, referred to as the *limits of stability*, he or she does not fall.

**Limits of stability.** "Limits of stability" refers to the sway boundaries in which an individual can maintain equilibrium without changing his or her BOS (Fig. 8.1).<sup>118</sup> These boundaries are constantly changing depending on the task, the individual's biomechanics, and aspects of the environment.<sup>159</sup> For example, the limits of stability for a person during quiet stance is the area encompassed by the outer edges of the feet in contact with the ground. Any deviations in the body's COM position relative to this boundary are corrected intermittently, producing a random

**FIGURE 8.1** Boundaries of the limits of stability while standing, walking, and sitting.

swaying motion. For normal adults, the anteroposterior sway limit is approximately  $12^\circ$  from the most posterior to most anterior position.<sup>121</sup> Lateral stability varies with foot spacing and height; adults standing with 4 inches between the feet can sway approximately  $16^\circ$  from side to side.<sup>120</sup> However, a person sitting without trunk support has much greater limits of stability than when standing because the height of the COM above the BOS is less and the BOS is much larger (i.e., perimeter of the buttocks in contact with a surface).

**Ground reaction force and center of pressure.** In accordance with Newton's law of reaction, the contact between our bodies and the ground due to gravity (action forces) is always accompanied by a reaction from it, the so-called ground reaction force.

The *center of pressure* (COP) is the location of the vertical projection of the ground reaction force.<sup>181</sup> It is equal and opposite to the weighted average of all the downward forces acting on the area in contact with the ground. If one foot is on the ground, the net COP lies within that foot. When both feet are on the ground, the net COP lies somewhere between the two feet, depending on how much weight is taken by each foot. When both feet are in contact, the COP under each foot can be measured separately. To maintain stability, a person produces muscular forces to continually control the position of the COG, which in turn changes the location of the COP. Thus, the COP is a reflection of the body's neuromuscular responses to imbalances of the COG.<sup>182</sup> A force plate is traditionally used to measure ground reaction forces (in Newton's [N]) and COP movements (in meters [m]).

## Balance Control

Balance is a complex motor control task involving the detection and integration of sensory information to assess the position and motion of the body in space and the execution of appropriate musculoskeletal responses to control body position within the context of the environment and task. Thus,

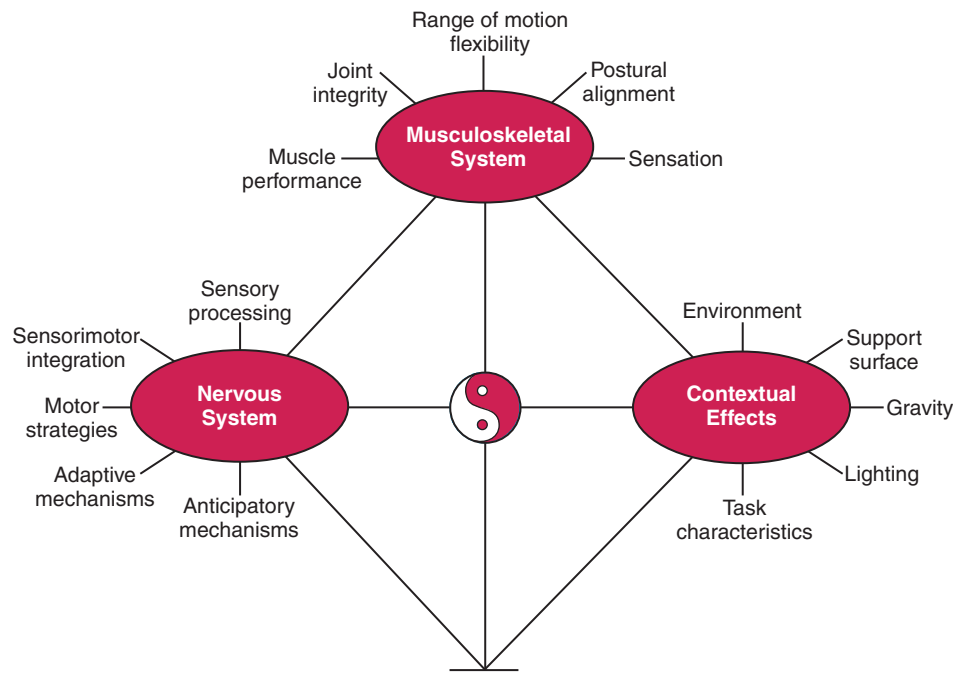

balance control requires the interaction of the nervous and musculoskeletal systems and contextual effects (Fig. 8.2).

- The *nervous system* provides the (1) sensory processing for perception of body orientation in space provided mainly by the visual, vestibular, and somatosensory systems; (2) sensorimotor integration essential for linking sensation to motor responses and for adaptive and anticipatory (i.e., centrally programmed postural adjustments that precede voluntary movements) aspects of postural control; and (3) motor strategies for planning, programming, and executing balance responses.<sup>67</sup>
- *Musculoskeletal contributions* include postural alignment, musculoskeletal flexibility such as joint range of motion (ROM), joint integrity, muscle performance (i.e., muscle strength, power, and endurance), and sensation (touch, pressure, vibration, proprioception, and kinesthesia).
- *Contextual effects* that interact with the two systems are the environment, whether it is closed (predictable with no distractions) or open (unpredictable and with distractions); the support surface (i.e., firm versus slippery, stable versus unstable, and type of shoes); the amount of lighting; effects of gravity and inertial forces on the body; and task characteristics (i.e., well learned versus new, predictable versus unpredictable, and single versus multiple tasks).

Even if all elements of the neurological and musculoskeletal systems are operating effectively, a person may fall if contextual effects force the balance control demands to be so high that the person's internal mechanisms are overwhelmed.

## Sensory Systems and Balance Control

Perception of one's body position and movement in space require a combination of information from peripheral receptors in multiple sensory systems, including the visual, somatosensory (proprioceptive, joint, and cutaneous receptors), and vestibular systems.

**FIGURE 8.2** Interactions of the musculoskeletal and nervous systems and contextual effects for balance control.

### Visual System

The visual system provides information regarding (1) the position of the head relative to the environment, (2) the orientation of the head to maintain level gaze, and (3) the direction and speed of head movements because as a person's head moves, surrounding objects move in the opposite direction. Visual stimuli can be used to improve a person's stability when proprioceptive or vestibular inputs are unreliable by fixating the gaze on an object. Conversely, visual inputs sometimes provide inaccurate information for balance control, such as when a person is stationary and a large object, such as a nearby bus, starts moving, causing the person to have an illusion of movement.

### Somatosensory System

The somatosensory system provides information about the position and motion of the body and body parts relative to each other and the support surface. Muscle proprioceptors, including muscle spindles and Golgi tendon organs (sensitive to muscle length and tension), joint receptors (sensitive to joint position, movement, and stress), and skin mechanoreceptors (sensitive to vibration, light touch, deep pressure, and skin stretch), are the dominant sensory inputs for maintaining balance when the support surface is firm, flat, and fixed. However, when standing on a surface that is moving (e.g., on a boat) or on a surface that is not horizontal (e.g., on a ramp), inputs about body position with respect to the surface are not appropriate for maintaining balance; therefore, a person must rely on other sensory inputs for stability in these conditions.<sup>159</sup>

Information from joint receptors does not contribute greatly to conscious joint position sense. It has been demonstrated that

local anesthetization of joint tissues and total joint replacement does not impair joint position awareness.<sup>56,57</sup> Muscle spindle receptors appear to be mostly responsible for providing joint position sense, whereas the primary role of joint receptors is to assist the gamma motor system in regulating muscle tone and stiffness to provide anticipatory postural adjustments and to counteract unexpected postural disturbances.<sup>131</sup>

### Vestibular System

The vestibular system provides information about the position and movement of the head with respect to gravity and inertial forces. Receptors in the semicircular canals (SCCs) detect angular acceleration of the head, whereas the receptors in the otoliths (utricle and saccule) detect linear acceleration and head position with respect to gravity. The SCCs are particularly sensitive to fast head movements, such as those made during walking or during episodes of imbalance (slips, trips, and stumbles), whereas the otoliths respond to slow head movements, such as during postural sway.<sup>66,159</sup>

By itself, the vestibular system can give no information about the position of the body. For example, it cannot distinguish a simple head nod (head movement on a stable trunk) from a forward bend (head movement in conjunction with a moving trunk).<sup>66</sup> Consequently, additional information, particularly from mechanoreceptors in the neck, must be provided for the central nervous system (CNS) to have a true picture of the orientation of the head relative to the body.<sup>131</sup>

The vestibular system uses motor pathways originating from the vestibular nuclei for postural control and coordination of eye and head movements. The vestibulospinal reflex brings about postural changes to compensate for tilts and

movements of the body through vestibulospinal tract projections to antigravity muscles at all levels of the spinal cord. The vestibulo-ocular reflex stabilizes vision during head and body movements through projections from the vestibular nuclei to the nuclei that innervate extraocular muscles.

### Sensory Organization for Balance Control

Vestibular, visual, and somatosensory inputs are normally combined seamlessly to produce our sense of orientation and movement.<sup>131</sup> Incoming sensory information is integrated and processed in the cerebellum, basal ganglia, and supplementary motor area.<sup>180</sup> Somatosensory information has the fastest processing time for rapid responses, followed by visual and vestibular inputs.<sup>180</sup> When sensory inputs from one system are inaccurate owing to environmental conditions or injuries that decrease the information-processing rate, the CNS must suppress the inaccurate input and select and combine the appropriate sensory inputs from the other two systems. This adaptive process is called *sensory organization*. Most individuals can compensate well if one of the three systems is impaired; therefore, this concept is the basis for many treatment programs.

### Types of Balance Control

Functional tasks require different types of balance control, including (1) static balance control to maintain a stable anti-gravity position while at rest, such as when standing and sitting; (2) dynamic balance control to stabilize the body when the support surface is moving or when the body is moving on a stable surface, such as sit-to-stand transfers or walking; and (3) automatic postural reactions to maintain balance

in response to unexpected external perturbations, such as standing on a bus that suddenly accelerates forward.

- *Feedforward (open loop motor control)* is utilized for movements that occur too fast to rely on sensory feedback (e.g., reactive responses) or for anticipatory aspects of postural control.
- *Anticipatory control* involves activation of postural muscles in advance of performing skilled movements, such as activation of posterior leg and back extensor muscles prior to a person pulling on a handle when standing<sup>32</sup> or planning how to navigate to avoid obstacles in the environment.
- *Closed loop control* is utilized for precision movements that require sensory feedback (e.g., maintaining balance while sitting on a ball or standing on a balance beam).

### Motor Strategies for Balance Control

To maintain balance, the body must continually adjust its position in space to keep the COM of an individual over the BOS or to bring the COM back to that position after a perturbation. Horak and Nashner<sup>68</sup> described three primary movement strategies used by healthy adults to recover balance in response to sudden perturbations of the supporting surface (i.e., brief anterior or posterior platform displacements) called ankle, hip, and stepping strategies (Fig. 8.3). Factors that determine which strategy most effectively addresses a balance disturbance are identified in Box 8.1. Results of research examining the patterns of muscle activity underlying these movement strategies suggest that preprogrammed muscle synergies comprise the fundamental movement unit used to

**FIGURE 8.3** Ankle, hip, and stepping strategies used by adults to control body sway.

### BOX 8.1 Factors Influencing Selection of Balance Strategies

- Speed and intensity of the displacing forces
- Characteristics of the support surface
- Magnitude of the displacement of the center of mass
- Subject's awareness of the disturbance
- Subject's posture at the time of perturbation
- Subject's prior experiences

restore balance.<sup>68,122,123</sup> A *synergy* is a functional coupling of groups of muscles, so they must act together as a unit; this organization greatly simplifies the control demands of the CNS.

The CNS uses three movement systems to regain balance after the body is perturbed: reflex, automatic, and voluntary systems. Table 8.1 summarizes the key characteristics of reflexes, automatic postural responses, and voluntary movements.<sup>120</sup>

- “*Stretch*” reflexes mediated by the spinal cord comprise the first response to external perturbations. They have the shortest latencies (<70 ms), are independent of task demands, and produce stereotyped muscle contractions in response to sensory inputs.
- *Voluntary responses* have the longest latencies (>150 ms), are dependent on task parameters, and produce highly variable motor outputs (e.g., reach for a nearby stable support surface or walk away from a destabilizing condition).
- *Automatic postural reactions* have intermediate latencies (80 to 120 ms) and are the first responses that effectively

prevent falls. They produce quick, relatively invariant movements among individuals (similar to reflexes), but they require coordination of responses among body regions and are modifiable depending on the demands of the task (similar to voluntary responses).

The reflex, automatic, and voluntary movement systems interact to ensure that the response matches the postural challenge.

### Ankle Strategy (Anteroposterior Plane)

In quiet stance and during small perturbations (i.e., low-speed perturbations usually occurring on a large, firm surface), movements at the ankle act to restore a person's COM to a stable position. For small external perturbations that cause loss of balance in a forward direction (i.e., platform displacements in a backward direction), muscle activation usually proceeds in a distal to proximal sequence: gastrocnemius activity beginning about 90 to 100 ms after perturbation onset, followed by the hamstrings 20 to 30 ms later, and finally paraspinal muscle activation.<sup>119,120</sup> In response to backward instability, muscle activity begins in the anterior tibialis, followed by the quadriceps and abdominal muscles.

### Weight-Shift Strategy (Lateral Plane)

The movement strategy utilized to control mediolateral perturbations involves shifting the body weight laterally from one leg to the other. The hips are the key control points of the weight-shift strategy. They move the COM in a lateral plane primarily through activation of hip abductor and adductor muscles, with some contribution from ankle invertors and evertors.<sup>120</sup>

**TABLE 8.1** Characteristics of the Three Movement Systems for Balance Control Following Perturbations

Characteristic	Reflex	Automatic	Voluntary
Mediating pathway	Spinal cord	Brain stem/subcortical	Cortical
Mode of activation	External stimulus	External stimulus	External stimulus or self-stimulus
Comparative latency of response	Fastest	Intermediate	Slowest
Response	Localized to point of stimulus and highly stereotyped	Coordinated among leg and trunk muscles; stereotypical but adaptable	Coordinated and highly variable
Role in balance	Muscle force regulation	Resist disturbances	Generate purposeful movements
Factors modifying the response	Musculoskeletal or neurological abnormalities	Musculoskeletal or neurological abnormalities; configuration of support; prior experience	Musculoskeletal or neurological abnormalities; conscious effort; prior experience; task complexity

Adapted from Nashner, LM: Sensory, neuromuscular, and biomechanical contributions to human balance. In Duncan, PW (ed): *Balance Proceedings of the APTA Forum*. Alexandria, VA: American Physical Therapy Association, 1990: 5-12.<sup>120</sup>

## Suspension Strategy

The suspension strategy is observed during balance tasks when a person quickly lowers his or her body COM by flexing the knees, causing associated flexion of the ankles and hips.<sup>118</sup> The suspension strategy can be combined with the ankle or the weight-shift strategy to enhance the effectiveness of a balance movement.<sup>118</sup>

## Hip Strategy

For rapid and/or large external perturbations or for movements executed with the COG near the limits of stability, a hip strategy is employed.<sup>118</sup> The hip strategy uses rapid hip flexion or extension to move the COM within the BOS.<sup>181</sup> As the trunk rotates rapidly in one direction, horizontal (shear) forces are generated against the support surface in the opposite direction, moving the COM in the opposite direction as the trunk.<sup>118</sup> The muscle activity associated with the hip strategy has been studied by having a person stand crosswise on a narrow balance beam while the support surface suddenly moves backward (i.e., person sways forward) or forward (i.e., person sways backward).<sup>68</sup> In response to a forward body sway, muscles are typically activated in a proximal to distal sequence: Abdominals beginning about 90 to 100 ms after perturbation onset followed by activation of the quadriceps. Backward body sway results in activation first of the paraspinals followed by the hamstrings. A person cannot use the hip strategy to restore balance while walking on slippery surfaces because the large horizontal forces generated cause the feet to slip.

## Stepping Strategy

If a large force displaces the COM beyond the limits of stability, a forward or backward step is used to enlarge the BOS and regain balance control. The uncoordinated step that follows a stumble on uneven ground is an example of a stepping strategy.

## Combined Strategies

Research has shown that movement response patterns to postural perturbations are more complex and variable than originally described by Nashner.<sup>87</sup> Most healthy individuals use combinations of strategies to maintain balance depending on the control demands. Balance control requirements vary depending on the task and the environment. For example, standing on a bus that is moving has higher control demands than standing on a fixed surface. Therefore, it is important during treatment of balance disorders to vary the task and environment so the person develops movement strategies for different situations.

## Balance Control Under Varying Conditions

### Balance During Stance

In quiet stance, the body sways like an inverted pendulum about the ankle joint.<sup>181</sup> The balance goal is to keep the

body's COM safely within the BOS. To accomplish this goal, an ankle strategy is utilized in which ankle muscles (i.e., ankle plantarflexors/dorsiflexors, invertors/evertors) are automatically and selectively activated to counteract body sway in different directions. Other muscles that are tonically active during quiet stance to maintain an erect posture are the gluteus medius and tensor fasciae latae, the iliopsoas to prevent hyperextension of the hip, and the thoracic paraspinals (with some intermittent abdominal activation).<sup>7</sup> Body alignment contributes to stability in quiet stance. Standing with the body in optimal body alignment allows the body to maintain balance with the least amount of muscle energy expenditure.<sup>159</sup>

### Balance With Perturbed Standing

Perturbations to balance in standing can be either internal (i.e., voluntary movement of the body) or external (i.e., forces applied to the body). Both types of perturbations involve activation of muscle synergies, but the response timing is proactive (i.e., anticipatory) for internally generated perturbations and reactive for externally generated perturbations.<sup>181</sup>

Moving platform experiments have provided much information about the motor strategies (i.e., ankle, hip, and stepping strategies) and associated muscle activation patterns that result when a person is standing on a surface that unexpectedly translates or tilts.<sup>88,117-119</sup> With repetition of a platform perturbation, learning adaptation occurs that is characterized by a significant reduction in the reactive response.<sup>106,117</sup> For example, Nashner<sup>117</sup> found that upward rotation of a platform initially elicited reflex contractions of the gastrocnemius muscles of subjects, giving them the false impression that their bodies were falling forward; with repeated tilts, the gastrocnemius response diminished, and by the fourth repetition, it was completely absent. Thus, prior experience and feedforward anticipatory control have an important influence on balance responses.

### Balance During Whole-Body Lifting

One of the most common ways that balance is challenged during everyday life is when lifting boxes or other large objects that are resting on the floor or at a level that is low relative to the person's COM (Fig. 8.4). Loss of balance during lifting may result in a fall, slip, or back injury.<sup>4,141,155</sup>

**COM shift.** During lifting, the movement of the body toward the load disturbs the position of the COM. When a load is lifted in front of the body, the COM is shifted forward during flexion of the trunk and legs, which is an internal disturbance to balance. The COM is further displaced forward when the load is added to the hands, creating an external disturbance to balance. In this case, anticipatory postural adjustments are needed to match whole-body backward momentum (horizontal linear and angular) to the displacement of the body and magnitude of the expected load.<sup>31,61,62</sup> The CNS estimates the amount of momentum necessary for lifting the load based on previous experience

**FIGURE 8.4** Balance during forward lifting with knees flexed.

with the load or other objects of similar physical properties (e.g., size, weight, and density).<sup>62</sup> The generation of backward horizontal linear momentum serves to keep the COM of the body within the base of support. The generation of angular momentum is essential for movement of the person with the load toward the upright posture.

**Anticipated weight and momentum.** The amount of whole-body momentum and the lifting force generated are scaled to the anticipated weight of the load.<sup>62</sup> When a heavy load is expected, sufficient levels of backward horizontal and

angular momentum are needed to counteract the additional load, which tends to pull and rotate the body COM forward. Subtle differences in lifting posture, which reflect the underlying differences in momentum, occur when subjects lift a light load versus a heavy load (Fig. 8.5). Subjects tend to flex their hips and knees more and shift their weight back when lifting a heavy load (dark circles) than when lifting a light load (light circles).

**Loss of balance.** Loss of balance during lifting can occur when subjects overestimate or underestimate the weight of the load.<sup>61</sup> When the load weight is overestimated, too much momentum is generated and the body tends to topple backward. Most subjects compensate for this loss of balance by taking a step backward. When the load weight is underestimated, too little momentum is generated and the body tends to topple forward, resulting in the load quickly coming back to the ground.

**Lifting style.** The lifting style does appear to affect the challenges to balance. Keeping the knees more extended during lifting (Fig. 8.6) reduces the risk of balance loss, especially when the quadriceps are weak. Research comparing lifting styles has found that loss of balance was more common when subjects used a style of lifting in which the knees were more flexed compared to when the knees were straighter.<sup>27,30,61,167</sup>

**Lifting instructions.** Clinicians frequently instruct patients to use the leg lifting style, with the knees bent and the trunk erect, when lifting loads (Fig. 8.7).<sup>112,162</sup> This recommendation is based on the assumption that leg lifting imposes lower compression loads on the spine than other styles of lifting, such as the stoop lift, with the knees straight and the trunk flexed.<sup>95</sup> This assumption is likely true when the

**FIGURE 8.5** Postural adjustments for lifting a heavy versus a light load. When subjects approach a load (indicated by the vertical bar at time 0), early in the lift subtle differences in the anticipatory postural adjustments are evident. When a heavy load is expected (dark circles) there is greater flexion of the trunk, hips, and knees compared to when a light load is expected (light circles). (Adapted from Heiss, DG, Shields, RK, and Yack, HJ: Anticipatory control of vertical lifting force and momentum during the squat lift with expected and unexpected loads. *J Orthop Sports Phys Ther* 31(12):708–723; discussion 724–709, 2001.<sup>61</sup>)

**FIGURE 8.6** Balance during forward lifting with knees extended.

**FIGURE 8.8** Straddle lift with trunk erect and object placed between the feet.

**FIGURE 8.7** Squat lift with trunk erect and object placed between the feet.

load to be lifted can be placed between the feet (Figs. 8.7 and 8.8). However, van Dieen and colleagues<sup>171</sup> found little evidence in the biomechanical literature to support that leg lifting generally results in lower loads on the spine than back lifting. Recent research, using sophisticated biomechanical

models, indicates that leg lifting results in higher compression forces on the spine compared to back lifting when the load is not positioned between the legs.<sup>23,36,89,139</sup> Although researchers have consistently found that bending moments and fascial strain are substantially greater with the back lift compared to the squat lift,<sup>36,37</sup> the magnitude of the bending moments on the spine appear to be well below the threshold for injury.<sup>2,36,172</sup>

Based on the current literature, it appears that if the objective of training for lifting is to reduce the load on the lumbar spine, other factors that have a more substantial effect on reducing the load on the lumbar spine should be emphasized over the selection of a lifting style, especially when placing the load between the legs is not feasible.

#### CLINICAL TIP

Important factors for safe lifting include maintaining a neutral spine, slowing the lifting speed, optimizing the horizontal and vertical position of the load, avoiding asymmetrical lifts (because of the increased lateral and twisting moments on the spine) (Fig. 8.9), and reducing the load weight.<sup>172</sup>

If maintaining balance is a concern—especially in the elderly—lifting styles in which the knees are more extended, such as with the semi-squat and stoop lift, are probably safer. In younger individuals with strong quadriceps, the straddle lift with one leg in front of the other to widen the base of support would reduce the risk of balance loss.

**FIGURE 8.9** Side lift with the right trunk in lateral flexion and rotation results in high loads on the lumbar spine and should be avoided.

### Balance in Unperturbed Human Gait

During walking, the COM is always outside the BOS except during the short double support period.<sup>181</sup> Therefore, the balance goal is to move the body outside the BOS by letting the body fall forward and yet prevent a fall. To accomplish this goal, a person must be able to maintain balance and posture of the upper body (i.e., head, arms, and trunk) and vertical alignment of the body against gravity. Trunk and hip muscles (flexors/extensors in the sagittal plane; abductors/adductors in the frontal plane) keep the upper body balanced, and extensor muscles of the lower extremities prevent vertical collapse.<sup>181,182</sup> The ankle muscles control anterior/posterior or medial/lateral acceleration of the body's COG but are not able to prevent falls.<sup>181</sup> Fine motor control of the foot during the swing phase involving anticipatory activation of the ankle dorsiflexors ensures minimum toe clearance (0.55 cm) to prevent trips.<sup>135</sup>

## Impaired Balance

Impaired balance can be caused by injury or disease to any structures involved in the three stages of information processing—sensory input, sensorimotor integration, and motor output generation.

### Sensory Input Impairments

Proprioceptive deficits have been implicated as contributing to balance impairments following lower extremity and trunk injuries or pathologies. Decreased joint position

sense has been reported in individuals with recurrent ankle sprains,<sup>14,46,49,54</sup> knee ligamentous injuries,<sup>6,134,148</sup> degenerative joint disease,<sup>6</sup> and low back pain (LBP).<sup>17,51,94</sup> These same conditions have been associated with increased postural sway compared to that of controls.<sup>3,33,46,49,94,113,129,178</sup> It is unclear whether decreased joint position sense is due to changes in joint receptors or in muscle receptors.

Somatosensory, visual, or vestibular deficits may impair balance and mobility.

- Reduced somatosensation in the lower extremities caused by peripheral polyneuropathies in the aged and in individuals with diabetes is associated with balance deficits<sup>143,144,160,169</sup> and an increased risk for falls.<sup>76,144</sup> These individuals tend to rely more heavily on a hip strategy to maintain balance than do those without somatosensory deficits.<sup>69</sup>
- Visual loss or specific deficits in acuity, contrast sensitivity, peripheral field vision, and depth perception caused by disease, trauma, or aging can impair balance and lead to falls.<sup>25,80</sup>
- Individuals with damage to the vestibular system due to viral infections, traumatic brain injury (TBI), or aging may experience vertigo (a feeling of spinning) and postural instability. Black and colleagues<sup>12</sup> found that patients with severe bilateral loss of vestibular function are unable to use hip strategies even when standing crosswise on a narrow beam, although ankle strategies are unaffected.

### Sensorimotor Integration Impairments

Damage to the basal ganglia, cerebellum, or supplementary motor area impairs processing of incoming sensory information, resulting in difficulty adapting sensory information in response to environmental changes and in disruption of anticipatory and reactive postural adjustments.<sup>70,120,159</sup> When stance is perturbed by platform translations, patients with Parkinson's disease tend to have a smaller than normal amplitude of movement due to co-activation of muscles on both sides of the body, whereas patients with cerebellar lesions typically demonstrate larger response amplitudes.<sup>159</sup>

Sensory organization problems that manifest as overreliance on one particular sense for balance control or a more generalized inability to select an appropriate sense for balance control when one or more senses give inaccurate information have been demonstrated in patients with a wide variety of neurological conditions.<sup>159</sup> Individuals who rely heavily on visual inputs (visually dependent) or somatosensory inputs (surface dependent) become unstable or fall under conditions in which the preferred sense is either absent or inaccurate, whereas those with generalized adaptation problems are unstable in any condition in which a sensory input is not accurate.

### Biomechanical and Motor Output Impairments

Deficits in the motor components of balance control can be caused by musculoskeletal (i.e., poor posture, joint ROM limitations, and decreased muscle performance) and/or

neuromuscular system (i.e., impaired motor coordination, and pain) impairments. Postural malalignment, such as the typical thoracic kyphosis of the elderly, that shifts the COM away from the center of the BOS increases a person's chance of exceeding his or her limits of stability.<sup>120</sup> Because each segment within the legs exerts forces on its adjunct segments, impaired ROM or muscle strength at one joint can alter posture and balance movements throughout the entire limb. For example, restriction of ankle motion by contractures or wearing ankle-foot orthoses and/or ankle dorsiflexor weakness eliminates the use of an ankle strategy, resulting in increased use of hip and trunk muscles for balance control.<sup>19,150</sup>

In individuals with neurological conditions (e.g., stroke, TBI, and Parkinson's disease), failure to generate adequate muscle forces due to abnormal tone or impaired coordination of motor strategies may limit the person's ability to recruit muscles required for balance.<sup>159</sup>

Pain can alter movements; reduce a person's normal stability limits; and, if persistent, produce secondary strength and mobility impairments.

## Deficits With Aging

Falls are common and are a major cause of morbidity, mortality, reduced functioning, and premature nursing home admissions in persons over age 65.<sup>25,38,126,147,149</sup> The most common risk factors associated with falls in the elderly are listed in Box 8.2. Most falls by the elderly are likely due to complex interactions between multiple risk factors. Clinicians are encouraged to follow published guidelines for the prevention of falls by older persons when prescribing fall prevention interventions.<sup>1</sup>

Declines in all sensory systems (somatosensory, vision, and vestibular) and all three stages of information processing (i.e., sensory processing, sensorimotor integration, and motor output) are found with aging.<sup>96,159</sup> In comparison to young adults, older adults have more difficulty maintaining

### BOX 8.2 Most Common Risk Factors for Falls Among the Elderly

- Muscle weakness
- History of falls
- Gait deficit
- Balance deficit
- Use of assistive device
- Visual deficit
- Arthritis
- Impaired activities of daily living
- Depression
- Cognitive impairment
- Age >80 years

(From American Geriatrics Society British Geriatrics Society, American Academy of Orthopaedic Surgeons Panel on Fall Prevention: Guidelines for the prevention of falls in older persons. *J Am Geriatr Soc* 49:664–672, 2001.<sup>1</sup>)

balance when sensory inputs from more than one system are greatly reduced, particularly when they must rely solely on vestibular inputs for balance control.<sup>144,184</sup> Studies of response patterns to platform perturbations in older adults have demonstrated the following motor strategy changes compared to those of young adults.

- Slower-onset latencies<sup>161,184</sup>
- More frequent use of a hip strategy for balance control<sup>71</sup>
- Limitations in the ability to maintain balance when challenged with perturbations of increasing magnitude and velocity<sup>97</sup>

Impaired anticipatory postural adjustments prior to making voluntary movements have been demonstrated in older individuals and may explain the high incidence of falls during activities such as walking, lifting, and carrying objects.<sup>45,79</sup> Valid and reliable outcome measures for assessing fall risk in the elderly are listed in Table 8.2. The BESTest, mini-BESTest, and Brief-BESTest are emerging fall risk assessments that have primarily been studied in the Parkinson's disease population.<sup>40</sup>

### CLINICAL TIP

*Divided attention* as when a person is doing two tasks simultaneously (i.e., walking while doing a secondary cognitive or motor task) can lead to postural instability and falls, particularly in the elderly.<sup>142,158</sup> Modified versions of the Timed Up-and-Go Test<sup>138</sup> with secondary cognitive and motor tasks can be used by clinicians to assess the influence of divided attention on balance control.<sup>104,156</sup> If deficits are found, patients should be allowed to practice walking while doing a secondary task and progress to doing multiple tasks according to their improvements in performance.

Elderly individuals who have experienced one or more falls may develop fear of falling, which leads to a loss of confidence in a person's ability to perform routine tasks, restricted activity, social isolation, functional decline, depression, and decreased quality of life.<sup>25,91</sup> The fear of falling arises more often from a person's fear of institutionalization than a fear of injury.<sup>75</sup> Individuals with fear of falling demonstrate perceived stability limits that are reduced from their actual stability limits and gait changes, including decreased stride length, reduced speed, increased stride width, and increased double-support time.<sup>24,105</sup> It is important that clinicians screen patients for fear of falling with instruments, such as the Activities-Specific Balance Confidence (ABC) Scale<sup>140</sup> or the Fall Efficacy Scale,<sup>166</sup> so evidence-based interventions that reduce fear of falling and promote physical, social, and functional activity are implemented.<sup>16,164,175</sup>

## Deficits From Medications

There is an increased risk of falling among older individuals who take four or more medications and among those taking certain medications (i.e., hypnotics, sedatives, tricyclic

**TABLE 8.2** Outcome Measures for Fall Risk Assessment

Outcome Measure	Perfect Score	Cut-off Score (Sensitivity, Specificity)*
Berg Balance Test	56	<46 (25%, 87% for predicting any fall and 42%, 87% for multiple falls) <sup>115</sup>
Tinetti Performance-Oriented Mobility Assessment	28 (Balance subscale 16, Gait subscale 12)	<20 for elderly (64%/66%)** <sup>42</sup> and individuals with Parkinson's disease (76%, 66%) <sup>86</sup>
Timed Up-and-Go Test	N/A (timed test)	>13.5 seconds (87%, 87%) <sup>156</sup>
Four-Square Step Test	N/A (timed test)	>15 seconds (89%, 85%) <sup>35</sup>
Dynamic Gait Index	24	<20 (67%, 86%) <sup>185</sup>
Functional Gait Assessment	30	<23 (100%, 72%) <sup>185</sup>
Five-Times-Sit-to-Stand Test	N/A (timed test)	>15 seconds (55%, 65%) <sup>18</sup>
ABC Scale	100%	<67% (84%, 88%) <sup>92</sup>

antidepressants, tranquilizers, and antihypertensive drugs) due to dizziness or other side effects.<sup>1,25</sup> Individuals who have fallen should have their medications reviewed and altered or stopped as appropriate to prevent future falls.

## Management of Impaired Balance

### Examination and Evaluation of Impaired Balance

The key elements of a comprehensive evaluation of individuals with balance problems include the following:

- A thorough history of falls (whether onset of falls is sudden versus gradual; the frequency and direction of falls; the environmental conditions, activities, and presence of dizziness, vertigo, or lightheadedness at time of the fall; current and past medications; and presence of fear of falling)
- Assessments to identify sensory input (proprioceptive, visual, and vestibular), sensory processing (sensorimotor integration, anticipatory and reactive balance control), and biomechanical and motor (postural alignment, muscle strength and endurance, joint ROM and flexibility, motor coordination, and pain) impairments contributing to balance deficits
- Tests and observations to determine the impact of balance control system deficits on functional performance
- Environmental assessments to determine fall risk hazards in a person's home.<sup>25</sup>

Commonly used tests and measures for each of the three categories of balance assessment are presented in Table 8.3. Clinicians should carefully select a variety of tests and measures that assess all of the various types of balance control.

### Static Balance Tests

Static balance can be assessed by observing the patient's ability to maintain different postures.

- The Romberg Test<sup>127</sup> tests the patient's ability to stand with the feet parallel and together with the eyes open and then closed for 30 seconds.
- The sharpened Romberg, also known as the tandem Romberg,<sup>127</sup> requires the patient to stand with the feet in a heel-to-toe position with arms folded across the chest and eyes closed for 1 minute. The Romberg and sharpened Romberg tests are screening tools that help the therapist to decide if more specific testing is needed to determine the cause of imbalance or to establish a person's balance status.
- The Single-Leg Balance Stance Test<sup>173</sup> (SLB) asks the patient to stand on one leg without shoes with arms crossed or hands on hips without letting the legs touch each other. Three 30-second trials are performed for each leg, and a best or a mean time of the three trials is recorded. The SLB is reliable and has been found to predict injurious falls in community-dwelling elderly<sup>173</sup> and ankle sprains in athletes.<sup>168</sup>
- The Stork Stand Test<sup>84</sup> is performed by having the patient stand on both feet with hands on the hips, then lift one leg and place the toes of that foot against the knee of the other leg. On command from the tester, the patient then raises the heel to stand on the toes and tries to balance for as long as possible without letting either the heel touch the ground or the other foot move away from the knee. Normal adults should be able to balance for 20 to 30 seconds on each leg.

### Dynamic Balance Tests

Dynamic balance control can be assessed by observations of how well the patient is able to stand or sit on unstable surfaces (e.g., foam or Swiss ball); transition from one position to another (e.g., supine-to-sit or sit-to-stand transfers); and

**TABLE 8.3** Balance Assessments and Interventions

Category of Balance Assessment	Clinical Tests/Measures*	Interventions if Deficits Present
Static	Observations of patient maintaining different postures; Romberg Test <sup>127</sup> ; sharpened (tandem) Romberg <sup>127</sup> ; Single-Leg Stance Test <sup>173</sup> ; Stork Stand Test <sup>84</sup>	Vary postures Vary support surface Incorporate external loads
Dynamic	Observations of patient standing or sitting on unstable surface or performing postural transitions and functional activities; Five-times-sit-to-stand test (5 × STS) <sup>34</sup>	Moving support surfaces Move head, trunk, arms, legs Transitional and locomotor activities
Anticipatory (feedforward)	Observations of patient catching ball, opening doors, lifting objects of different weights; Functional Reach Test <sup>39</sup> ; Multidirectional Reach Test <sup>128</sup> ; Star Excursion Balance Test <sup>132</sup> ; Y-Balance Test <sup>152</sup>	Reaching Catching Kicking Lifting Obstacle course
Reactive (feedback)	Observation of patient's responses to pushes (small or large, slow or rapid, anticipated and unanticipated); Pull Test <sup>116</sup> ; Push and Release Test (PRT) <sup>81</sup> ; Postural Stress Test <sup>183</sup>	Standing sway Ankle strategy Hip strategy Stepping strategy Perturbations
Sensory organization	Clinical Test of Sensory Integration on Balance Test (CTSIB) <sup>157</sup> or modified CTSIB, Balance Error Scoring System (BESS) <sup>58</sup>	Reduce visual inputs Reduce somatosensory cues
Balance during functional activities	Berg Balance Scale (BBS) <sup>11</sup> ; Timed Up and Go Test (TUG) <sup>138</sup> ; Tinetti Performance-Oriented Mobility Assessment (POMA) <sup>165</sup> ; Balance Evaluation Systems Test (BESTest) or mini-BESTest <sup>72</sup> ; Four Square Step Test (4SST) <sup>35</sup> ; Dynamic Gait Index (DGI) <sup>159</sup> ; Functional Gait Assessment (FGA) <sup>186</sup> ; Community Balance and Mobility Scale <sup>73</sup> ; High Level Mobility Assessment (HiMat) <sup>179</sup> ; Dizziness Handicap Inventory (DHI) <sup>82</sup>	Functional activities Dual or multitask activities (e.g., walking with secondary cognitive or motor task)
Safety during gait, locomotion, or balance	Observations; home assessments; Falls Efficacy Scale <sup>166</sup> ; Activities-Specific Balance Confidence (ABC) Scale <sup>140</sup>	Balance within stability limits, environmental modifications, assistive devices, external support

\*Tests are listed in relative order of least to most difficult to perform.

perform activities such as walking, jumping, hopping, and skipping.

- The Five-times-sit-to-stand test (5 × STS) can be used to evaluate balance control when moving between sitting and standing.<sup>34</sup> The person is seated in a chair with the arms across the chest and then stands up and sits back down as quickly as possible five times consecutively while being timed. A score of >15 seconds on the 5 × STS was found to predict recurrent falls (sensitivity 55%, specificity 65%) in 2,735 community-dwelling elderly individuals.<sup>18</sup>

### Anticipatory Postural Control Tests

Anticipatory postural control is evaluated by having the patient perform voluntary movements that require the development of a postural set to counteract a predicted postural disturbance. The patient's ability to catch balls, open doors,

lift objects of different weights, and reach without losing balance is indicative of adequate anticipatory control.

- The Functional Reach Test<sup>39</sup> and the Multi-Directional Reach Test<sup>128</sup> require the patient to reach in different directions as far as possible without changing the BOS. Normative data are available, and the tests are reliable and valid.<sup>128</sup>
- The Star Excursion Balance Test (SEBT) is a test of lower extremity reach that challenges an individual's limits of stability.<sup>132</sup> The patient is instructed to reach as far as possible with one leg in each of eight prescribed directions while maintaining balance on the contralateral leg. The test is reliable<sup>64,90</sup> and has validity to detect dynamic balance deficits in individuals with chronic ankle instability, anterior cruciate ligament deficiency, or patellofemoral pain syndrome; to predict risk of lower extremity injury in high school athletes; and to show improvement in performance

after balance training in patients with chronic ankle instability and healthy adults.<sup>8,55,137</sup> A more time-efficient test based on research suggesting redundancy in the eight directions of the SEBT is the Y-Balance Test (YBT).<sup>152</sup> The patient reaches with one leg in only three directions (anterior, posteromedial, and posterolateral). The YBT has been found to be reliable and valid and is predictive of lower extremity injury in athletes.<sup>93,136,137,152</sup>

### Reactive Postural Control Tests

Automatic postural responses or reactive control can be assessed by the patient's response to external perturbations.

- Pushes (small or large, slow or rapid, and anticipated and unanticipated) applied in different directions to the sternum, posterior trunk, or pelvis are used widely, but they are not quantifiable or reliable. The clinician subjectively rates the responses as normal, good, fair, poor, or unable.
- The Pull Test,<sup>116</sup> Push and Release Test,<sup>81</sup> and Postural Stress Test<sup>183</sup> are more objective and reliable measures of reactive postural control.

### Sensory Organization Tests

The Clinical Test of Sensory Integration on Balance Test (CTSIB), also called the "Foam and Dome" Test,<sup>157</sup> measures the patient's ability to balance under six different sensory conditions:

1. Standing on a firm surface with the eyes open (visual, somatosensory, and vestibular information accurate)
2. Standing on a firm surface with the eyes closed (somatosensory and vestibular information accurate)
3. Standing on a firm surface wearing a dome made from a modified Japanese lantern (somatosensory and vestibular information accurate, visual information inaccurate)
4. Standing on a foam cushion with the eyes open (visual and vestibular information accurate, somatosensory inaccurate)
5. Standing on foam with the eyes closed (vestibular information accurate, somatosensory information inaccurate)
6. Standing on foam wearing the dome (vestibular information accurate, somatosensory and visual information inaccurate).

The patient stands with feet parallel and arms at sides or hands on hips. A minimum of three 30-second trials of each condition are performed.

- Individuals who rely heavily on visual inputs for balance (i.e., visual dependent) will become unstable or fall in conditions 2, 3, 5, and 6.
- Those who rely heavily on somatosensory inputs (i.e., surface dependent) will show deficits with conditions 4, 5, and 6.
- Individuals with generalized adaptation problems will be unstable in conditions 3, 4, 5, and 6.
- Individuals with vestibular loss will be very unstable in conditions 5 and 6.

**NOTE:** Because no difference was found in scores between conditions 2 and 3 and conditions 5 and 6,<sup>29</sup> the dome portions

have been removed from the CTSIB. The modified version consists of the four conditions of eyes open and closed while standing on the floor and then on a piece of foam. A computerized version of the CTSIB using a moveable force plate and visual surround is called the Sensory Organization Test.<sup>120</sup>

The Balance Error Scoring System (BESS) is a clinical test of postural stability that requires an individual to assume three different stance positions (double leg, single leg, and tandem) while standing on a firm surface and then standing on a piece of foam with eyes closed for a total of six 20-second trials.<sup>58</sup> The tester observes for six types of errors in performance such as opening the eyes, steps, stumbles, or falls. Performance is scored by adding one error point for each error committed. The BESS has moderate to good interrater reliability and is useful for identifying balance deficits in individuals with concussion, functional ankle instability, external ankle bracing, fatigue, and older age.<sup>9,58</sup>

### Functional Tests

Functional tests are used to determine activity limitations and participation restrictions and to identify tasks that a patient needs to practice. Four mobility scales (i.e., Tinetti Performance-Oriented Mobility Assessment [POMA],<sup>165</sup> Timed Up and Go Test [TUG],<sup>138</sup> Berg Balance Scale, and Four Square Step Test [4SST<sup>35</sup>]) and two gait scales (i.e., Dynamic Gait Index<sup>159</sup> and Functional Gait Assessment<sup>186</sup>) can be easily used to assess balance performance during functional activities. Most of these tests were designed to assess fall risk in the elderly, with the exception of the Functional Gait Assessment, which was developed specifically for use with patients with vestibular disorders. The most comprehensive clinical balance tool currently available is the Balance Evaluation Systems Test (BESTest), a 36-item test consisting of balance tasks borrowed from several balance measures that assesses 6 systems underlying balance control (i.e., biomechanical constraints, stability limits/verticality, anticipatory postural adjustments, postural responses, sensory orientation, and stability in gait).<sup>72</sup> The BESTest was shortened to 14 items (mini-BESTest) and then to 6 items (brief-BESTest) to increase its use in the clinical setting.<sup>44, 133</sup> The Community Balance and Mobility Scale<sup>73</sup> and the High Level Mobility Assessment Tool<sup>179</sup> can be used to evaluate balance and mobility in people who are ambulatory and functioning at a high level, yet have some balance deficits. The 25-item Dizziness Handicap Scale is a questionnaire that can evaluate the self-perceived impact of dizziness and unsteadiness on functional activities in people with vestibular disorders.<sup>82</sup>

### Balance Training

There are many factors to consider when developing an intervention program for balance impairments. Most balance intervention programs require a multisystem approach. For example, an individual who has experienced prolonged bed rest or inactivity following an illness may require a program

that includes stretching the lower extremities and trunk to improve postural alignment and mobility; strengthening exercises to improve motor performance; and dynamic, functional balance activities to improve the ability to perform daily activities safely.

The focus of attention is important when improving balance performance through training. An *external focus of attention* means that the performer is attending to the external environment when practicing balance control.<sup>26,188</sup> For example, if balancing on a tilt board, the instruction would be to keep the board horizontal; or, if holding a bar in an outstretched hand, the instruction would be to keep the bar horizontal.<sup>10,26</sup> An external focus of attention is more effective for motor learning than instruction or feedback that promotes an *internal focus of attention*, which directs the learner to focus on body movements or positions—for example, keeping the feet horizontal on a tilt board or keeping the trunk posture straight. It is suggested that an external focus of attention facilitates the use of unconscious, fast, and reflexive control processes (e.g., automaticity) and speeds up the learning process.<sup>26,187,189</sup>

The following elaborates on the interventions suggested previously (see Table 8.3), which are based on identified deficits in static, dynamic, anticipatory, and reactive control, as well as problems involving sensory organization, function, and safety. For specific procedures to address musculoskeletal problems such as strength, joint mobility, flexibility, or posture, refer to the chapters of this textbook addressing these interventions or to chapters focused on specific regions of the body.

Because balance training often involves activities that challenge the patient's limits of stability, it is important that the therapist takes steps to ensure the patient's safety. Box 8.3 lists safety measures that should be considered and utilized to prevent falls and injuries during therapy.

### BOX 8.3 Safety During Balance Training

1. Use a gait belt any time the patient practices exercises or activities that challenge or destabilize balance.
2. Stand slightly behind and to the side of the patient with one arm holding or near the gait belt and the other arm on or near the top of the shoulder (on the trunk, not the arm).
3. Perform exercises near a railing or in parallel bars to allow patient to grab when necessary.
4. Do not perform exercises near sharp edges of equipment or objects.
5. Have one person in front and one behind when working with patients at high risk of falling or during activities that pose a high risk of injury.
6. Check equipment to ensure that it is operating correctly.
7. Guard patient when getting on and off equipment (such as treadmills and stationary bikes).
8. Ensure that the floor is clean and free of debris.

### CLINICAL TIP

*Cognitive deficits* can considerably impact the success of balance training programs. If deficits are moderate to severe and a person is unable to follow directions, then performance of specific balance exercises may be unsafe and have limited success. In these cases, repetitive practice of common functional activities is advised.

### Static Balance Control

Activities to promote static balance control include having the patient maintain sitting, half-kneeling, tall kneeling, and standing postures on a firm surface.

- To promote an *external focus of attention*, have the patient hold a bar in the outstretched hand and instruct him/her to maintain the bar in a horizontal position.
- More challenging activities include practice in the tandem and single-leg stance (Fig. 8.10), lunge, and squat positions.
- Progress these activities by working on soft surfaces (e.g., foam, sand, and grass), narrowing the base of support, moving the arms, or closing the eyes.
- Provide resistance via handheld weights or elastic resistance (Figs. 8.11 and 8.12).
- Add a secondary task (i.e., catching a ball or mental calculations) to further increase the level of difficulty (Fig. 8.13).

FIGURE 8.10 Balance during single leg stance.

**FIGURE 8.11** Balance while standing with resistance provided to the arms via elastic resistance.

**FIGURE 8.13** Balance while standing and catching a ball.

**FIGURE 8.12** Balance while standing with arm abducting and holding a weight.

### Dynamic Balance Control

To promote dynamic balance control, interventions may involve the following:

- Have the patient practice balance control while on moving surfaces, such as sitting on a therapeutic ball, standing on wobble boards (Fig. 8.14), or bouncing on a mini-trampoline. To promote an external focus, instruct the patient to focus on keeping the ball from rolling or the wobble board level.
- Progress the activities by superimposing movements such as shifting the body weight, rotating the trunk, and moving the head or arms (Fig. 8.15).
- Vary the position of the arms from out to the side to above the head (Fig. 8.16).
- Practice stepping exercises starting with small steps and then mini-lunges to full lunges. For external focus, imagine you have a plank against your back and push as hard as you can on the floor underneath the stance leg.
- Progress the exercise program to include hopping, skipping, rope jumping, and hopping down from a small stool while maintaining balance.
- Have the patient perform arm and leg exercises while standing with normal stance, tandem stance, and single-leg stance (Fig. 8.17).

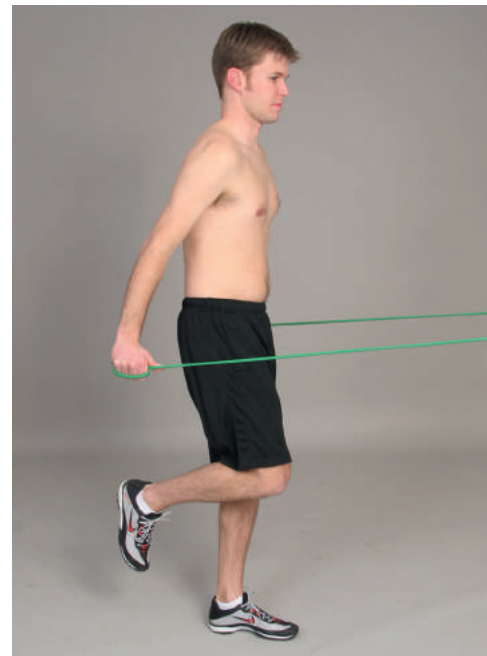

**FIGURE 8.14** Balance while standing on wobble boards.

**FIGURE 8.16** Balance while standing on wobble boards with arms above the head.

**FIGURE 8.15** Balance while standing on wobble boards with arm movements.

**FIGURE 8.17** One-legged stance with resisted shoulder extension using elastic resistance.

### Anticipatory Balance Control

Practice anticipatory balance control by performing the following:

- Reach in all directions to touch or grasp objects, catching a ball, or kicking a ball. To promote external focus, instruct the patient to focus on the object. For example, touch the object lightly, catch the ball softly, or kick the ball far.
- Use different postures for variation (e.g., sitting, standing, and kneeling) and throwing or rolling the ball at different speeds and heights (Fig. 8.18).
- Use functional tasks that involve multiple parts of the body to increase the challenge to anticipatory postural control by having the patient lift objects of varying weight in different postures at varying speeds, open and close doors with different handles and heaviness, or maneuver through an obstacle course.

**FIGURE 8.18** Balance when standing while reaching and catching the ball overhead.

### Reactive Balance Control

Train reactive balance control by using the following activities:

- Have the patient work to gradually increase the amount of sway in different directions while standing on a firm, stable

surface. Have the patient concentrate on how much force the feet are pushing on the floor to promote an external focus of attention.

- To emphasize training of the *ankle strategy*, have the patient practice while standing on one leg with the trunk erect.
- To emphasize training of the *hip strategy*, have the patient walk on balance beams or lines drawn on the floor; perform tandem stance and single-leg stance with trunk bending; or stand on a mini-trampoline, rocker balance, or sliding board.
- To emphasize the *stepping strategy*, have the patient practice stepping up onto a stool or stepping with legs crossed in front or behind other leg (e.g., weaving or braiding).
- To increase the challenge during these activities, add anticipated and unanticipated external forces. For example, have the patient lift boxes that are identical in appearance but of different weights; throw and catch balls of different weights and sizes; or while on a treadmill, suddenly stop/start the belt or increase/decrease the speed.

### Sensory Organization

Many of the activities previously described can be utilized while varying the reliance on specific sensory systems.

- To reduce or destabilize the *visual inputs*, have the patient close the eyes, wear prism glasses, or move the eyes and head together during the balance activity.
- To decrease reliance on *somatosensory cues*, patients can narrow the BOS, stand on foam, or stand on an incline board.

### Balance During Functional Activities

Focus on activities similar to the functional limitations identified in the evaluation. For example:

- If reaching is limited, have the patient work on activities, such as reaching for a glass in a cupboard, reaching behind (as putting arm in a sleeve), or catching a ball off center. To promote an external focus, instruct the patient to focus on the object (e.g., keep the water in the glass level or catch the ball softly).
- Perform two or more tasks simultaneously to increase the level of task complexity.
- Practice recreational activities the patient enjoys, such as golf, to increase motivation while challenging balance control (Fig. 8.19).

**FIGURE 8.19** Functional balance during a golf swing.

### Safety During Gait, Locomotion, or Balance

To emphasize safety, have the patient practice postural sway activities within the person's actual stability limits and progress dynamic activities with emphasis on promoting function and an external focus of attention. If balance deficits cannot be changed, environmental modifications, assistive devices, and increased family or external support may be required to ensure safety.

#### CLINICAL TIP

*Assistive devices*, such as rollator walkers, are often appropriately prescribed as a compensatory measure for people with a variety of balance impairments. However, clinicians should be aware that assistive devices that are incorrectly fitted or used by a patient can precipitate falls. Therefore, clinicians must properly adjust and provide instruction on proper use of assistive devices to prevent unnecessary falls.

### Health and Environmental Factors

In addition to exercise and balance training activities, clinicians should address several other factors affecting balance to reduce the risk of falls.<sup>102</sup>

#### Low Vision

To address low vision issues, encourage regular eye examinations with adjustments to lens prescriptions and cataract surgery, if necessary. Wearing a hat and sunglasses in bright sunlight, taking extra precautions when it is dark, and making

sure lights are on when walking about the house at night are other recommendations. Advise patients to avoid using bifocal glasses when walking, because single lens glasses are safest for improving depth perception and contrast sensitivity, especially on stairs.<sup>101</sup>

#### Sensory Loss

For individuals with sensory loss in the legs, caution them to take extra care when walking on soft carpet or uneven ground and use a cane or other device if necessary. Recommend that they wear firm rubber shoes with low heels. Regular medical examinations should be encouraged to ensure that a patient's blood glucose levels and other factors (i.e., cholesterol, lipids) are under control to minimize damage to sensory nerves from diseases such as diabetes and peripheral vascular disease. Advise patients to seek medical attention if they experience any symptoms of dizziness.

#### Medications

Patients should be educated about the influence of certain medications, such as sedatives and antidepressants, on their risk of falling. For example, if such medications are used at night as a sleep aid, an individual should take extra precautions when getting up to use the bathroom.

### Evidence-Based Balance Exercise Programs for Fall Prevention in the Elderly

With at least one-third of people aged 65 years or more falling at least once each year, physical therapists can play a major role in the prevention of falls. Mounting evidence from randomized clinical trials indicates that therapeutic exercise is an effective tool in the prevention of falls, especially if it is incorporated with a comprehensive strategy targeting health, environmental, and behavioral risk factors that contribute to falls.<sup>52,111</sup> The selection of exercises and activities for balance training should be based on two major factors: the person's fall risk and the setting in which the training will take place. Economic and transportation factors also play a role in these decisions. Since people can fall while participating in balance training and exercise programs, it is critical that adequate protections are in place to prevent falls. Based on these issues, the following guidelines are proposed.

- Elderly individuals who have no history of falls and do not have scores that are within the "at risk" category on standardized balance tests should participate in an individual or community-based group exercise program incorporating muscle strengthening, balance, and coordination exercises.
- Individuals who are at risk of falls, based on standardized balance tests, but have not developed a history of falls should participate in individual or group exercise programs in which there are well-trained leaders and support staff who appropriately supervise and guard the person during the activities that challenge balance.

- People who are at risk of falls and have a history of falls require an individually tailored, supervised, exercise program by a physical therapist or physical therapist assistant and, if appropriate, a caregiver who is trained to supervise and guard the person during the home exercise activities. This program may take place in a clinic- or home-based setting.

### CLINICAL TIP

According to current best evidence, an exercise program to reduce risk of falls should include at least 2 hours per week devoted to exercises and activities to improve balance.<sup>154</sup>

Exercise programs that incorporate multiple types of exercise, such as balance training, strength/resistance training, and constant repetitive movements through all 3 planes (e.g., tai chi or square stepping), are effective for reducing both rate of falls and risk of falling.<sup>53</sup>

Although walking has many health benefits, the time devoted to a walking exercise program should be *in addition* to time spent in balance training and not a substitute for it.

## Home Exercise Program for Reducing Risk of Falls for People at High Risk

The home setting may be the best option for an exercise-based falls prevention program for some people who are at high risk of falls. Reasons why the home may be the best location for such programs include (1) the person functions most often in this environment, and therefore the training takes place in the location where falls are most likely to occur, and (2) the person may participate more fully to his or her physical capacity without the stress and fatigue that may be associated with transportation issues.

### Otago Home Exercise Program

The Otago Exercise Program<sup>20,48,145</sup> is a cost-effective home program supervised by a physical therapist that reduces falls in frail older adults. This program consists of a series of 17 strength and balance exercises that are individually tailored and performed at least three times per week. The 30-minute exercise program is complemented with a walking plan with the goal of walking 30 minutes at least twice per week. The program is designed to be performed for 1 year under the supervision of physical therapists or health professionals trained by the physical therapist.<sup>48</sup> The first 2 months of the Otago program is the Physical Therapy Management Phase during which the physical therapist conducts the initial evaluation, instructs the patient in the exercises, and progresses the exercise and walking program.<sup>22</sup> The Self-Management Phase follows in which the patient carries out the program with assistance of a caregiver, if necessary. Follow-up visits by the physical therapist are scheduled at 6, 9, and 12 months. Physical therapists can obtain online training and free resources for implementing the Otago Exercise Program through the Carolina

Geriatric Education Center at the University of North Carolina at Chapel Hill.<sup>22</sup>

- The patient receives a manual with illustrations and instructions on each exercise. Videos are also available online.
- Ankle weights are used to provide resistance during the leg strengthening exercises that target the muscles that extend and abduct the hip and flex and extend the knee.<sup>48</sup>
  - The amount of resistance should be based on the amount of weight that the person can lift for 8 to 10 repetitions of the exercise before fatiguing. Most people start with 1- or 2-kg (2.2- or 4.4-lb) cuff weights.
  - The goal is for the person to be able to do 2 sets of 10 repetitions before the amount of weight is increased.
  - The ankle dorsiflexor and plantarflexor muscles are strengthened using body weight as the resistance (Fig. 8.20 and Fig. 8.21).
  - Box 8.4 provides a list of the strengthening exercises in the Otago program.
- The balance training component of the Otago Exercise Program is also tailored to the individual and emphasizes dynamic exercises that are closely related to functional activities (Fig 8.22).<sup>48</sup> Depending on the ability of the individual, the balance exercises may be performed by holding on to a large, stable piece of furniture or a kitchen counter and progressed by performing the exercises without support (Fig 8.23). Balance training exercises are listed in Box 8.4.
- A walking program is part of the Otago Exercise Program.<sup>48</sup> People are told to walk for at least 30 minutes per day at their usual pace. The walking plan may be accomplished by taking walks of smaller intervals (e.g., 10 minutes) throughout the day.

**FIGURE 8.20** Rising up on toes to strengthen plantarflexors.

**FIGURE 8.21** Rocking back onto the heels while raising the toes to strengthen dorsiflexors.

**FIGURE 8.22** Practicing the sit-to-stand transfer is an important functional activity to strengthen the legs and improve dynamic balance.

### BOX 8.4 The Otago Home Exercise Program<sup>22,48</sup>

#### Warm Up Exercises

Perform five repetitions of each of the following flexibility exercises:

- Stand up tall and look ahead. Turn head slowly to the right and then to the left as far as possible.
- Stand up tall and look straight ahead. Place one hand on the chin. Guide the head straight back (tuck chin).
- Stand up tall with feet shoulder width apart. Place the hands on the small of the lower back. Gently arch the back (extension).
- Stand up tall and place the hands on the hips. Do not move the hips. Turn as far as possible to the right, comfortably. Turn as far as possible to the left, comfortably.
- Either sit or stand. Point the foot up and then point the foot down.

#### Lower Extremity Strengthening\*

##### Balance Training\*\*

With the person sitting in a straight-back chair with the back well supported:

- Add appropriate ankle cuff weight. Have the patient perform unilateral knee extension. Repeat for the opposite leg.

With the person standing up tall and facing a table with both hands on the table:

- Add appropriate ankle cuff weight and have patient perform unilateral knee flexion. Repeat for the opposite leg.
- Adjust cuff weight if necessary and have patient perform unilateral hip abduction. Repeat for the opposite leg.

- Calf raises—raise up on toes to strengthen ankle plantarflexors.
- Toe raises - rock back on heels for ankle dorsiflexors.
- Knee bends—10 repetitions, 3 times.
- Backwards walking—10 steps, 5 times.
- Walking and turning around—Make a figure “8” 2 times.
- Sideways walking—10 steps, 5 times.
- Heel toe standing—10 seconds with each foot.
- Heel toe walking—10 steps, 5 times.
- One leg stand - hold up to 30 seconds, repeat for the opposite leg.
- Heel walking—10 steps, 5 times.
- Toe walking—10 steps, 5 times.
- Heel toe walking backwards—10 steps, 5 times.
- Sit to stand—with two hands, with one hand, or with no support based on ability. Repeat 5 or 10 times.
- Stair walking—using handrail, go up and down 12 steps.

\*Each exercise is to be done slowly (e.g., 2–3 seconds to lift the weight and 4–6 seconds to lower the weight) and through the full functional range of motion. The goal is to perform each exercise for 2 sets of 10 repetitions. To advance the calf raises and toe raises, have the patient try the exercise without having the hands on the table.

\*\*The easiest level for the balance exercises is to use two hands for support. Progression to harder levels (to one hand support and no hands for support) depends on the ability to complete the targeted number of repetitions or amount of time using smooth, controlled movements. To progress to exercises without holding onto support, the instructor must be confident that the person can safely recover balance using lower-body strategies such as stepping. The number of repetitions listed represents the most advanced level.

**FIGURE 8.23** Tandem walking (A) performed with light touch on a firm surface for support and (B) performed without external support. Note that the therapist closely guards the patient for safety.

### Supervised Group Program Incorporating Strengthening, Walking, and Functional Activities

Multimodal exercise programs incorporating muscle strengthening, gait, balance, coordination, and functional exercises have beneficial effects on balance, at least in the short term.<sup>74</sup> The more effective programs for improving balance are carried out three times per week for at least three months and include dynamic exercises in standing.<sup>74</sup>

#### FOCUS ON EVIDENCE

One example of a supervised group program comes from a study by Means and colleagues<sup>111</sup> that investigated the effects of a program designed to improve balance in community-residing elders with or without a history of falls. The program incorporated activities such as stretching, strengthening, coordination exercises, body mechanics, balance training, survival training maneuvers, and walking for endurance. The participants attended 90-minute exercise sessions three times per week in groups of six to eight. The exercises were performed under the direction of a physical therapist. Initially, participants were encouraged to exercise at a “fairly light” level (equal to 11 on the 6- to 20-point Borg perceived exertion scale<sup>13</sup>). After the first week, participants were encouraged to exercise at a level of intensity that was “somewhat hard” (equal to 13 on the Borg scale). The participants who attended this 6-week comprehensive exercise program showed a reduction

in the time to complete an obstacle course (e.g., walking, climbing stairs, opening doors, getting up from a chair, and stepping over objects) and in the number of fall and fall-related injuries for up to 6 months after participation.

Box 8.5 provides general guidelines for exercise repetitions, duration of endurance walking, and progression of a supervised group program.<sup>111</sup>

### Multisystem Group Exercise Program Incorporating a Circuit of Activities to Address Balance Impairments and Function

Nitz and Choy<sup>130</sup> investigated the efficacy of a balance training program that integrated individual and group exercises targeting strength, coordination, sensory systems (vision, perception, vestibular), cognition, reaction time, and static and dynamic stability. Community-residing elderly individuals with a recent history of falls were randomly assigned to two groups. One group participated in the balance training program that addressed multisystem activities. The control group participated in a more traditional group exercise program. Participants in both groups received an educational booklet on how to prevent falls in the home and attended a 1-hour exercise session once a week for 10 weeks. The exercises were led by a physical therapist assisted by one or two students when small group activities (six participants per group) were performed.

After the intervention, both groups reported a reduction in the number of falls. The reduction in falls was greater in

**BOX 8.5 Balance Exercise Program Incorporating Strengthening, Walking, and Functional Activities****Week 1**

Flexibility exercises (5 repetitions, 15-second hold)  
 Hamstring stretch  
 Gluteus maximus and hip flexor stretch  
 Gastrocnemius and soleus stretch  
 Paraspinal stretch  
 Strengthening exercises (baseline determination of preferred elastic-band strengths for lower limb exercises—1 repetition maximum)  
*Lower limb muscles* (elastic band: 1 set of 8–10 repetitions for each leg)  
 Quadriceps (sitting and straight leg raises)  
 Hamstrings  
 Gluteus maximus  
 Gluteus medius  
*Upper limb muscles* (5–10 repetitions)  
 Push-ups  
*Abdominal muscles* (5 repetitions)  
 Curl-ups with arms behind head

**Instruction in body mechanics for:**

Standing  
 Sitting  
 Lying  
 Lifting  
 Reaching  
 Carrying  
 Arising from floor  
 Ascending/descending stairs  
 Baseline walking evaluation (determine maximum comfortable distance)

**Week 2**

Flexibility exercises (as above)  
 Strengthening exercises: lower limb muscles (elastic band: 1 set of 10 repetitions, each leg), upper limb muscles (10 repetitions), abdominal muscles (5–10 repetitions)  
 Postural exercises (10 repetitions, 10-second hold)  
 Head and neck  
 Trunk

**Coordination exercises**

Reciprocal leg movements (10 repetitions, eyes closed)  
 Bridging (10 repetitions)  
 Sitting/standing (5 repetitions)  
 Braiding exercises (2 repetitions)  
 Reciprocal ankle motion (10 repetitions)  
 Rung ladder: forward stepping (2 repetitions)

**“Survival” maneuvers**

Floor recovery exercises—“how to get up if you should fall”  
 Ascending and descending stairs safely (individual practice)

Endurance walking (begin at 75%–100% of baseline minutes walked; increase at comfortable pace)

**Week 3**

Flexibility exercises (5 repetitions, 20-second hold)  
 Strengthening exercises: lower limb (2 sets of 10 repetitions), upper limb (push-ups, 10–15 repetitions), abdominals (curl-ups, 10–15 repetitions)  
 Postural exercises (15 repetitions, 10-second hold)  
 Coordination exercises (repetitions increased)  
 Survival maneuvers: practice (floor recovery/stairs)  
 Endurance walking (0–6 minutes, comfortable pace)

**Week 4**

Flexibility exercises (5 repetitions, 25-second hold)  
 Strengthening exercises: lower limb (2–3 sets of 10 repetitions), upper limb (push-ups, 15 repetitions), abdominals (curl-ups, 15 repetitions)  
 Postural exercises (20 repetitions, 10-second hold)  
 Coordination exercises (repetitions increased)  
 Reciprocal legs (eyes closed)  
 Braiding (no holding, eyes open)  
 Rung ladder (forward, side, and backward stepping)  
 Survival maneuvers: practice (floor recovery/stairs)  
 Endurance walking (3–8 minutes, comfortable pace)

**Week 5**

Flexibility exercises (5 repetitions, 30-second hold)  
 Strengthening exercises: lower limb (3 sets of 10 repetitions), upper limb (push-ups, 15–20 repetitions), abdominals (curl-ups, 15–20 repetitions)  
 Postural exercises (25 repetitions, 10-second hold)  
 Coordination exercises: as above with increased repetitions, plus:  
 Braiding (no holding, eyes closed)  
 Reciprocal ankle dorsi/plantar flexion (25 repetitions)  
 Survival maneuvers: practice (floor recovery/stairs)  
 Endurance walking (6–10 minutes, comfortable pace)

**Week 6**

Flexibility exercises (5 repetitions, 30-second hold)  
 Strengthening exercises: lower limb (3 sets of 10 repetitions), upper limb (push-ups, 20 repetitions), abdominals (curl-ups, 15–20 repetitions)  
 Postural exercises (25 repetitions, 10-second hold)  
 Coordination exercises (as above with increased repetitions)  
 Endurance walking (8–12 minutes, comfortable pace)  
 Survival maneuvers: practice (floor recovery/stairs)

the group that performed the circuit training program; they also showed greater improvements in functional tests of the ability to perform activities of daily living. Although the circuit training program devised by Nitz and Choy<sup>130</sup> clearly incorporates many important activities to address multiple systems affecting balance, the results should be

interpreted with caution because there was a small sample size and a high proportion of dropouts throughout the study.

Table 8.4 provides the details of the balance exercise program, consisting of circuit training and group activities, from the Nitz and Choy study.<sup>130</sup>

**TABLE 8.4** Circuit Training Program to Address Balance Impairments and Function<sup>130</sup>

Activity	Responses Targeted	Progression of Activity
Sit-to-stand-to-sit	Lower limb strength Functional ability Multiple tasks	Lower the height of the chair Add/remove upper limb assistance Hold an item in the hands, balance a cup with/without water on a saucer/tray Add a cognitive task to the manual task
Stepping in all directions (forward, side, back)	Choice step reaction time Lower limb strength and coordination	Increase speed of step Perform stepping on a soft surface Close eyes
Reaching to limits of stability	Challenging limits of stability Vestibular stimulation and integration Upper and lower limb strengthening	Stick objects on a wall in the front by reaching to limits in all directions up and down while keeping feet in one position Lunge forward to pick up objects that are shifted to a high shelf to the side and behind; progress by reaching further and increasing the weight and size of objects
Step up and down	Lower limb strengthening and endurance Step reaction time	Step up forward, backward, and sideways over blocks of various heights; increase height, repetitions, and speed of stepping
Ankle, hip, and upper limb balance strategy practice	Lower limb strengthening Balance strategy training	Stand in front of a wall with toe touching a line 0.5 meter from the wall. Lean back toward the wall, keeping balance and dorsiflexing the feet and using arm movement to balance while lowering toward the wall
Sideways reach task	Mediolateral muscle strengthening in lower limbs Vestibular stimulation and integration Challenging limits of stability Multiple tasks and confounded proprioceptive input	Stand between a high and a low table positioned on either side; pick up objects from one table and transfer to other table Move the tables farther apart and increase the weight and size of the objects to increase the challenge Perform task while standing on an exercise mat on the floor
Ball games	Multiple tasks Hand-eye coordination Vestibular stimulation Ballistic upper and lower limb activity	Use inflated beach balls and progress to smaller or harder balls or two or three balls at once Add a cognitive task such as naming an animal that starts with a G, while throwing and catching or kicking the ball
Card treasure hunt/sort into suits	Coping strategies with visual conflict Vestibular stimulation and challenge of limits of stability	Prior to the session, hide playing cards in the room such that to collect the cards the participants have to bend and look under furniture, reach up high, or detect the card from a visually confounding background. Red and black teams are possible, and the team with the most cards returned to a collecting point inside 5 minutes is the winner Add the cognitive challenge of finding/sorting cards into order according to suit

### Tai Chi for Balance Training

Tai chi has become a popular form of exercise for balance training. Tai chi is a traditional Chinese exercise program consisting of a sequence of whole-body movements that are performed in a slow, relaxed manner with an emphasis on awareness of posture alignment and synchronized breathing. The four styles of tai chi are Yang, Sun, Chen, and Wu, and they differ in terms of principles, forms, and function.

Yang style tai chi is the most popular and widely practiced style today and consists of 24 forms (postures and movements).<sup>103</sup> Tai chi programs for the elderly may adopt a short form of tai chi with only 6 to 12 forms.<sup>103</sup> During tai chi training, participants learn to control the displacement of the body COM while standing and increase their lower extremity strength and flexibility during the regimens of physical movement.<sup>28</sup>

Some of the characteristics of tai chi exercise and the therapeutic rationale for why tai chi may affect posture and balance include the following:<sup>176</sup>

- The slow, continuous, even rhythm of the movements facilitates sensorimotor integration and awareness of the external environment (see Fig. 8.2).
- The emphasis on maintaining a vertical posture enhances postural alignment and perception of orientation.
- The continuous weight shifting from one leg to the other facilitates anticipatory balance control, motor coordination, and lower extremity strength.
- Finally, the large dynamic, flowing, and circular movements of the extremities promote joint ROM and flexibility (Fig 8.24). These characteristics should be considered when recommending tai chi classes to patients to ensure that instructors are following these principles and that the patients are appropriate for these activities.

### FOCUS ON EVIDENCE

The effectiveness of tai chi training depends on the duration of the program, which may range from 4 weeks to 1 year, and the targeted populations. Studies have shown that tai chi improves standing balance control through performing head, trunk, and arm movements simultaneously with weight shifting.<sup>5,77</sup> Elderly individuals who participated in a tai chi group program had significant reductions in reported fear of falling compared to those who did not exercise, perhaps because the training leads to an increased self-awareness of balance.<sup>5,151,191</sup>

**FIGURE 8.24** In this tai chi form, the participant shifts the body-weight toward one leg while moving the arms.

However, tai chi training has shown less robust improvements in dynamic balance during functions such as gait and turning.<sup>5,77,98,151</sup> This may explain why there is conflicting evidence as to whether tai chi reduces falls or the risk of falls among people over the age of 50.<sup>59,98,103</sup> For this reason, Tai Chi should be considered as only one part of a comprehensive fall prevention program rather than being advocated as the sole exercise intervention.

## Evidence-Based Balance Exercise Programs for Specific Musculoskeletal Conditions

Evidence is growing that specific balance exercise programs can effectively prevent and/or treat balance control deficits associated with lower extremity and trunk injuries and pathologies.

### Ankle Sprains

Therapeutic activities such as single-leg balance training on unstable surfaces are recommended in the postacute phase of rehabilitation for ankle sprains for their potential to improve static and dynamic balance control.<sup>107</sup> Because of the interdependency between the segments of the lower extremity and trunk, especially during sports activities where energy is transferred from the legs through the trunk to the arms, or vice versa, it is also important to consider the regions above the ankle when designing a program for rehabilitation of ankle sprains.<sup>83,125</sup> Therefore, training for balance control should incorporate activities that require recruitment and coordination of the hip and trunk musculature. The BESS test, SEBT, or the YBT have been used to document deficits in balance control and improvements in performance with ankle injuries.<sup>107</sup>

Systematic reviews have concluded that balance training programs can improve static and dynamic balance and reduce the risk of ankle sprains in individuals with a history of ankle sprains.<sup>65,78,109,177</sup> Successful programs utilized wobble or unstable balance platforms, single-leg stance progressions, and resisted kicks of the uninjured leg against an elastic band or tubing.<sup>41,60,108,114,146,174</sup> Programs typically were conducted for at least three times per week throughout a competitive season for prevention or two to three times per week for approximately 6 to 8 weeks post injury. Refer to Chapter 22 for additional information on rehabilitation following ankle sprain.

### FOCUS ON EVIDENCE

A balance program developed by McGuine and Keene<sup>108</sup> reduced the risk of ankle sprains by 38% in male ( $n = 112$ ) and female ( $n = 261$ ) high school soccer and basketball players, especially in those with a history of ankle sprains. Participants performed the single-leg stance (Fig. 8.25), progressing from standing on the floor to standing on a wobble board with and

**FIGURE 8.25** Balance program for reducing the incidence of ankle sprains in athletes using a wobble board: **(A)** single-leg squat (knee bent 30° to 45°), **(B)** single-leg stance while rotating the board, and **(C)** single-leg stance while performing functional activities (i.e., catching a ball).

without eyes open. They performed the balance activities 5 days a week for the first 5 weeks and then 3 days a week for the rest of the season. Each exercise was performed for a duration of 30 seconds per leg, and legs were alternated during a rest period of 30 seconds between repetitions.

### Anterior Cruciate Ligament Injuries

Proprioceptive and balance training programs either alone or in combination with neuromuscular training that includes lower extremity plyometrics (as described in Chapter 23), trunk stabilization and strengthening (refer to Chapter 16), and sport-specific functional training (refer to Chapters 21 and 23) have been shown to reduce the incidence of anterior cruciate ligament (ACL) injuries by about 50% in adolescents and adults.<sup>47,163</sup> These proprioceptive and balance training programs frequently consisted of double and single leg balance exercises progressing from firm to unstable surfaces, such as ankle disks, tilt boards, or foam, with variations such as squatting or catching a ball.<sup>21,43,50,110</sup> Balance exercises usually were done 10 to 15 minutes daily during preseason training and 3 times a week during the season for prevention. Neuromuscular training sessions longer than 20 minutes appear to be more effective than shorter sessions for reducing ACL injuries in female athletes.<sup>163</sup>

Benjaminse and colleagues<sup>10</sup> have recently proposed novel techniques to enhance balance training for ACL injury prevention. These techniques build on the concept that motor learning is enhanced when instructional strategies incorporate an external focus of attention, especially for complex motor skills required for sports. One easy technique to implement in the clinical setting is the use of dyad training,

where athletes practice in pairs, observing and providing feedback of each other's performance. For example, one athlete performs an exercise such as the single leg hop in forward-backward and side-to-side directions and ends by landing on two feet. The second athlete observes the performance, provides feedback after one set of hops, and then performs the exercise while the first athlete plays the role of observer and coach.<sup>10</sup> Alternating back and forth between the role of performer and observer, promoting dialog between learners, seems to encourage more cognitive effort and processing, which may explain why studies have shown enhanced retention and transfer of the motor skill when dyad training is employed compared to other forms of individual or group practice.<sup>153,190</sup>

### Low Back Pain

Individuals with LBP show altered postural responses in laboratory studies that induce perturbations to balance.<sup>85,99</sup> In response to disturbances to balance, the most common compensatory strategy exhibited by people with chronic LBP is to co-contract the trunk muscles in order to stiffen the spine.<sup>124,170</sup> Deficits in postural control may be detected by balance testing such as the SEBT described in this chapter.<sup>132</sup> Since the trunk makes up about half of the mass of the body, from a biomechanical standpoint, it is reasonable to propose that balance training should be incorporated into a comprehensive, multimodal intervention for LBP as described in Chapters 15 and 16. Evidence to date suggests that interventions designed to improve neuromuscular control of the trunk in persons with LBP contribute to patient reports of reduced pain and improved function; however, demonstrated improvements in balance or postural reactions remain elusive.<sup>99,100,124</sup>

## Independent Learning Activities

### Critical Thinking and Discussion

1. A person is experiencing falls when rising from a chair. Using biomechanical principles of balance, what adjustments can the person immediately make to increase his or her stability and prevent falls?
2. Differentiate and describe several balance movements that rely primarily on feedforward or open-loop motor control versus those that utilize closed-loop control.
3. Review the ankle, hip, and stepping strategies and discuss how the strategies are elicited and what key muscles are activated to control balance.
4. Think about the times you have fallen in the past. What activity were you doing at the time that you fell? What musculoskeletal, neurological, and/or contextual factors contributed to the fall occurrence? What were the consequences of the fall? What differences would you expect between your falls and those experienced by an elderly person?
5. Differentiate and discuss treatment activities that you would use to train static, dynamic, anticipatory, reactive, and sensory organization aspects of balance control. Provide examples of how you would progress each of the activities.
6. For an elderly person with a history of falls, what aspects of the home environment might need to be modified to maximize the individual's safety and independence?
7. Differentiate between internal versus external focus of attention. Provide examples of verbal cues that you would use to promote external focus of attention for training static, dynamic, anticipatory, and reactive balance control.
8. The success of balance training programs depends on the compliance by the patient. What strategies would you use to increase the likelihood that a person would adhere to a home exercise program and ensure that his or her treatment outcomes are attained? Refer to Chapter 1 for discussion on teaching strategies for effective exercise.

### Laboratory Practice

1. With a partner, mount a yardstick on the wall at the person's shoulder height. Measure the maximum amount of anterior and posterior sway by recording the maximum shoulder displacement during a 30-second period of quiet stance in each of the following conditions.
  - Standing on a firm surface with feet together, arms on hips, and eyes open
  - Standing on a firm surface with feet together, arms on hips, and eyes closed
  - Standing on a soft foam surface with feet together, arms on hips, and eyes open
  - Standing on a soft foam surface with feet together, arms on hips, and eyes closed

For each of the conditions, what sensory inputs are available to the person for maintaining balance? How does the amount of sway vary with each condition and why?

2. With a partner, observe body movement during the following activities.
  - Standing with feet shoulder width apart, perform self-initiated forward and backward body sways progressing from small to large amplitudes.
  - Standing with feet apart, have your partner place his or her hand on your sternum and nudge you backward gently and then again with a larger force.
  - Standing with the feet placed heel to toe, have your partner gently nudge you backward.
  - Put on ankle-foot orthoses or ski boots that restrict ankle movements and have your partner gently nudge you backward.

Which movement strategy is elicited with each activity and why?

3. Practice performing treatment activities that you would use to train static, dynamic, anticipatory, reactive, and sensory organization aspects of balance control as described in Table 8.2. Progress each of the activities to maximally challenge your balance. Practice performing treatment activities that promote external focus of attention during static, dynamic, anticipatory, and reactive balance.

### Case Studies

1. A 20-year-old male soccer player sustained a right midtibial fracture in a motor vehicle accident and was required to wear a long-leg rigid cast for 6 weeks. You are seeing the patient 1 week after cast removal for physical therapy. He would like to return to playing soccer but is currently unable to maintain balance on his right leg to kick a soccer ball. What underlying impairments might be causing this individual's balance problems, and how would you design an exercise program that would allow him to reach his goals? How could you incorporate external focus of attention into his training program?
2. A 75-year-old woman fell in her bathtub and sustained a right pelvic fracture, requiring bed rest for 2 weeks. You are seeing the patient in her home following her hospital discharge. She has generalized weakness, deconditioning, is unsteady on her feet, and is fearful of falling. Currently, she is using a walker for ambulation. Prior to her fall, she was completely independent in all activities of daily living and enjoyed going on walks in her neighborhood in the evenings. Design a progressive balance program for this woman to restore her to her prior level of functioning.
3. A 70-year-old retiree has had bilateral knee replacement surgeries. He would like to resume his favorite hobby of

boating but lacks confidence in his ability to balance under dynamic conditions. Design an exercise and balance training program that will help him return to his recreational pursuits. What suggestions do you have to increase his safety when boating? What if his hobby was golfing instead of boating? Compare and contrast the activities and exercises you would prescribe for these two different issues. How can you incorporate external focus of attention to help him improve his golf swing?

4. A 56-year-old obese woman with diabetes is being treated for low back pain. She reports unsteadiness when walking,

particularly in darkened environments. She has difficulty maintaining her balance during conditions 2, 3, 5, and 6 of the CTSIB test. What factors could be contributing to her unsteadiness? Design an exercise program that addresses her balance impairments.

5. An active, vibrant 70-year-old female seeks your advice on how to best maintain her health and fitness. What are the major components of a comprehensive exercise program for her? Give examples of exercises she should include.

Aquatic therapy, the use of water for rehabilitation purposes, traces its origin back several centuries. The use of water for restorative purposes has grown in popularity and has gained increased use in facilitating therapeutic exercise. The unique properties of the aquatic environment provide clinicians with treatment options that may otherwise be difficult or impossible to implement on land. Using buoyant devices and varied depths of immersion, the practitioner has flexibility in positioning the patient (supine, seated, kneeling, prone, side-lying, or vertically) with any desired amount of weight bearing. Aquatic exercise has been successfully used for a wide variety of rehabilitation populations including pediatric,<sup>8,30,39,49,55,73,78,84</sup> orthopedic,\* neurological,<sup>41,54,56,61,63</sup> and cardiopulmonary patients.<sup>23,48,77</sup>

## Background and Principles for Aquatic Exercise

### Definition of Aquatic Exercise

*Aquatic exercise* refers to the use of water (in multidepth immersion pools or tanks) that facilitates the application of established therapeutic interventions, including stretching, strengthening, joint mobilization, balance and gait training, and endurance training.

\*1,4,9,11,12,13,14,19,21,27,31,41,50,68,80

## Goals and Indications for Aquatic Exercise

The specific purpose of aquatic exercise is to facilitate functional recovery by providing an environment that augments a patient's and/or practitioner's ability to perform various therapeutic interventions. Aquatic exercise can be used to achieve the following specific goals:

- Facilitate range of motion (ROM) exercise<sup>33,82</sup>
- Initiate resistance training<sup>25,50,66,76,81</sup>
- Facilitate weight-bearing activities<sup>4</sup>
- Enhance delivery of manual techniques<sup>5,69</sup>
- Provide three-dimensional access to the patient<sup>16,69</sup>
- Facilitate cardiovascular exercise<sup>17,58,59,72</sup>
- Initiate functional activity replication<sup>53,57,76,82</sup>
- Minimize risk of injury or re-injury during rehabilitation<sup>29,82</sup>
- Enhance patient relaxation<sup>33,46</sup>

Although research studies support these goals for aquatic exercise, Hall and associates<sup>41</sup> cited the need for more research with robust designs that address temperature, depth of immersion, and care settings.

## Precautions and Contraindications to Aquatic Exercise

Most patients easily tolerate aquatic exercise. However, the practitioner must consider several physiological and psychological aspects of immersion that affect selection of an aquatic environment.

### Precautions

#### Fear of Water

Fear of water can limit the effectiveness of any immersed activity. Fearful patients often experience increased symptoms during and after immersion because of muscle guarding, stress response, and improper form with exercise. Often patients require an orientation period designed to provide instruction regarding the effects of immersion on balance, control of the immersed body, and proper use of flotation devices.<sup>57</sup>

#### Neurological Disorders

Ataxic patients may experience increased difficulty controlling purposeful movements. Patients with heat-intolerant multiple sclerosis may fatigue with immersion in temperatures greater than 33°C.<sup>12,59,61</sup> Patients with controlled epilepsy require close monitoring during immersed treatment and must be compliant with medication prior to treatment.<sup>16,47</sup>

#### Respiratory Disorders

Water immersion may adversely affect the breathing of the patient with a respiratory disorder. Lung expansion tends to be inhibited due to hydrostatic pressure against the chest wall.

Additionally, increased circulation in the chest cavity may further inhibit lung expansion due to increased circulation to the center of the body. Maximal oxygen uptake is lower during most forms of water exercise than during land exercise.<sup>12,16</sup>

### FOCUS ON EVIDENCE

Although the above precautions have been cited, Kurabayashi and associates<sup>48</sup> compared nose and mouth immersion to non-immersion. Participants spent 30 minutes a day for 5 days a week for 2 months in the pool with water temperature set at 38°C. There was a significant difference in the immersion group with increased %FVC ( $p = 0.058$ ), increased FEV<sub>1.0%</sub> ( $p = 0.018$ ), increased peak flow ( $p = 0.039$ ), and increased P<sub>ao2</sub> ( $p = 0.010$ ). Based on their findings, they recommended the use of subtotal immersion to improve respiratory function for individuals with chronic pulmonary emphysema. Pechter and colleagues<sup>59</sup> compared 30 minutes of water-based aerobics to land-based aerobics done twice weekly for 12 weeks. The water-based group demonstrated increases in peak VO<sub>2</sub>, peak O<sub>2</sub> pulse, peak ventilation, and peak load, as well as decreases in serum creatinine, glomerular filtration rate, cystatin-c in serum, protein/creatinine ratio, systolic and diastolic blood pressure, total serum cholesterol, and serum triglycerides. They recommended the use of low-intensity aquatic exercise to improve cardiorespiratory and renal function in individuals with chronic renal failure.

### Cardiac Dysfunction

Patients with angina, abnormal blood pressure, heart disease, or compromised pump mechanisms also require close monitoring.<sup>20,23,77,79</sup> Cider and colleagues<sup>24</sup> demonstrated significant increases in work rate, VO<sub>2peak</sub> and walking capacity, and muscle function in patients with congestive heart failure and type 2 diabetes mellitus. Teffaha and colleagues<sup>74</sup> demonstrated similar results of increased VO<sub>2peak</sub> in patients with chronic heart failure or coronary artery disease with normal left ventricular function.

### FOCUS ON EVIDENCE

Meyer and Leblanc<sup>55</sup> provided an algorithm for clinical decision-making when prescribing aquatic therapy for patients with left ventricular dysfunction and/or stable congestive heart failure. In their review of the literature, they suggested the following for rehabilitation and secondary prevention: (1) Temporary abnormal hemodynamic responses may be elicited by immersion to the neck; (2) water therapy is absolutely contraindicated in patients with decompensated congestive heart failure; (3) feeling good in water does not equate with left ventricular tolerance of increased volume loading caused by immersion; (4) if patients with previous severe myocardial infarctions and/or congestive heart failure can sleep supine, they may be able to tolerate bathing in a half-sitting position provided immersion does not exceed the xiphoid process; and (5) patients with Q-wave

myocardial infarctions older than 6 weeks may exercise in a pool for orthopedic reasons provided they do so in an upright position and immersion does not exceed the xiphoid process.

### Small, Open Wounds and Lines

Small, open wounds and tracheotomies may be covered by waterproof dressings. Patients with intravenous lines, Hickman lines, and other open lines require proper clamping and fixation.<sup>16</sup> Precautions should also be exercised with patients having G-tubes and suprapubic appliances. Observation for adverse reactions to aquatic therapy is essential.<sup>18</sup>

## Contraindications

Contraindications to aquatic therapy include any situation creating the potential for adverse effects to either the patient or the water environment.<sup>10</sup> Such factors include:

- Incipient cardiac failure and unstable angina
- Respiratory dysfunction, vital capacity of less than 1 liter
- Severe peripheral vascular disease
- Danger of bleeding or hemorrhage
- Severe kidney disease (patients are unable to adjust to fluid loss during immersion)
- Open wounds without occlusive dressings, colostomy, and skin infections, such as tinea pedis and ringworm
- Uncontrolled bowel or bladder (bowel accidents require pool evacuation, chemical treatment, and possibly drainage)
- Menstruation without internal protection
- Water and airborne infections or diseases (examples include influenza, gastrointestinal infections, typhoid, cholera, and poliomyelitis)
- Uncontrolled seizures during the last year (they create a safety issue for both clinician and patient if immediate removal from the pool is necessary)<sup>18</sup>

## Properties of Water

The unique properties of water and immersion have profound physiological implications in the delivery of therapeutic exercise. To utilize aquatics efficiently, practitioners must have a basic understanding of the clinical significance of the static and dynamic properties of water as they affect human immersion and exercise.

### Physical Properties of Water

The properties provided by buoyancy, hydrostatic pressure, viscosity, and surface tension have a direct effect on the body in the aquatic environment.<sup>12,35,40</sup>

#### Buoyancy (Fig. 9.1)

**Definition.** Buoyancy is the upward force that works opposite to gravity.

## Weight Bearing with Immersion

**FIGURE 9.1** Percentage of weight bearing at various immersion depths.

**Properties.** Archimedes' principle states that an immersed body experiences upward thrust equal to the volume of liquid displaced.<sup>40</sup>

**Clinical significance.** The effects of buoyancy include the following:

- Buoyancy provides the patient with relative weightlessness and joint unloading by reducing the force of gravity on the body. In turn, this allows the patient to perform active motion with increased ease.
- Buoyancy provides resistance to movement when an extremity is moved against the force of buoyancy. This technique can be used to strengthen muscles.
- The amount of air in the lungs will affect buoyancy of the body. Buoyancy will be increased with fully inflated lungs and decreased with deflated lungs.
- Body composition will also affect buoyancy. Obese patients will have increased buoyancy due to fat tissue having a lower specific gravity. Patients with increased bone density will have less buoyancy than those with decreased bone density.
- Buoyancy allows the practitioner three-dimensional access to the patient.

### CLINICAL TIP

Rotator cuff pathology. A patient recovering from rotator cuff repair can use the buoyancy force to increase range of motion in shoulder abduction and/or flexion while performing the motion in neck-deep water.<sup>14</sup> When performing shoulder extension from a 90° flexed position, the force of buoyancy becomes a resistance as the patient pulls the arm downward through the water.

### Hydrostatic Pressure

**Definition.** Hydrostatic pressure is the pressure exerted by the water on immersed objects.

**Properties.** Pascal's law states that the pressure exerted by fluid on an immersed object is equal on all surfaces of the object. As

the density of water and depth of immersion increase, so does hydrostatic pressure.

**Clinical significance.** The effects of hydrostatic pressure include the following:

- Increased pressure reduces or limits effusion, assists venous return, induces bradycardia, and centralizes peripheral blood flow.
- The proportionality of depth and pressure allows patients to perform exercise more easily when closer to the surface.

### CLINICAL TIP

Regulation of performance. Barbosa and colleagues<sup>6</sup> compared the physiological adaptations of aquatic exercise with different levels of immersion to land exercise. Participants performed the same exercise on land, immersed to the hip, and immersed to the breast for 6 minutes. Physiological responses were higher when exercising immersed to the hip than when immersed to the breast and when exercising on land than immersed to either depth. The clinician should consider a progression from immersion to breast, to immersion to hip, to exercises on land in order to increase the physiological demands on the patient.

### Viscosity

**Definition.** Viscosity is friction occurring between molecules of liquid resulting in resistance to flow.

**Properties.** Resistance from viscosity is proportional to the velocity of movement through liquid.

**Clinical significance.** Water's viscosity creates resistance with all active movements.

- Increasing the velocity of movement increases the resistance.
- Increasing the surface area moving through water increases resistance.

### CLINICAL TIP

Lymphedema. Jamison<sup>44,45</sup> cited the effectiveness of hydrostatic pressure and viscosity for increasing lymph flow and reducing edema in patients with lymphedema. However, caution is needed as the dependent position of the extremity may cancel this effect. Recommended aquatic activities include Watsu® (a form of water Zen Shiatsu incorporating stretches that release blockages and produce relaxation), Jahara, Ai Chi (a form of water tai chi), water aerobics, the Halliwick Method® (a technique that increases balance, strength, coordination, and flexibility), and aquatic proprioceptive neuromuscular facilitation. The reader is referred to the following list of references for further information on these interventions:

- Aquatic PNF: Jamison, L, and Ogden, D: *Aquatic Therapy Using PNF Patterns*. Tuscon, AZ: Therapy Skills Builders, 1994.

### Surface Tension

**Definition.** The surface of a fluid acts as a membrane under tension. Surface tension is measured as force per unit length.

**Properties.** The attraction of surface molecules is parallel to the surface. The resistive force of surface tension changes proportionally to the size of the object moving through the fluid surface.

**Clinical significance.** The effect of surface tension includes the following:

- An extremity that moves through the surface performs more work than if kept under water.
- Using equipment at the surface of the water increases the resistance.

### Hydromechanics

**Definition.** Hydromechanics comprise the physical properties and characteristics of fluid in motion.<sup>40</sup>

**Components of flow motion.** Three factors affect flow; they are laminar flow, turbulent flow, and drag.

- *Laminar flow.* Movement in which all molecules move parallel to each other, typically slow movement.
- *Turbulent flow.* Movement in which molecules do not move parallel to each other, typically faster movements.
- *Drag.* The cumulative effects of turbulence and fluid viscosity acting on an object in motion.

**Clinical significance of drag.** As the speed of movement through water increases, resistance to motion increases.<sup>7</sup>

- Moving water past the patient requires the patient to work harder to maintain his or her position in pool.
- Application of equipment (glove/paddle/boot) increases drag and resistance as the patient moves the extremity through water.<sup>62</sup>

### CLINICAL TIP

Increasing resistance to motion. If the goal is to increase muscular force production during the early part of knee extension, the clinician should consider the use of a hydro-boot or similar

device to increase the drag force on the leg/foot. Barbosa and associates<sup>5</sup> measured hydrodynamic drag in barefoot and hydro-boot conditions to determine the coefficients of drag on a human leg/foot model during simulated knee extension-flexion exercise. The influence of water resistance created higher drag force when using the hydro-boot during the early part of extension.

## Thermodynamics

Water temperature has an effect on the body and therefore on performance in an aquatic environment.<sup>16</sup>

### Specific Heat

**Definition.** Specific heat is the amount of heat (calories) required to raise the temperature of 1 gram of substance by 1°C.<sup>40</sup>

**Properties.** The rate of temperature change is dependent on the mass and the specific heat of the object.

**Clinical significance.** Water retains heat 1,000 times more than air. Differences in temperature between an immersed object and water equilibrate with minimal change in the temperature of the water.

### Temperature Transfer

- Water conducts temperature 25 times faster than air.
- Heat transfer increases with velocity. A patient moving through the water loses body temperature faster than an immersed patient at rest.

## Center of Buoyancy (Fig. 9.2)

Center of buoyancy, rather than center of gravity, affects the body in an aquatic environment.<sup>33,39,40</sup>

**Definition.** The center of buoyancy is the reference point of an immersed object on which buoyant (vertical) forces of fluid predictably act.

**Properties.** Vertical forces that do not intersect the center of buoyancy create rotational motion.

**Clinical significance.** In the vertical position, the human center is located at the sternum.

- In the vertical position, posteriorly placed buoyancy devices cause the patient to lean forward; anterior buoyancy causes the patient to lean back.
- During unilateral manual resistance exercises, the patient revolves around the practitioner in a circular motion.
- A patient with a unilateral lower extremity amputation leans toward the residual limb side when in a vertical position.
- Patients bearing weight on the floor of the pool (i.e., sitting, kneeling, or standing) experience aspects of both the center of buoyancy and center of gravity.

FIGURE 9.2 Center of buoyancy.

## Aquatic Temperature and Therapeutic Exercise

A patient's impairments and the intervention goals determine the water temperature selection. In general, utilize cooler temperatures for higher intensity exercise and utilize warmer temperatures for mobility and flexibility exercise and for muscle relaxation.<sup>12,16,18</sup> The ambient air temperature should be 3°C higher than the water temperature for patient comfort. Incorrect water or ambient air temperature selection may adversely affect a patient's ability to tolerate or maintain immersed exercise.

### Temperature Regulation

- Temperature regulation during immersed exercise differs from that during land exercise because of alterations in temperature conduction and the body's ability to dissipate heat.<sup>2,12,16,18</sup> With immersion there is less skin exposed to air, resulting in less opportunity to dissipate heat through normal sweating mechanisms.
- Water conducts temperature 25 times faster than air<sup>12</sup>—more if the patient is moving through the water and molecules are forced past the patient.
- Patients perceive small changes in water temperature more profoundly than small changes in air temperature.
- Over time, water temperature may penetrate to deeper tissues. Internal temperature changes are known to be inversely proportional to subcutaneous fat thickness.<sup>12</sup>
- Patients are unable to maintain adequate core warmth during immersed exercise at temperatures less than 25°C.<sup>12,26</sup>

- Conversely, exercise at temperatures greater than 37°C may be harmful if prolonged or maintained at high intensities. Hot water immersion may increase the cardiovascular demands at rest and with exercise.<sup>67</sup>
- In waist-deep water exercise at 37°C, the thermal stimulus to increase the heart rate overcomes the centralization of peripheral blood flow due to hydrostatic pressure.
- At temperatures greater than or equal to 37°C, cardiac output increases significantly at rest alone.<sup>18</sup>

## Mobility and Functional Control Exercise

- Aquatic exercises, including flexibility, strengthening, gait training, and relaxation, may be performed in temperatures between 26°C and 35°C.<sup>2,12,16,18</sup>
- Therapeutic exercise performed in warm water (33°C) may be beneficial for patients with acute painful musculoskeletal injuries because of the effects of relaxation, elevated pain threshold, and decreased muscle spasm.<sup>2,12,16,18</sup>

## Aerobic Conditioning

Cardiovascular training and aerobic exercise should be performed in water temperatures between 26°C and 28°C. This range maximizes exercise efficiency, increases stroke volume, and does not elevate the heart rate to the extent that warmer water does.<sup>2,12,16,71</sup>

- Intense aerobic training performed above 80% of a patient's maximum heart rate should take place in temperatures between 22°C and 26°C to minimize the risk of heat illness.<sup>2,16,22,71</sup>

### CLINICAL TIP

There are several considerations for immersion times and pool temperatures.<sup>12,15,16,65,79</sup>

Because of the increased demands placed on the patient's temperature regulating systems when exercising in a pool the following are recommended:

- Generally, use a maximum immersion time of 20 minutes for patients with noncompromised cardiopulmonary systems. Begin with 10-minute sessions and increase the time as tolerated.
- Always monitor vital signs to ensure patient safety.
- Generally, water temperatures between 36°C and 37°C are considered high and temperatures between 26°C and 35°C are considered low. In addition to the following guidelines, the patient's fatigue factor needs to be considered.
- Higher temperatures are recommended for patients with rheumatoid arthritis except in the acute stage.
- Lower temperatures are recommended for patients with spasticity or for those whose immersion time lasts 20 to 45 minutes.

- For general flexibility, strengthening, gait training and relaxation, the range may be between 26°C and 35°C.<sup>2,12,16,18</sup>
- Cardiovascular training and aerobic exercise should be performed in water temperatures between 26°C and 28°C.

## Pools for Aquatic Exercise

Pools used for aquatic therapy vary in shape and size. The rooms in which pools are housed need to be adequately ventilated to avoid the accumulation of condensation on walls, windows, and floors. A dressing room should be provided for changing clothes and showering.

### Traditional Therapeutic Pools (Fig. 9.3)

Traditional therapeutic pools measure at least 100 feet in length and 25 feet in width. Depth usually begins at 3 to 4 feet with a sloping bottom, progressing to 9 or 10 feet.

- This larger type pool may be used for groups of patients and the therapists conducting the session while in the pool.
- Entrance to larger therapeutic pools includes ramps, stairs, ladders, or mechanical overhead lifts.
- These pools have built-in chlorination and filtration systems.

**FIGURE 9.3** Traditional therapeutic pool. (Courtesy of F.A. Davis Co., Philadelphia, PA.)

### Individual Patient Pools (Fig. 9.4)

Pools designed for individual patient use are usually smaller, self-contained units.

- These self-contained pools are entered via a door or one to two steps on the side of the unit.
- The therapist provides instructions or cueing from outside the unit.

**FIGURE 9.4** Hydro Track®, self-contained underwater treadmill system. (Courtesy of Ferno-Washington, Inc., Wilmington, OH.)

- In addition to built-in filtration systems, these units may include treadmills, adjustable currents, and varying water depths.

## Special Equipment for Aquatic Exercise

A large variety of equipment exists for use with aquatic exercise. Aquatic equipment is used to provide buoyant support to the body or an extremity, challenge or assist balance, and generate resistance to movement. Resistive paddles, floats, paddle boards, and weighted stools and chairs are just a few of the many types of available equipment. By adding or removing equipment, the practitioner can progress exercise intensity. Type of equipment used is determined by the current functional level of the patient and the specific goals for the therapy session.

### Collars, Rings, Belts, and Vests

Equipment designed to assist with patient positioning by providing buoyancy assistance can be applied to the neck, extremities, or trunk. Inflatable cervical collars are used for the supine patient to support the neck and maintain the head out of the water (Fig. 9.5). Flotation rings come in various sizes and are used to support the extremities in any immersed position

**FIGURE 9.5** Cervical collar. (Courtesy of Rothhammer International, Inc., San Luis Obispo, CA.)

(Fig. 9.6). Often the rings are used at the wrists and ankles during manual techniques to assist with patient positioning and relaxation. Several types of belts exist that may be used to assist with buoyancy of an extremity or the entire body (Fig. 9.7). Belts and vests are used to position patients supine, prone, or vertically for shallow and deep water activities.

**FIGURE 9.6** Flotation rings. (Courtesy of Rothhammer International, Inc., San Luis Obispo, CA.)

**FIGURE 9.7** Buoyancy belts. (Courtesy of Rothhammer International, Inc., San Luis Obispo, CA.)

## Swim Bars

Buoyant dumbbells (swim bars) are available in short and long lengths. They are useful for supporting the upper body or trunk in upright positions and the lower extremities in the supine or prone positions (Fig. 9.8). Patients can balance

**FIGURE 9.8** Swim bars. (Courtesy of Rothhammer International, Inc., San Luis Obispo, CA.)

(seated or standing) on long swim bars in deep water to challenge balance, proprioception, and trunk strength.

## Gloves, Hand Paddles, and Hydro-tone® Bells

Resistance to upper extremity movements is achieved by applying webbed gloves or progressively larger paddles to the hands (Fig. 9.9). These devices are not buoyant and therefore only resist motion in the direction of movement. Hydro-tone® bells are large, slotted plastic devices that increase drag during upper extremity motions. The bells generate substantially more resistance than gloves or hand paddles.

**FIGURE 9.9** Hand paddles. (Courtesy of Rothhammer International, Inc., San Luis Obispo, CA.)

## Fins and Hydro-tone® Boots

The application of fins or boots to the feet during lower extremity motions generates resistance by increasing the surface area moving through the water. Fins are especially useful for challenging hip, knee, and ankle strength. Hydro-tone® boots are most effective during deep water walking and running (Fig. 9.10).

**FIGURE 9.10** Hydro-tone® boots and bells. (Courtesy of Rothhammer International, Inc., San Luis Obispo, CA.)

## Kickboards

The shapes and styles of kickboards (Fig. 9.11) vary extensively among manufacturers. Nevertheless, kickboards remain a versatile and effective aquatic tool for augmenting any exercise program. Kickboards may be used to provide buoyancy in the prone or supine positions; to create resistance to walking patterns in shallow water when held vertically; or to challenge seated, kneeling, or standing balance in the deep water.

**FIGURE 9.11** Kickboards. (Courtesy of Rothhammer International, Inc., San Luis Obispo, CA.)

## Pool Care and Safety

Therapeutic pools require regular care and cleaning to avoid *Pseudomonas aeruginosa* (an infection causing folliculitis).<sup>33,42,43,51</sup> Frequent use increases the total organic carbon as well as ammonia and organic nitrogen found in the pool.

- Cleaning should occur at least twice weekly, and chlorine and pH level tests should be done twice daily.

- All walking surfaces near and around the pool should be slip-resistant and free of barriers. Water splashes should be dried immediately to prevent slips and falls.
- Safety rules and regulations are a must, as are emergency procedures, and should be posted and observed by all involved in therapeutic pool use.<sup>83</sup>
- Life preservers should be readily available, and at least one staff member who is CPR certified should be present at all times.

### CLINICAL TIP

Prior to the first therapeutic session, the treatment schedule, procedures to be used, and proper pool attire should be discussed with the patient. This is a good time to review their previous pool experiences and their expectations for the sessions, any bowel or bladder problems, use of any assistive or adaptive equipment, and medications.

## Exercise Interventions Using an Aquatic Environment

### Stretching Exercises

Patients may tolerate immersed stretching exercises better than land stretching because of the effects of relaxation, soft tissue warming, and ease of positioning.<sup>1,21,33,82</sup> However, buoyancy creates an inherently less stable environment than the land. Therefore, careful consideration is warranted when recommending aquatic stretching.

### Manual Stretching Techniques

Manual stretching is typically performed with the patient supine in waist depth water with buoyancy devices at the neck, waist, and feet. Alternatively, the patient may be seated on steps. The buoyancy-supported supine position improves (versus land techniques) both access to the patient and control by the practitioner, as well as the position of the patient.

However, turbulence from wave activity can adversely affect both the patient's and the practitioner's ability to perform manual stretching. Difficulties may be experienced maintaining and perceiving the subtleties of end-range stretching and scapular stabilization in the supine buoyancy supported position. Anecdotal evidence indicates that careful consideration of all factors is warranted prior to initiating manual stretching in an aquatic environment.<sup>5,69</sup>

The manual stretching techniques described in this section are considered passive techniques but may be adapted to utilize muscle inhibition techniques. The principles of stretching are the same as those discussed in Chapter 4.

The following terms are used to describe the stretching techniques:

- **Practitioner position.** Describes the orientation of the practitioner to the patient.
- **Patient position.** Includes buoyancy-assisted (BA) seated or upright positioning and buoyancy-supported (BS) supine positioning.
- **Hand placement.** The fixed hand, which stabilizes the patient, is typically the same (ipsilateral) hand as the patient's affected extremity, and it is positioned proximally on the affected extremity. The movement hand, which guides the patient's extremity through the desired motion and applies the stretch force, is typically the opposite (contralateral) hand as the patient's affected extremity and is positioned distally.
- **Direction of movement.** Describes the motion of the movement hand.

## Spine Stretching Techniques

Cervical Spine: Flexion

### Practitioner Position

Stand at the patient's head facing caudally.

### Patient Position

BS supine without cervical collar.

### Hand Placement

Cup the patient's head with your hands, the forearms supinated and thumbs placed laterally. Alternatively, place your hands in a pronated position with the thumbs at the occiput. This results in a more neutral wrist position at end-range stretch.

### Direction of Movement

As you flex the cervical spine, the patient has a tendency to drift away from you if care is not taken to perform the motion slowly.

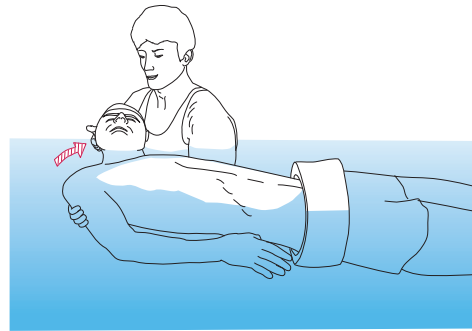

## Cervical Spine: Lateral Flexion (Fig. 9.12)

### Practitioner Position

Stand at the side facing the patient.

### Patient Position

BS supine without a cervical collar.

**FIGURE 9.12** Hand placement and stabilization for stretching to increase cervical lateral flexion.

### Hand Placement

Reach the fixed hand dorsally under the patient and grasp the contralateral arm; support the head with the movement hand.

### Direction of Movement

Move the patient into lateral flexion and apply stretch force at desired intensity. This position prevents patient drift as the fixed hand stabilizes the patient against the practitioner.

## Thoracic and Lumbar Spine: Lateral Flexion/Side Bending (Fig. 9.13)

### Practitioner Position

Stand on the side opposite that to be stretched, facing cephalad with ipsilateral hips in contact (e.g., if stretching the left side of the trunk, the therapist's right hip is against patient's right hip).

### Patient Position

BS supine, if tolerated. The patient's stretch side arm is abducted to end-range to facilitate stretch.

### Hand Placement

Grasp the patient's abducted arm with the fixed hand; alternatively, grasp at the deltoid if patient's arm is not abducted. The movement hand is at the lateral aspect of the lower extremity of the side to be stretched (more distal placement improves leverage with stretch).

**FIGURE 9.13** Hand placement and stabilization for stretching to increase lateral trunk flexion.

**Direction of Movement**

With the patient stabilized by your hip, pull the patient into lateral flexion. This technique allows variability in positioning and hand placement to isolate distinct segments of the spine.

**Shoulder Stretching Techniques****Shoulder Flexion (Fig. 9.14)****Practitioner Position**

Stand on the side to be stretched facing cephalad.

**Patient Position**

BS supine with the affected shoulder positioned in slight abduction.

**FIGURE 9.14** Hand placement and stabilization for stretching to increase shoulder flexion.

**Hand Placement**

Grasp the buoyancy belt with the fixed hand; the movement hand is at the elbow of the affected extremity.

**Direction of Movement**

After positioning the arm in the desired degree of abduction, direct the arm into flexion and apply the stretch force with the movement hand.

**Shoulder Abduction****Practitioner Position**

Stand on the affected side facing cephalad with your hip in contact with the patient's hip.

**Patient Position**

BS supine.

**Hand Placement**

Stabilize the scapula with the fixed hand; the movement hand grasps medially on the affected elbow joint.

**Direction of Movement**

Guide the arm into abduction and apply the stretch force. The hip contact provides additional stabilization as the stretch force is applied.

**Shoulder External Rotation****Practitioner Position**

Stand lateral to the affected extremity facing cephalad.

**Patient Position**

BS supine; position arm in desired degree of abduction with elbow flexed to 90°.

**Hand Placement**

Grasp the medial side of the patient's elbow with the palmar aspect of the fixed hand while fingers hold laterally; grasp the midforearm with the movement hand.

**Direction of Movement**

Movement hand guides forearm dorsally to externally rotate the shoulder and apply stretch force.

**Shoulder Internal Rotation****Practitioner Position**

Stand lateral to the patient's affected extremity facing caudally.

**Patient Position**

BS supine; position arm in desired degree of abduction with elbow flexed to 90°.

**Hand Placement**

Stabilize the scapula with the dorsal aspect of the fixed hand entering from the axilla; the movement hand is at the distal forearm.

**Direction of Movement**

Direct the forearm palmarward and apply the stretch force. Use care to observe the glenohumeral joint to avoid a forward thrust and substitution.

**Hip Stretching Techniques****Hip Extension****Practitioner Position**

Kneel on one knee at the patient's affected side.

**Patient Position**

BS supine with the hip extended and the knee slightly flexed.

**Hand Placement**

Stabilize the patient's affected extremity by hooking the top of the foot with your ipsilateral thigh. Grasp the buoyancy belt with the movement hand and guide the motion with the fixed hand on the knee.

**Direction of Movement**

Direct the patient caudally with the movement hand. To increase the stretch on the rectus femoris, lower the patient's knee in the water. Motion is performed slowly to limit spinal and pelvic substitution.

**Hip External Rotation****Practitioner Position**

Face the lateral aspect of the patient's thigh with your ipsilateral arm under the patient's flexed knee.

**Patient Position**

BS supine; hip flexed 70° and knee flexed 90°.

**Hand Placement**

Grasp the buoyancy belt with the contralateral (fixed) hand while the ipsilateral (movement) hand grasps the thigh.

**Direction of Movement**

Externally rotate hip with the movement hand as the patient's body lags through water to create stretch force.

**Hip Internal Rotation****Practitioner Position**

Face the lateral aspect of the involved thigh with the ipsilateral arm under the flexed knee.

**Patient Position**

BS supine, hip flexed 70° and knee flexed 90°.

**Hand Placement**

Stabilize the buoyancy belt with the contralateral (fixed) hand while grasping the thigh with the ipsilateral (movement) hand.

**Direction of Movement**

Internally rotate the hip as the patient's body lags through water to create the stretch force.

**Knee Stretching Techniques****Knee Extension With Patient on Steps****Practitioner Position**

Half-kneel lateral to the affected knee with the ankle of the affected extremity resting on your thigh.

**Patient Position**

Semi-reclined on pool steps.

**Hand Placement**

Place one hand just proximal and one just distal to the knee joint.

**Direction of Movement**

Extend the patient's knee.

**Knee Flexion With Patient on Steps****Practitioner Position**

Half-kneel lateral to the affected knee.

**Patient Position**

Semi-reclined on pool steps.

**Hand Placement**

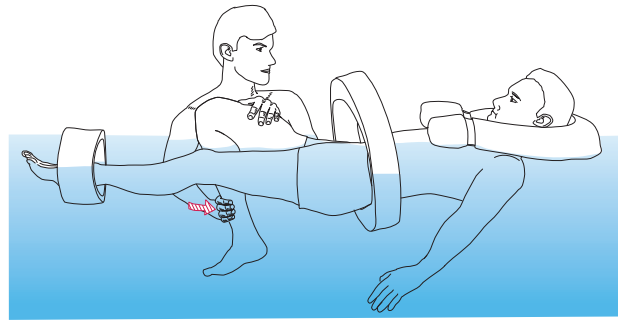

Grasp the distal tibia with the ipsilateral hand; the contralateral hand stabilizes the lateral aspect of affected knee.

**Direction of Movement**

The stretch force into flexion.

**Knee Flexion With Patient Supine (Fig. 9.15)****Practitioner Position**

Half-kneel lateral to the affected knee with the dorsal aspect of the patient's foot hooked under the ipsilateral thigh.

**FIGURE 9.15** Hand placement and stabilization for stretching to increase knee flexion.

**Patient Position**

BS supine, affected knee flexed.

**Hand Placement**

Place the ipsilateral (fixed) hand on distal tibia and the contralateral (movement) hand on buoyancy belt to pull the body over the fixed foot.

**Direction of Movement**

Pull the patient's body over the fixed foot, creating the stretch to increase knee flexion. Lower the patient's knee into the water to extend the hip and increase the stretch on the rectus femoris. Perform the motion slowly to limit spinal and pelvic substitution.

**Hamstrings Stretch****Practitioner Position**

Face the patient and rest the patient's affected extremity on your ipsilateral shoulder.

**Patient Position**

BS supine, knee extended.

**Hand Placement**

Place both hands at distal thigh.

**Direction of Movement**

Start in the squatting position and gradually stand to flex the hip and apply the stretch force. Maintain knee extension by pulling the patient closer and increasing the stretch.

**Self-Stretching With Aquatic Equipment**

Often the intervention plan is to instruct the patient to perform independent stretching.<sup>12,16,71,75</sup> Self-stretching can be performed in either waist-deep or deep water. The patient frequently utilizes the edge of the pool for stabilization in both waist-deep and deep water.

Applying buoyancy devices may assist with stretching and increase the intensity of the aquatic stretch.<sup>82</sup> However, buoyancy devices are not required to achieve BA stretching—that is, as buoyancy acts on any submersed extremity, correct patient positioning adequately produces a gentle stretch. The

following guidelines describe the use of equipment for mechanical stretching; the descriptions apply similarly for use without buoyancy equipment. Providing verbal cueing and visual demonstration for patient positioning and form aids in achieving the desired stretching effects.

Positioning for self-stretching of every body part is not described in this section. Typically, positioning for immersed self-stretches reflects traditional land positioning.

The following terms are used to describe the self-stretching techniques:

- *Patient position.* Includes BA (seated/upright), BS (supine), or vertical.
- *Buoyancy-assisted.* Using the natural buoyancy of water to “float” the extremity toward the surface.
- *Equipment-assisted.* Includes use of buoyancy devices attached or held distally on an extremity.

The following are some examples of self-stretching.

### Shoulder Flexion and Abduction

#### Patient Position

Upright, neck level immersion.

#### Equipment

Small or large buoyant dumbbell or wrist strap.

#### Direction of Movement

Grasping the buoyant device with the affected extremity allows the extremity to float to the surface as the buoyancy device provides a gentle stretch.

### Hip Flexion (Fig. 9.16)

#### Patient Position

Upright, immersed to waist, or seated at edge of pool/on steps with hips immersed.

#### Equipment

Small buoyant dumbbell or ankle strap. For hip flexion with knee flexion, place strap/dumbbell proximal to the knee. For hip flexion with knee extension (to stretch the hamstrings), place strap/dumbbell at the ankle.

**FIGURE 9.16** Self-stretching technique to increase hip flexion (stretch the hamstrings) using aquatic equipment.

### Direction of Movement

Allow buoyancy device to float hip into flexion, applying stretch to hip extensors or hamstrings.

### Knee Extension

#### Patient Position

Seated on steps/edge of pool with knee in a position of comfort.

#### Equipment

Small dumbbell or ankle strap.

#### Direction of Movement

Allow buoyancy device to extend knee toward the surface applying stretch to increase knee extension.

### Knee Flexion

#### Patient Position

Stand immersed to waist with hip and knee in neutral position; increasing the amount of hip extension increases the stretch on the two joint knee extensors.

#### Equipment

Small dumbbell or ankle strap.

#### Direction of Movement

Allow buoyancy device to flex the knee toward the surface, applying stretch to knee extensors.

## Strengthening Exercises

By reducing joint compression, providing three-dimensional resistance, and dampening perceived pain, immersed strengthening exercises may be safely initiated earlier in the rehabilitation program than traditional land strengthening exercises.<sup>76,82</sup> Both manual and mechanical immersed strengthening exercises typically are done in waist-deep water. However, some mechanical strengthening exercises may also be performed in deep water. Frequently, immersion alters the mechanics of active motion. For example, the vertical forces of buoyancy support the immersed upper extremity and alter the muscular demands on the shoulder girdle.<sup>82</sup> Furthermore, studies have demonstrated that lower extremity demand is inversely related to the level of immersion during closed-chain strengthening.<sup>6,7</sup>

### Manual Resistance Exercises

Application of aquatic manual resistance exercises for the extremities typically occurs in a concentric, closed-chain fashion.<sup>5,69</sup> Manual aquatic resistance exercises are designed to fixate the distal segment of the extremity as the patient contracts the designated muscle group(s). The practitioner's hands provide primary fixation and guidance during contraction. As the patient contracts his or her muscles, the body moves over or away from the fixed distal segment (generally over the fixed segment for the lower extremity and away from

the fixed segment for the upper extremity). The patient's movement through the viscous water generates resistance, and the patient's body produces the drag forces. Verbal cueing by the practitioner is essential to direct the patient when to contract and when to relax, thereby synchronizing practitioner and patient.

Stabilization of the distal extremity segment is essential for maintaining proper form and isolating desired muscles. However, appropriate stabilization is not possible in the BS supine position for eccentric exercises or rhythmic stabilization of the extremities. The patient's body will have a tendency to tip and rotate in the water. In addition, the practitioner will have difficulty generating adequate resistance force, and the patient's body will move easily across the surface of the water with minimal drag producing inadequate counterforce to the practitioner's resistance. When supine, some motions, including horizontal shoulder adduction and abduction, should be avoided because of the difficulty the patient may have isolating proper muscle groups. Nevertheless, for many motions, the aquatic environment allows closed-chain resistive training through virtually limitless planes of motion.

The following terms refer to manual resistance exercise in water.

- **Practitioner position.** Describes the orientation of the practitioner to the patient.
- **Patient position.** BS in the supine position.
- **Hand placement.** The guide hand is generally the ipsilateral hand as the patient's affected extremity and typically is positioned more proximally. It directs the patient's body as muscles contract to move the body through the water. The resistance hand is generally the contralateral hand and typically is placed at the distal end of the contracting segment. More distal placement increases overall resistance.
- **Direction of movement.** Describes the motion of the patient.

## Upper Extremity Manual Resistance Techniques

### Shoulder Flexion/Extension (Fig. 9.17 A and B)

#### Practitioner Position

Face caudal, lateral to the patient's affected shoulder.

#### Patient Position

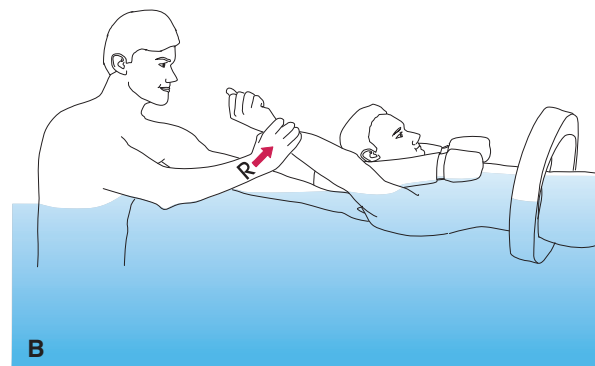

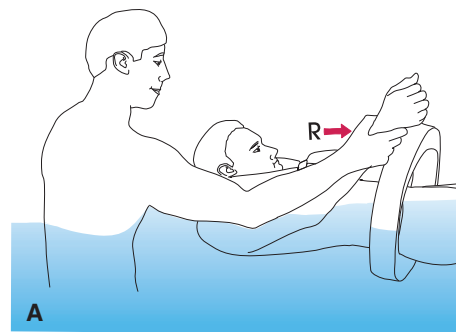

BS supine; affected extremity flexed to 30°.

#### Hand Placement

Place the palmar aspect of the guide hand at the patient's acromioclavicular joint. The resistance hand grasps the distal forearm. An alternative placement for the resistance hand may be the distal humerus; this placement alters muscle recruitment.

#### Direction of Movement

Active shoulder flexion against the resistance hand causes the body to move away from the practitioner. Active shoulder

**FIGURE 9.17** Manual resistance exercise for strengthening shoulder flexion; (A) start position and (B) end position.

extension from a flexed position causes the body to glide toward the practitioner.

**NOTE:** The patient must be able to actively flex through 120° for proper resistance to be provided.

## Shoulder Abduction

### Practitioner Position

Face medially, lateral to the patient's affected extremity.

### Patient Position

BS supine; affected extremity in neutral.

### Hand Placement

Place the palmar aspect of guide hand at the proximal humerus as the thumb wraps anteriorly and the fingers wrap posteriorly. Place the resistance hand at the lateral aspect of distal humerus.

### Direction of Movement

The practitioner determines the amount of external rotation and elbow flexion. Active abduction against the resistance hand causes the body to glide away from the affected extremity and the practitioner.

## Shoulder Internal/External Rotation (Fig. 9.18 A and B)

### Practitioner Position

Face medially on the lateral side of the patient's affected extremity.

**FIGURE 9.18** Manual resistance exercise for strengthening shoulder external rotation; (A) start position and (B) end position.

#### Patient Position

BS supine; affected extremity's elbow flexed to 90° with the shoulder in the desired amount of abduction and initial rotation.

#### Hand Placement

Place the palmar aspect of the guide hand at the lateral aspect of the elbow. The resistance hand grasps the palmar aspect of the distal forearm. An alternative method requires the practitioner to “switch” hands. The practitioner's ipsilateral hand becomes the guide hand and grasps the buoyancy belt laterally. The practitioner's contralateral hand becomes the resistance hand. This approach allows improved stabilization; however, the practitioner loses contact with the patient's elbow and must cue the patient to maintain the desired degree of shoulder abduction during the exercise.

#### Direction of Movement

Active internal rotation by the patient against the resistance hand causes the body to glide toward the affected extremity; active external rotation causes the body to glide away from the affected extremity.

### Unilateral Diagonal Pattern: D<sub>1</sub> Flexion/Extension of the Upper Extremity

#### Practitioner Position

Stand lateral to the patient's unaffected extremity and face medially and caudally.

#### Patient Position

BS supine; affected extremity internally rotated and pronated with slight forward flexion.

#### Hand Placement

Secure the medial and lateral epicondyles of the distal humerus with the guide hand. Place the resistance hand on the dorsal surface of the distal forearm.

#### Direction of Movement

Prior to contraction, cue the patient to execute the specific joint motions expected in the diagonal patterns. Active contraction through the D<sub>1</sub> flexion pattern causes the body to glide away from the practitioner. At the end position of D<sub>1</sub>, secure the medial and lateral epicondyles of the distal humerus with the guide hand. The resistance hand will be on the palmar aspect of the distal forearm. From the flexed position, the practitioner cues the patient to contract through the D<sub>1</sub> extension pattern.

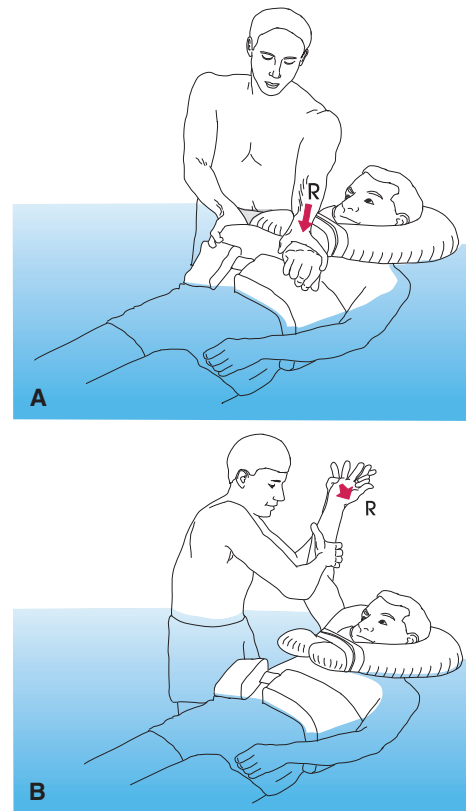

### Unilateral Diagonal Pattern: D<sub>2</sub> Flexion/Extension of the Upper Extremity (Fig. 9.19 A and B)

#### Practitioner Position

Stand lateral to the patient's affected shoulder; face medially and caudally.

#### Patient Position

BS supine; affected extremity adducted and internally rotated.

**FIGURE 9.19** Manual resistance exercise for upper extremity unilateral diagonal D<sub>2</sub> flexion pattern; (A) start position and (B) end position.

**Hand Placement**

Secure the medial and lateral epicondyles of the distal humerus with the guide hand. Wrap the palmar aspect of the resistance hand on the dorsal wrist medial to the palmar surface.

**Direction of Movement**

Active movement through the D<sub>2</sub>flexion pattern causes the body to glide away from the practitioner. From the fully flexed position, cue the patient to then move into the D<sub>2</sub>extension pattern. This causes the body to glide toward the practitioner.

**Bilateral Diagonal Pattern: D<sub>2</sub>Flexion/Extension of the Upper Extremities (Fig. 9.20 A and B)****Practitioner Position**

Stand cephalad to patient, facing caudally.

**Patient Position**

BS supine; upper extremities adducted and internally rotated.

**Hand Placement**

Use both hands to provide resistance. Grasp the dorsal aspect of each of the patient's wrists, wrapping medially to the palmar surface.

**Direction of Motion**

Active contraction through the D<sub>2</sub>flexion pattern causes the body to glide away from the practitioner. From the fully flexed position, cue the patient to contract through D<sub>2</sub>extension, causing the patient to move toward the practitioner.

**FIGURE 9.20** Manual resistance exercise for upper extremity bilateral diagonal D<sub>2</sub> pattern; (A) start position and (B) end position.

**Lower Extremity Manual Resistance Techniques****Hip Adduction****Practitioner Position**

Stand lateral to the patient's affected extremity and face medially.

**Patient Position**

BS supine; hip abducted.

**Hand Placement**

Place the guide hand on the buoyancy belt and the resistance hand on the patient's medial thigh.

**Direction of Movement**

Active contraction of the hip adductors causes the affected leg to adduct as the contralateral leg and body glides toward the affected leg and the practitioner.

**Hip Abduction (Fig. 9.21)****Practitioner Position**

Stand lateral to patient's affected extremity, facing medially.

**Patient Position**

BS supine; hip adducted.

**Hand Placement**

Place the guide hand on the buoyancy belt or lateral thigh and the thumb and base of the resistance hand on the patient's lateral leg.

**Direction of Movement**

Active contraction of the hip abductors causes the affected leg to abduct as the contralateral leg and body glide away from the affected leg and the practitioner.

**FIGURE 9.21** Manual resistance exercise for strengthening hip abduction with resistance applied to lateral aspect of the leg.

**Hip Flexion With Knee Flexion (Fig. 9.22)****Practitioner Position**

Stand at the side of the patient's affected extremity, facing cephalad.

**FIGURE 9.22** Manual resistance exercise for strengthening hip and knee flexion.

### Patient Position

BS supine.

### Hand Placement

Place the guide hand on the buoyancy belt or lateral hip. The resistance hand grasps proximal to the distal tibiofibular joint.

### Direction of Movement

Active contraction of the hip and knee flexors causes the patient's body to glide toward the practitioner and fixed distal extremity.

## Hip Internal/External Rotation

### Practitioner Position

Stand lateral to the patient's affected extremity, facing medially.

### Patient Position

BS supine; hip in neutral at 0° extension with knee flexed to 90°.

### Hand Placement

Contact the distal thigh medially with the guide hand for resisted internal rotation and laterally for resisted external rotation. Place the resistance hand at the distal leg.

### Direction of Movement

Active contraction of hip rotators (alternating between internal and external rotation) causes the patient's body to glide away from the distal fixed segment.

**PRECAUTION:** Avoid this exercise for patients with possible medial or lateral knee joint instability.

## Knee Extension

### Practitioner Position

Stand at the patient's feet, facing cephalad.

### Patient Position

BS supine.

### Hand Placement

Place the guide hand at the patient's lateral thigh and the resistance hand on the dorsal aspect of the distal tibiofibular joint.

## Direction of Movement

Active contraction of the quadriceps against the practitioner's resistance hand directs the body away from the practitioner as the knee extends.

## Ankle Motions

### Practitioner Position

Stand lateral to the affected leg, facing caudally.

### Patient Position

BS supine.

### Hand Placement

The hand placement creates a short lever arm at the patient's ankle. As the patient moves through the resisted ankle motions, the patient's entire body moves through the water, producing a significant amount of drag and demand on the ankle complex.

**PRECAUTION:** For patients with ligamentous laxity and unstable ankles or compromised ankle musculature, the practitioner should cue the patient to avoid maximum effort during contraction to avoid potential injury.

## Ankle Dorsiflexion and Plantarflexion

### Hand Placement

Place the guide hand on the lateral aspect of the leg and the resistance hand over the dorsal aspect of the foot to resist dorsiflexion and on the plantar aspect to resist plantarflexion.

### Direction of Movement

The body moves toward the practitioner during dorsiflexion and away from the practitioner during plantarflexion.

## Ankle Inversion and Eversion

### Hand Placement

Place the guide hand on the lateral aspect of the lower leg during inversion and on the medial aspect of tibia during eversion. To resist inversion, grasp the dorsal medial aspect of the foot and to resist eversion grasp the lateral foot.

### Direction of Movement

During inversion, the body glides toward the practitioner, and during eversion, the body glides away from the practitioner.

## Dynamic Trunk Stabilization

By applying concepts utilized for spinal stabilization exercises on land (see Chapters 15 and 16), the practitioner can challenge the dynamic control and strength of the trunk muscles in the aquatic environment. The BS supine position creates a unique perceptual environment for the patient.

### Dynamic Trunk Stabilization: Frontal Plane (Fig. 9.23)

#### Practitioner Position

Hold the patient at the shoulders or feet.

**FIGURE 9.23** Isometric trunk stabilization exercise using side-to-side motions of the trunk.

### Patient Position

Typically, the patient is placed in a supine position with buoyancy devices at the neck, waist, and legs.

### Execution

Have the patient identify his or her neutral spine position, perform a “drawing-in maneuver” (see Chapter 16), and maintain the spinal position (isometric abdominal contraction). Move the patient from side to side through the water; monitor and cue the patient to avoid lateral trunk flexion, an indication that the patient is no longer stabilizing the spine.

### Intensity

Moving the patient through the water faster increases drag and exercise intensity. Holding the patient more distally increases exercise intensity.

## Dynamic Trunk Stabilization: Multidirectional

### Practitioner Position

Stand at the shoulders or feet of the patient and grasp the patient’s extremity to provide fixation as the patient contracts.

### Patient Position

Typically, the patient is placed in a supine position with buoyancy devices at the neck, waist, and legs.

### Execution

Instruct the patient to assume a neutral spine, perform the drawing-in maneuver, and “hold” the spine stable. Instruct the patient to perform either unilateral or bilateral resisted extremity patterns while maintaining a neutral spine and abdominal control. Monitor and cue the patient to avoid motion at the trunk, an indication that the patient is no longer stabilizing with the deep abdominal and global muscles. Upper extremity motions include shoulder flexion, abduction, and diagonal patterns. Lower extremity motions include hip and knee flexion and hip abduction and adduction.

### Intensity

Unilateral patterns are more demanding than bilateral patterns. Increasing speed or duration increases exercise intensity.

## Independent Strengthening Exercises

Often patients perform immersed strengthening exercises independently. Because the resistance created during movement through water is speed dependent, patients are able to control the amount of work performed and the demands imposed on contractile elements.<sup>2,16,38</sup> Typically, positioning and performance of equipment-assisted strengthening activities in water reflect that of traditional land exercise. However, the aquatic environment allows patients to assume many positions (supine, prone, side-lying, seated, and vertical). Attention to specific patient positioning allows the practitioner to utilize the buoyant properties of water and/or the buoyant and resistive properties of equipment that can either assist or resist patient movement.<sup>2,14,16,62</sup> Before initiating immersed strengthening activities, patients should be oriented to the effects of speed and surface area on resistance. Specific exercises for mechanical strengthening of every body part are not described. Only selected exercises are discussed and illustrated to reinforce major concepts and principles of application.

The following terms are used for equipment-assisted exercise.

- Buoyancy-assisted: Vertical movement directed parallel to vertical forces of buoyancy that assist motion (patient may use buoyant equipment to assist with motion).
- Buoyancy-supported: Horizontal movement with vertical forces of buoyancy eliminating or minimizing the need to support an extremity against gravity (patient may use buoyant equipment to assist with motion).
- Buoyancy-resisted: Movement directed against or perpendicular to vertical forces of buoyancy, creating drag (performed without equipment).
- Buoyancy-superresisted: Use of equipment generates resistance by increasing the total surface area moving through water by creating greater drag. Increasing the speed of motion through water generates further drag.

## Extremity Strengthening Exercises (Fig. 9.24 A, B, C, D, and E)

The most common aquatic upper and lower extremity strengthening exercises are outlined in Table 9.1.<sup>2,16</sup> Typically, patients are positioned standing immersed to shoulder level for upper extremity strengthening and to midtrunk level for lower extremity strengthening. However, many exercises may be performed with the patient positioned vertically in deep water. The prone or supine position is useful when practitioners wish to progress patients or when patients require position-specific or sports-specific strengthening. Some exercises, most notably bilateral lower extremity diagonals, require the patient to be positioned supine, prone, or vertical in deep water.

**FIGURE 9.24** Mechanical resistance for strengthening (A) shoulder internal and external rotation, (B) elbow flexion and extension, (C) hip flexion and extension, (D) functional squatting, and (E) ankle plantarflexion.

### Lumbar Spine Strengthening

Spinal stabilization may be performed in shallow, mid-depth, or deep water levels. Typically, patients are instructed to maintain a neutral spine with the drawing-in maneuver (see Chapter 16) while performing functional activities or moving the extremities. The patient's ability to stabilize the spine can be challenged by increasing the duration of the activity, the speed or surface area moving through water, and by the addition of buoyant devices in the deep water. The exercises are summarized in Table 9.2.

### Trunk-Strengthening Exercises: Standing

- Have the patient hold a kickboard vertically in the water to increase resistance while walking in various patterns.

- Have the patient use unilateral or bilateral stance while performing upper extremity motions. The buoyant and turbulent forces of the water require co-contraction of the trunk muscles to stabilize the immersed body. Use equipment (Hydro-tone® bells, paddles, and resistive tubing) to increase resistance and the need for co-contraction of the trunk muscles.

### Trunk-Strengthening Exercises: Semi-Reclined

Patients may use noodles, dumbbells, or kickboards for support. The practitioner can further challenge the patient by having him or her hold buoyant equipment, such as paddles, and then stabilize the trunk against the movement. A variety of lower extremity movements are suggested in Table 9.2.

**TABLE 9.1** Summary of Motions Used for Upper and Lower Strengthening Exercises

Shoulder	Flexion/extension
	Abduction/adduction
	Horizontal abduction/adduction
	Internal/external rotation
	Unilateral diagonals
Elbow	Flexion/extension
	Diagonals
	Push/pull
Hip	Flexion/extension
	Abduction/adduction
	Internal/external rotation
	Unilateral diagonals
	Bilateral diagonals
Knee	Flexion/extension
	Diagonals

### Trunk-Strengthening Exercises: Supine

Various swimming kicks are used in the supine position. Instruct the patient to concentrate on the drawing-in maneuver and on maintaining the neutral spine position while moving the legs. Bridging while maintaining a neutral spine can be done with a long dumbbell placed at the knees.

### Trunk-Strengthening Exercises: Prone

In the prone position, various swimming kicks, such as the flutter kick, are used while the patient performs the drawing-in maneuver and maintains a neutral spine.

### Trunk-Strengthening Exercises in Deep Water

Stabilization exercises performed in deep water with the patient positioned vertically typically require the patient to brace with the abdominal muscles.<sup>68,80</sup> Emphasize identifying the neutral spine, activating the drawing-in maneuver, and holding the spine in the stable position while performing the various activities. Utilize any combination of unilateral or bilateral upper and/or lower extremity motions to further challenge the stabilization effort. Add equipment devices to the hands or legs for additional resistance and increased challenge when the patient can maintain good stabilization control. Variations include:

- Altering trunk positions such as the pike position or the iron-cross position.

**TABLE 9.2** Summary of Lumbar Spine-Strengthening Exercises

Standing	Walking patterns: forward, backward, lateral, lunge walk, high stepping
	Unilateral/bilateral stance with upper extremity motions
Semi-reclined	Bicycling
	Hip abduction/adduction
	Flutter kick
Supine	Bilateral lower extremity proprioceptive neuromuscular facilitation patterns
	Unilateral/bilateral hip and knee flexion/extension
Prone	Bridging with long dumbbell placed at knees
	Swimming kicks
Deep water	Swimming kicks
	Vertical stabilization exercises; abdominal bracing with arm and leg motions in the pike and iron-cross positions
	Seated on dumbbell; abdominal bracing and balance while performing unilateral or bilateral arm motions
	Standing on a kickboard or dumbbell; abdominal bracing and balance while performing bicycling motions and/or arm motions

- Sitting on a dumbbell and bicycling forward or backward or moving the upper extremities through any combination of motions.
- Standing on a kickboard or dumbbell and moving the upper extremities through various combinations of motions, first without and then with equipment. Such standing activities typically induce obligatory abdominal bracing and challenges to balance.

## Aerobic Conditioning

Aquatic exercise that emphasizes aerobic/cardiovascular conditioning can be an integral component of many rehabilitation programs.<sup>58,81</sup> Aerobic/cardiovascular exercise typically takes place with the patient suspended vertically in deep water pools without the feet touching the pool bottom. Alternative

activities that may be performed in midlevel water, 4 to 6 feet in depth, include jogging, swimming strokes, immersed cycling, and immersed treadmill. Understanding the various treatment options, physiological responses, monitoring methods, proper form, and equipment selection allows the clinician to use this form of exercise effectively and safely in a rehabilitation program.

## Treatment Interventions

**Deep-water walking/running (Fig. 9.25).** Deep water walking and running are the most common vertical deep-water cardiovascular endurance exercises. Alternatives include cross-country motions and high-knee marching. Deep-water cardiovascular training, which may be used as a precursor to midwater or land-based cardiovascular training, eliminates the effects of impact on the lower extremities and spine.

The patient can be tethered to the edge of the pool to perform deep-water running in those pools with limited space. Some small tanks provide resistance jets for the patient to move against.

**FIGURE 9.25** Deep-water walking/jogging. (Courtesy of Rothhammer International, Inc., San Luis Obispo, CA.)

**Mid-water jogging/running (immersed treadmill running).** Midwater aerobic exercise, which may be used as a precursor to land training, lessens the effects of impact on the spine and lower extremities. As a patient's tolerance to impact improves, midwater jogging may be performed in progressively shallower depths to provide increased weight bearing and functional replication. In pools with

limited space, tethering with resistive tubing can provide resistance.

**Immersed equipment.** Immersed equipment includes an immersed cycle, treadmill, or upper body ergometer.

**Swimming strokes.** For patients able to tolerate the positions necessary to perform various swim strokes (neck and shoulder ROM and prone, supine, or side-lying positions), swimming can be an excellent tool to train and improve cardiovascular fitness. Swimming may elicit significantly higher elevations of heart rate, blood pressure, and  $VO_{2max}$  than other aquatic activities. Swimming contributes the added benefit of hip and trunk strengthening for some patients with spinal conditions.

**PRECAUTION:** Recommending swimming for poorly skilled swimmers with cardiac compromise may adversely challenge the patient's cardiovascular system.

## Physiological Response to Deep-Water Walking/Running

Various physiological responses to deep-water walking and running have been reported.<sup>3,17,28,36,37,64</sup>

**Cardiovascular response.** Patients without cardiovascular compromise may experience dampened elevation of heart rate, ventilation, and  $VO_{2max}$  compared to similar land-based exercise. During low-intensity exercise, cardiac patients may experience lower cardiovascular stresses.<sup>55</sup> As exercise intensity increases, cardiovascular stresses approach those of related exercise on land.<sup>6,77</sup>

**Training effect.** Patients experience carryover gains in  $VO_{2max}$  from aquatic to land conditions.<sup>43</sup> Additionally, aquatic cardiovascular training maintains leg strength and maximum oxygen consumption in healthy runners.<sup>36,37,47</sup>

## Proper Form for Deep-Water Running

**Instruction for beginners.** Proper instruction is important to ensure correct form because many beginners experience a significant learning curve.<sup>12</sup> Once immersed, the patient should maintain a neutral cervical spine and slightly forward flexed trunk with the arms at the sides. During running the hips should alternately flex to approximately  $80^\circ$  with the knee extended and then extend to neutral as the knee flexes.

**Accommodating specific patient populations.** For patients with positional pain associated with spinal conditions, a posterior buoyancy belt helps maintain a slightly forward flexed position, and a flotation vest helps maintain more erect posture and a relatively extended spine. Patients with unilateral lower extremity amputations may have difficulty maintaining a vertical position. Placing the buoyancy belt laterally (on the contralateral side of the amputation) allows the patient to remain vertical more easily.

## Exercise Monitoring

**Monitoring intensity of exercise.** Monitor the rate of perceived exertion and heart rate.

- **Rate of perceived exertion.** Because skill may affect technique, subjective numerical scales depicting perceived effort may inadequately identify the level of intensity for novice deep-water runners. However, at both submaximal and maximal levels of exertion, subjective numerical rating of effort appears to correlate adequately with the heart rate during immersed exercise.<sup>36</sup>
- **Heart rate.** Because of the physiological changes that occur with neck level immersion, various adjustments have been suggested in the literature to lower the immersed maximum heart rate during near-maximum cardiovascular exercise.<sup>3,17,64</sup> The suggested decreases range from 7 to 20 beats per minute.<sup>3,17,64</sup> The immersed heart rate can be reliably monitored manually or with water-resistant electronic monitoring devices.

**Monitoring beginners.** Care should be taken to monitor regularly the cardiovascular response of novice deep-water runners or patients with known cardiac, pulmonary, or peripheral vascular disease.<sup>55</sup> Novice deep-water runners may experience higher levels of perceived exertion and  $\text{VO}_{2\text{max}}$  than they would during similar land exercise.<sup>28</sup>

## Equipment Selection

**Deep water equipment.** Selection of buoyancy devices should reflect the desired patient posture, comfort, and projected intensity level. The most common buoyant device for deep-water running is the flotation belt positioned posteriorly (see Fig. 9.7). Patients presenting with injuries or sensitivity of the trunk may require an alternative buoyant device, such as vests, flotation dumbbells, or noodles. Providing the patient with smaller buoyant equipment (i.e., smaller belts, fewer noodles) requires the patient to work harder to maintain adequate buoyancy, thereby increasing the intensity of the activity. Fins and specially designed boots can be applied to the legs and feet to add resistance. Also, bells or buoyant dumbbells can be held in the hands to increase resistance (see Fig. 9.10).

**Midwater equipment.** Specially designed socks can help eliminate the potential problem of skin breakdown on the feet during impact activities, such as running. Patients can run against a forced current or tethered with elastic tubing for resistance. Using noodles around the waist or running while holding a kickboard increases the amount of drag and resistance against which the patient must move.

## Independent Learning Activities

### Case Studies

#### Postoperative Arthroscopic Knee Meniscectomy

Mike is a 54-year-old man who tore his right medial meniscus playing basketball. He is 2 weeks status postarthroscopic débridement of the torn piece of cartilage. Mike has returned to his desk job as a computer programmer but has a strong desire to return to his active workout schedule and weekend sports leagues. The surgeon has told Mike that he has no limitations except pain.

**Past Medical History:** Mike is healthy with no prior medical problems. He has never had an injury that made him miss more than a few days of sports participation.

**Functional Status:** Mike is ambulating without assistive devices, but he limps slightly because of a stiff knee. He is able to go up and down stairs but only one step at a time and has to lead with his left leg.

**Musculoskeletal Status:** Mike has only minimal swelling of the right knee. He rates his pain as a 1 out of 10 at rest and a 3 out of 10 with activity. His active knee ROM is 5° to 100°. He has normal ROM in the remaining joints of the right leg. Mike is able to perform a straight leg raise and has good quadriceps contraction. Manual muscle testing reveals 4/5 quadriceps strength and 4/5 hamstring

and gastrocnemius strength. He has good patellofemoral joint mobility.

**Physician Referral:** The prescription Mike's physician gave him states, "Evaluate and treat right knee, S/P arthroscopic meniscal débridement; may utilize land and aquatic exercise for ROM and strength."

- Formalize a program to utilize the shallow water (4-ft depth) to start Mike with independent exercises for strength and flexibility.
- Describe what manual techniques you might be able to perform with Mike for strength or flexibility.
- As Mike progresses to full ROM and near-normal strength, how could you use aquatics to replicate the demands of basketball?
- What can Mike do in the pool to maintain his cardiovascular fitness while his knee heals?

#### Calf Tear

Cecily is a 30-year-old weather anchor who happens to be an elite marathon runner. Four days ago, she was running up a hill and felt a "pulling" in her left calf just distal to the knee. She decided to run in a 10K race the next day but had to quit after about 5K because of a sharp pain in her calf. The doctor has told her to use crutches and remain 25% weight bearing for the

next 3 days. After that she can gradually begin to increase the weight she puts through the leg over the next week. The doctor has told Cecily that she should be full weight bearing in 1 week and able to run in 3 weeks. Cecily is anxious to return to her intensive training schedule.

**Past Medical History:** Cecily is healthy with no prior medical problems. She has worn orthotic inserts in her shoes for “flat feet” for as long as she can remember. She says she has pulled her left calf several times during a running career that goes back to high school.

**Functional Status:** Cecily enters the facility ambulating with crutches. She is putting about 25% of her weight through her left foot. She is able to perform stairs without difficulty using the crutches and/or a railing.

**Musculoskeletal Status:** Cecily has a visible bruise at the medial head of the left gastrocnemius muscle belly. She is very tender to palpation there and has some swelling. She rates her pain at rest as 1 on a 10-point scale and her pain with activity as 2. Her ankle ROM is normal for all motions actively and passively with the exception of dorsiflexion. She dorsiflexes actively 5° and passively 8°. You grade her ankle strength as 5/5 except for plantarflexion, which you grade as a 4/5; this may be limited due to pain. You also notice that her left hip flexors, quadriceps, and hamstrings are all tight.

**Physician Referral:** The prescription that Cecily’s doctor gives her states, “Aquatic therapy; evaluate and treat for left calf strain: gait training, ROM, strength. Progress to land as tolerated.”

- Write up a program to address Cecily’s dysfunctions and impairments utilizing the aquatic environment.
- At what depth of midwater does Cecily need to be to gait train in the water and still maintain 25% weight bearing?
- Write up a program for the deep water to help Cecily maintain her high level of cardiovascular fitness.
- What equipment might be useful to assist her with independent stretching in the deep water and for cardiovascular training in the deep water?

### Chronic Low Back Pain

Develop an aquatic program for a patient who has chronic low back pain and needs a comprehensive flexibility and strengthening program for the legs and trunk. The patient has only one visit approved by the insurance company. However, the patient has a pool in his or her back yard that gradually goes from 3 feet to 7 feet in depth. The 7-foot deep area is only 10 feet long and 5 feet wide. The patient has no other medical problems that would limit his or her performance of the aquatic program.

## Independent Learning Activities 334

The effective use of therapeutic exercise in the management of musculoskeletal disorders depends on sound clinical reasoning based on the best evidence available that supports the selection of the treatment interventions. Examination of the involved region is an important prerequisite to identify the impairments that are limiting or may be preventing full participation in desired activities. It is also important during the examination process to determine whether the tissues involved are in the acute, subacute, or chronic stage of recovery so that the type and intensity of exercises do not interfere with recovery but can most effectively facilitate healing for maximum return of functioning and prevention of further problems. This chapter and subsequent chapters in this book have been written with the assumption that the reader has a foundation of knowledge and skills in examination, evaluation, and program planning for orthopedically related problems in order to make effective choices of exercises that will meet the goals.

Utilizing the principles presented in this chapter, the reader should be able to design therapeutic exercise programs and choose techniques for intervention that are at an appropriate intensity for the stage of healing of connective tissue disorders. Specific joint, soft tissue, bony, and nerve lesions, as well as common surgical interventions, are presented in the remaining chapters.

## Soft Tissue Lesions

### Examples of Soft Tissue Lesions: Musculoskeletal Disorders

- Strain: Overstretching, overexertion, or overuse of soft tissue; tends to be less severe than a sprain, occurs from slight trauma or unaccustomed repeated trauma of a minor degree.<sup>4</sup> This term is frequently used to refer specifically to some degree of disruption of the musculotendinous unit.<sup>13</sup>
- Sprain: Severe stress, stretch, or tear of soft tissues, such as joint capsule, ligament, tendon, or muscle. This term is frequently used to refer specifically to injury of a ligament and is graded as a first (mild), second (moderate), or third (severe) degree sprain.<sup>13</sup>
- Dislocation: Displacement of a part, usually the bony partners in a joint, resulting in loss of the anatomical relationship and leading to soft tissue damage, inflammation, pain, and muscle spasm.
- Subluxation: An incomplete or partial dislocation of the bony partners in a joint that often involves secondary trauma to surrounding soft tissue.
- Muscle/tendon rupture or tear: If a rupture or tear is partial, pain is experienced in the region of the breach when the muscle is stretched or when it contracts against resistance.

If a rupture or tear is complete, the muscle does not pull against the injury, so stretching or contraction of the muscle does not cause pain.<sup>6</sup>

- **Tendinopathy/tendinous lesions:** *Tendinopathy* is the general term that refers to tendon injury affected by mechanical loading.<sup>23,26</sup> *Tenosynovitis* is inflammation of the synovial membrane covering a tendon. *Tendinitis* is inflammation of a tendon; there may be resulting scarring or calcium deposits. *Tenovaginitis* is inflammation with thickening of a tendon sheath. *Tendinosis* is degeneration of the tendon due to repetitive microtrauma.
- **Synovitis:** Inflammation of a synovial membrane; an excess of normal synovial fluid in a joint or tendon sheath caused by trauma or disease.
- **Hemarthrosis:** Bleeding into a joint, usually due to severe trauma.
- **Ganglion:** Ballooning of the wall of a joint capsule or tendon sheath. Ganglia may arise after trauma, and they sometimes occur with rheumatoid arthritis.
- **Bursitis:** Inflammation of a bursa.
- **Contusion:** Bruising from a direct blow, resulting in capillary rupture, bleeding, edema, and an inflammatory response.
- **Overuse syndromes, cumulative trauma disorders, and repetitive strain injury:** Repeated, submaximal overload and/or frictional wear to a muscle or tendon resulting in inflammation and pain.

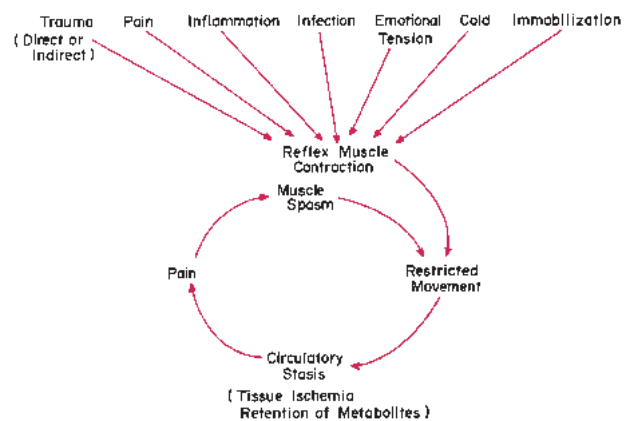

## Clinical Conditions Resulting From Trauma or Pathology

In many conditions involving soft tissue, the primary pathology is difficult to define or the tissue has healed with limitations, resulting in secondary loss of function. The following are examples of clinical manifestations resulting from a variety of causes, including those listed under the previous section.

- **Dysfunction:** Loss of normal function of a tissue or region. The dysfunction may be caused by adaptive shortening of the soft tissues, adhesions, muscle weakness, or any condition resulting in loss of normal mobility.
- **Joint dysfunction:** Mechanical loss of normal joint play in synovial joints; commonly causes loss of function and pain. Precipitating factors may be trauma, immobilization, disuse, aging, or a pathological condition such as rheumatoid arthritis.
- **Contracture:** Adaptive shortening of skin, fascia, muscle, or a joint capsule that prevents normal mobility or flexibility of that structure.
- **Adhesion:** Abnormal adherence of collagen fibers to surrounding structures during immobilization, after trauma, or as a complication of surgery, which restricts normal elasticity and gliding of the structures involved.
- **Reflex muscle guarding:** Prolonged contraction of a muscle in response to a painful stimulus. The primary pain-causing lesion may be in nearby or underlying tissue, or it may be a referred pain source. When not referred, the contracting muscle functionally splints the injured tissue

against movement. Guarding ceases when the painful stimulus is relieved.

- **Intrinsic muscle spasm:** Prolonged contraction of a muscle in response to the local circulatory and metabolic changes that occur when a muscle is in a continued state of contraction. Pain is a result of the altered circulatory and metabolic environment, so the muscle contraction becomes self-perpetuating regardless of whether the primary lesion that caused the initial guarding is still irritable (Fig. 10.1). Spasm may also be a response of muscle to viral infection, cold, prolonged periods of immobilization, emotional tension, or direct trauma to muscle.

**FIGURE 10.1** Self-perpetuating cycle of muscle spasm.

- **Muscle weakness:** A decrease in the strength of muscle contraction. Muscle weakness may be the result of a systemic, chemical, or local lesion of a nerve of the central or peripheral nervous system or the myoneural junction. It may also be the result of a direct insult to the muscle or simply due to inactivity.
- **Myofascial compartment syndromes:** Increased interstitial pressure in a closed, nonexpanding, myofascial compartment that compromises the function of the blood vessels, muscles, and nerves. It results in ischemia and irreversible muscle loss if there is no intervention.<sup>11</sup> Causes include, but are not limited to, fractures, repetitive trauma, crush injuries, skeletal traction, and restrictive clothing, wraps, or casts.

## Severity of Tissue Injury

- **Grade 1 (first degree).** Mild pain at the time of injury or within the first 24 hours. Mild swelling, local tenderness, and pain occur when the tissue is stressed.<sup>13,14</sup>
- **Grade 2 (second degree).** Moderate pain that requires stopping the activity. Stress and palpation of the tissue greatly increase the pain. When the injury is to ligaments, some of the fibers are torn, resulting in some increased joint mobility.<sup>13,14</sup>
- **Grade 3 (third degree).** Near-complete or complete tear or avulsion of the tissue (tendon or ligament) with severe

pain. Stress to the torn tissue is usually painless; palpation may reveal the defect. A torn ligament results in instability of the joint.<sup>13,14</sup>

### Irritability of Tissue: Stages of Inflammation and Repair

After any insult to connective tissue, whether it is from mechanical injury (including surgery) or chemical irritant, the vascular and cellular response is similar (Table 10.1).<sup>16</sup> Tissue irritability, or sensitivity, is the result of these responses and is typically divided into three overlapping stages of inflammation, repair, and maturation/remodeling.<sup>16,27,29</sup> The following table summarizes the clinical signs and symptoms.

#### Acute Stage (Reaction and Inflammation)

During the acute stage, the signs of inflammation develop; they are swelling, redness, heat, pain at rest, and loss of function.<sup>16</sup> When testing the range of motion (ROM), movement is painful and the patient usually guards against the motion before completion of the range is possible (Fig. 10.2 A). The pain and impaired movement are from the altered chemical state that irritates the nerve endings, increased tissue tension due to edema or joint effusion, and muscle guarding, which is the body’s way of immobilizing a painful area. This stage usually lasts 4 to 6 days unless the insult is perpetuated.

**FIGURE 10.2** Pain experienced with ROM when involved tissue is in the (A) acute stage, (B) early subacute stage, and (C) late subacute or chronic stage.

**TABLE 10.1** Stages of Tissue Healing: Characteristics, Clinical Signs, and Interventions

Acute Stage: Inflammation	Subacute Stage: Proliferation, Repair, and Healing	Chronic Stage: Maturation and Remodeling
<b>Tissue responses and characteristics</b>		
Vascular changes Exudation of cells and chemicals Clot formation Phagocytosis, neutralization of irritants Early fibroblastic activity	Removal of noxious stimuli Growth of capillary beds into area Collagen formation Granulation tissue Very fragile, easily injured tissue	Maturation of connective tissue Contracture of scar tissue Remodeling of scar Collagen aligns to stress
<b>Clinical signs</b>		
Inflammation Pain before tissue resistance	Decreasing inflammation Pain synchronous with tissue resistance	Absence of inflammation Pain after tissue resistance
<b>Physical therapy goals and interventions for phases of rehabilitation</b>		
<b>Phase I</b> Maximum Protection	<b>Phase II</b> Moderate Protection/ Controlled-Motion	<b>Phase III</b> Minimum to No Protection/ Return to Function
<i>Control effects of inflammation:</i> selective rest, ice, compression, elevation <i>Prevent deleterious effects of rest:</i> nondestructive movement: passive ROM, massage, and muscle setting with caution	<i>Develop mobile scar:</i> selective stretching, mobilization/manipulation of restrictions <i>Promote healing:</i> nondestructive active, resistive, open- and closed-chain stabilization, muscular endurance, and cardiopulmonary endurance exercises, carefully progressed in intensity and range	<i>Increase tensile quality of scar:</i> progressive strengthening and endurance exercises <i>Develop functional independence:</i> functional exercises and specificity drills

### Subacute Stage (Proliferation, Repair, and Healing)

During the subacute stage, the signs of inflammation progressively decrease and eventually are absent. When testing ROM, the patient may experience pain synchronous with encountering tissue resistance at the end of the available ROM (Fig. 10.2 B). Pain occurs only when the newly developing tissue is stressed beyond its tolerance or when tight tissue is stressed. Muscles may test weak, and function is limited as a result of the weakened tissue. This stage usually lasts 10 to 17 days (14 to 21 days after the onset of injury) but may last up to 6 weeks in some tissues with limited circulation, such as tendons.<sup>8,27,29</sup>

### Chronic Stage (Maturation and Remodeling)

There are no signs of inflammation during the chronic stage. There may be contractures or adhesions that limit range, and there may be muscle weakness limiting normal function. During this stage, connective tissue continues to strengthen and remodel in response to the stresses applied to it.<sup>7,23,27,29</sup> A stretch pain may be felt when testing tight structures at the end of their available range (Fig. 10.2C). Function may be limited by muscle weakness, poor endurance, or poor neuromuscular control. This stage may last 6 months to 1 year depending on the tissue involved and amount of tissue damage.

### Chronic Inflammation

A state of prolonged inflammation may occur if injured tissue is continually stressed beyond its ability to repair. There are symptoms of increased pain, swelling, and muscle guarding that last more than several hours after activity. There are also increased feelings of stiffness after rest, loss of ROM 24 hours after activity, and progressively greater stiffness of the tissue as long as the irritation persists.

### Chronic Pain Syndrome

Chronic pain syndrome is a state that persists longer than 6 months. It includes pain that cannot be linked to a source of irritation or inflammation resulting in activity limitations and participation restrictions that affect many parameters of function.

## Management During the Acute Stage

### Tissue Response: Inflammation

The inflammatory stage involves cellular, vascular, and chemical responses in the tissue. During the first 48 hours after insult to soft tissue, vascular changes predominate. Exudation of cells and solutes from the blood vessels takes place, and clot formation occurs. During this period, neutralization of the chemical irritants or noxious stimuli, phagocytosis (cleaning up of dead tissue), early fibroblastic activity, and formation

of new capillary beds begin. These physiological processes serve as a protective mechanism as well as a stimulus for subsequent healing and repair.<sup>16</sup> Usually this stage lasts 4 to 6 days unless the insult is perpetuated.

### Management Guidelines: Maximum Protection (Phase I)

The therapist's role during the protection phase of intervention is to control the effects of the inflammation, facilitate wound healing, and maintain normal functioning in unaffected tissues and body regions. The information provided here is summarized in Box 10.1.

### Patient Education

Inform the patient about the expected duration of symptoms (4 to 6 days), what he or she can do during this stage, any precautions or contraindications, and what to expect when the symptoms lessen. Patients need reassurance that the acute symptoms are usually short-lived, and they need to learn what is safe to do during this stage of healing.

### Protection of the Injured Tissue

To minimize musculoskeletal pain and promote healing, protection of the part affected by the inflammatory process is necessary during the first 24 to 48 hours. This is usually provided by rest (orthosis, tape, cast), cold (ice), compression, and elevation. Depending on the type and severity of the injury, manual methods of pain and edema control, such as massage and gentle (grade I) joint oscillations, may be beneficial. If a lower extremity is involved, protection with assistive devices for partial or nonweight-bearing ambulation may be required.

### Prevention of Adverse Effects of Immobility

Complete or continuous immobilization should be avoided whenever possible as it can lead to adherence of the developing fibrils to surrounding tissue, weakening of connective tissue, and changes in articular cartilage.<sup>6,24,25</sup>

A *long-term goal of treatment* is the formation of a strong, mobile scar at the site of the lesion, so there is complete and painless restoration of activities. Initially, the network of fibril formation is random. It acquires an organized arrangement depending on the mechanical forces acting on the tissue.<sup>15</sup> To influence the development of an organized scar, begin treatment during the acute stage, when tolerated, with carefully controlled *passive movements*.

**Tissue-specific movement.** Tissue-specific movements should be directed to the structure involved to prevent abnormal adherence of the developing fibrils to surrounding tissue and thus avoid future disruption of the scar. Tissue-specific techniques are described below.

**Intensity of movement.** The intensity (dosage) of movement should be gentle enough so the fibrils are not detached from the site of healing. Too much movement too soon is painful

### BOX 10.1 MANAGEMENT GUIDELINES— Acute Stage/Maximum Protection

#### Impairments of Body Structure and Function:

Inflammation, pain, edema, muscle spasm  
 Impaired movement  
 Joint effusion (if the joint is injured or if there is arthritis)  
 Restricted use of associated areas

#### Plan of Care

#### Intervention (up to 1 week postinjury)

1. Educate the patient.	1. Inform patient of anticipated recovery time and how to protect the part while maintaining appropriate functional activities.
2. Control pain, edema, and spasm.	2. Cold, compression, elevation, and massage (48 hours). Immobilize the part (rest, orthosis, tape, cast). Avoid positions of stress to the part. Gentle (grade I or II) joint oscillations with joint in pain-free position.
3. Maintain soft tissue and joint integrity and mobility.	3. Appropriate dosage of passive movements within limit of pain, specific to structure involved. Appropriate dosage of intermittent muscle setting or electrical stimulation.
4. Reduce joint swelling if symptoms are present.	4. May require medical intervention if swelling is rapid (blood). Provide protection (orthosis, cast).
5. Maintain integrity and function of associated areas.	5. Active-assistive, free, resistive, and/or modified aerobic exercises, depending on proximity to associated areas and effect on the primary lesion. Adaptive or assistive devices as needed to protect the part during functional activities.

**PRECAUTIONS:** The proper dosage of rest and movement must be used during the inflammatory stage. Signs of too much movement are increased pain or increased inflammation.

**CONTRAINDICATIONS:** Stretching and resistance exercises should not be performed at the site of the inflamed or swollen tissue.

and reinjures the tissue. The dosage of passive movement depends on the severity of the lesion. Some patients tolerate no movement during the first 24 to 48 hours; others tolerate only a few degrees of gentle passive movement. Continuous passive movement (see Chapter 3) has been useful immediately after various types of surgery to joints—intra-articular, metaphyseal, and diaphyseal fractures; surgical release of extra-articular contractures and adhesions; and other select conditions.<sup>24,25</sup> Any movement tolerated at this stage is beneficial, but it must *not* increase the inflammation or pain. Active movement is usually *contraindicated* at the site of an active pathological process unless it is a chronic disease, such as rheumatoid arthritis.

**General movement.** Active movement is appropriate in neighboring regions to maintain integrity in uninjured tissue and to aid in circulation and lymphatic flow.

**PRECAUTION:** If movement increases pain or inflammation, it is either of too great a dosage or it should not be done. Extreme care must be used with movement at this stage.

### Specific Interventions and Dosages

**Passive ROM (PROM).** PROM within the limit of pain is valuable for maintaining mobility in joints, ligaments, tendons, and muscles, as well as improving fluid dynamics and maintaining nutrition in the joints.<sup>24,25</sup> Initially, the range is probably very small.<sup>31</sup> Stretching at this stage is contraindicated. Any motion gained from the PROM techniques is because of decreased pain, swelling, and muscle guarding.

**Low-dosage joint mobilization/manipulation techniques.** Grade I or II distraction and glide techniques have the benefit of improving fluid dynamics in the joint to maintain cartilage

health. These techniques may also reflexively inhibit or gate the perception of pain. Low-dosage joint mobilizations are beneficial with joint pathologies and any other connective tissue injury that affects joint motion during the acute stage.

**Muscle setting.** Gentle isometric muscle contractions performed intermittently and at a very low intensity so as not to cause pain or joint compression have several purposes. The pumping action of the contracting muscle assists the circulation and, therefore, fluid dynamics. If there is muscle damage or injury, the setting techniques are done with the muscle in the shortened position to help maintain mobility of the actin-myosin filaments without stressing the breached tissue. If there is joint injury, the position during the setting techniques is dictated by pain; usually the resting position for the joint is most comfortable. If tolerated, the intermittent setting techniques are performed in several positions.

**Massage.** Massage serves the purpose of moving fluid, and if it is applied cautiously and gently to injured tissue, it may assist in preventing adhesions. Tendinous lesions are treated with a gentle dosage applied transverse to the fibers to smooth roughened surfaces or to maintain mobility of the tendon in its sheath. When applied, the tendon is kept taut. When treating muscle lesions, the muscle is usually kept in its shortened position so as not to separate the healing breach.<sup>6</sup> Massage to manage the effects of edema is discussed in Chapter 26.

### Interventions for Associated Areas

During the protection phase, maintain as normal a physiological state as possible in related areas of the body. Include techniques to maintain or improve the following areas.

**Range of motion.** These techniques may be done actively or passively, depending on the proximity to and the effect on the injured tissue.

**Resistance exercise.** Resistance exercises may be applied at an appropriate dosage to muscles not directly related to the injured tissue to prepare the patient for use of assistive devices, such as crutches or a walker, and to improve ability to perform needed activities.

**Functional activities.** Supportive or adaptive devices may be necessary depending on area of injury and expected activities.

### CLINICAL TIP

It is important to prevent vascular stasis, which may occur due to swelling and immobility. Circulation is helped by encouraging activities within safe parameters and by using supportive elastic wraps, elevating the part, and using appropriate massage and muscle-setting techniques. In the lower extremities, active ankle and toe ROM should be performed if possible.

## Management During the Subacute Stage

### Tissue Response: Proliferation, Repair, and Healing

During the second to fourth days after tissue injury, the inflammation begins to decrease, the clot starts resolving, and repair of the injured site begins. This usually lasts an additional 10 to 17 days (14 to 21 days after the onset of injury) but may last up to 6 weeks.

The synthesis and deposition of collagen characterize this stage. Noxious stimuli are removed, and capillary beds begin to grow into the area. Fibroblastic activity, collagen formation, and granulation tissue development increase. Fibroblasts are present in tremendous numbers by the fourth day after injury and continue in large number until about day 21.<sup>28</sup> The fibroblasts produce new collagen, and this immature collagen replaces the exudate that originally formed the clot. In addition, myofibroblastic activity begins about day 5, causing scar shrinkage (contraction).<sup>28,29</sup> Depending on the size of injury, wound closure usually takes 5 to 8 days in muscle and skin and 3 to 6 weeks in tendons and ligaments.<sup>8,29</sup>

During this stage of healing, the immature connective tissue that is produced is thin and unorganized. It is extremely fragile and easily injured if overstressed, yet proper growth and alignment can be stimulated by appropriate tensile loading in the line of normal stresses for that tissue. At the same time, adherence to surrounding tissues can be minimized.<sup>5</sup>

### Management Guidelines: Moderate Protection/Controlled Motion (Phase II)

The therapist's role during this stage of healing is critical. The patient feels much better because the pain is no longer constant, and active movement can begin. It is easy to begin too much movement too soon or, conversely, to be tempted to approach intervention cautiously and not progress rapidly enough. Understanding the healing process and tissue response to stresses underlies the critical decisions that are made throughout this phase of intervention. The key is to initiate and progress *non-destructive* exercises and activities, that is to perform exercises and activities that are within the tolerance of the healing tissues, which can then heal without re-injury or inflammation.<sup>7</sup> The information that follows is summarized in Box 10.2.

### Patient Education

Inform the patient about what to expect at this stage, the time frame for healing, and what signs and symptoms indicate that he or she is pushing beyond tissue tolerance.

- Encourage the patient to return to normal activities that do not exacerbate symptoms, but caution against participating in recreational, sports, or work-related activities at this time that would be detrimental to the healing process.

### BOX 10.2 MANAGEMENT GUIDELINES— Subacute Stage/Controlled Motion

#### Impairments of Body Structure and Function:

Pain when end of available ROM is reached  
 Edema (decreasing but may still be present)  
 Joint effusion (decreasing but may still be present if joints are involved)  
 Soft tissue, muscle, and/or joint contractures (developing in immobilized region)  
 Muscle weakness from reduced usage or pain  
 Restricted ADLs and IADLs related to involved tissues

Plan of Care	Intervention (up to 3 weeks postinjury)
1. Educate the patient.	1. Inform patient of anticipated healing time and importance of following guidelines. Teach home exercises and encourage functional activities consistent with plan; monitor and modify as patient progresses.
2. Promote healing of injured tissues.	2. Monitor response of tissue to exercise progression; decrease intensity if pain or inflammation increases. Protect healing tissue with assistive devices, orthoses, tape, or wrap; progressively increase amount of time the joint is free to move each day and decrease use of assistive device as strength in supporting muscles increases.
3. Restore soft tissue, muscle, and/or joint mobility.	3. Progress from passive to active-assistive to active ROM within limits of pain. Gradually increase mobility of scar, specific to structure involved. Progressively increase mobility of related structures if limiting ROM; use techniques specific to tight structure.
4. Develop neuromuscular control, muscle endurance, and strength in involved and related muscles.	4. Initially, progress multiple-angle isometric exercises within patient's tolerance; begin cautiously with mild resistance. Initiate AROM, protected weight bearing, and stabilization exercises. As ROM, joint play, and healing improve, progress isotonic exercises with increased repetitions. Emphasize control of exercise pattern and proper mechanics. Progress resistance later in this stage.
5. Maintain integrity and function of associated areas.	5. Apply progressive strengthening and stabilizing exercises, monitoring effect on the primary lesion. Resume low-intensity activities involving the healing tissue that do not exacerbate the symptoms.

**PRECAUTIONS:** The signs of inflammation or joint swelling normally decrease early in this stage. Some discomfort will occur as the activity level is progressed, but it should not last longer than a couple of hours. Signs of too much motion or activity are resting pain, fatigue, increased weakness, and spasm lasting beyond 24 hours.

- Teach the patient a home exercise program and help him or her adapt work and recreational activities that are consistent with intervention strategies so the patient becomes an active participant in the recovery process.
- As new exercises are introduced or as the intensity of exercises is progressed, monitor the patient's response. Exercises progressed too vigorously or activities begun too early can be injurious to the fragile, newly developing tissue and may delay recovery, cause pain, and perpetuate the inflammatory response.<sup>7,27</sup> If symptoms increase, modify the intensity of exercises.

### Management of Pain and Inflammation

Pain and inflammation decrease as healing progresses.

- Criteria for initiating active exercises and stretching during the early subacute stage include decreased swelling, pain that is no longer constant, and pain that is not exacerbated by motion in the available range.

### Initiation of Active Exercises

Because of the restricted use of the injured region, there is muscle weakness even in the absence of muscle pathology.

The subacute stage of healing is a transition period during which active exercises within the pain-free range of the injured tissue can begin and be progressed to muscular endurance and strengthening exercises with care, keeping within the tolerance of the healing tissues (nondestructive motion). If activity is kept within a safe intensity and frequency, symptoms of pain and swelling progressively decrease each day. Patient response is the best guide to how quickly or vigorously to progress. Clinically, if signs of inflammation increase or the ROM progressively decreases, the intensity of the exercise and activity must decrease, because chronic inflammation has developed and a retracting scar will become more limiting.<sup>2,3,17</sup> Signs of excessive stress with exercise or activities are highlighted in Box 10.3.

**Multiple-angle, submaximal isometric exercises.** Submaximal isometric exercises are used during the early subacute stage to initiate control and strengthening of the muscles in the involved region in a nonstressful manner. They may also help the patient become aware of using the correct muscles. The intensity and angles for resistance are determined by the absence of pain.

- To initiate isometric exercise in an injured, healing muscle, place it in the shortened or relaxed position so the new scar is not pulled from the breached site.<sup>5,27</sup>
- To initiate isometric exercises when there is joint pathology, the resting position for the joint may be the most comfortable position. The intensity of contraction should be kept below the perception of pain.

**Active ROM (AROM) exercises.** AROM activities in pain-free ranges are used to develop control of the motion.

- Initially, use isolated, single plane motions. Emphasize control of the motion using light-resistive, concentric exercises of involved muscle and muscles needed for proper joint mechanics.

### BOX 10.3 Signs of Excessive Stress With Exercise or Activities

- Exercise or activity soreness that does not decrease after 4 hours and is not resolved after 24 hours
- Exercise or activity pain that comes on earlier or is increased over the previous session
- Progressively increased feelings of stiffness and decreased ROM over several exercise sessions
- Swelling, redness, and warmth in the healing tissue
- Progressive weakness over several exercise sessions
- Decreased functional usage of the involved part

Exercise progressions may cause some temporary soreness that can last 4 hours, but if the above signs and symptoms occur, the activity, exercise, or stretching maneuvers are too stressful and should be modified or reduced in intensity.

- Use combined motions or diagonal patterns to facilitate contraction of the desired muscles, but do not use patterns of motion that are dominated by stronger muscles with the weaker muscles not effectively participating at this early stage. Do not stress beyond the ability of the involved or weakened muscles to participate in the motion.

**Muscular endurance exercises.** Exercises for muscle endurance are emphasized during the subacute phase because slow-twitch muscle fibers are the first to atrophy when there is joint swelling, trauma, or immobilization.

- Initially, use only active ROM, with emphasis on control. Later during the healing phase, low-intensity, high-repetition exercise with light resistance is used rather than high-intensity resistance.
- Be certain that the patient is using correct movement patterns without substitution and is informed of the importance of stopping the exercise or activity when the involved muscle fatigues or involved tissue develops symptoms. For example, if the patient is doing shoulder flexion or abduction activities, substitution with scapular elevation should be avoided, or if the patient is doing leg-lift exercises, proper stabilization of the pelvis and the spine is important to ensure safety and correct motor learning.

**Protected weight-bearing exercises.** Partial weight bearing within the tolerance of the healing tissues may be used early to load the region in a controlled manner and stimulate stabilizing co-contractions in the muscles.

- Provide reinforcement to help develop awareness of appropriate muscle contractions and to help develop control while the patient shifts his or her weight in a side-to-side or anterior-to-posterior motion. As tolerated by the patient, progress by increasing the amplitude of movement or by decreasing the amount of support or protection.
- Add resistance to progress strength in the weight-bearing and stabilizing muscles.

**PRECAUTION:** Eccentric and heavy-resistance exercises, including progressive resistance exercise may cause added trauma to muscle and are not used in the early subacute stage after muscle injury when the weak tensile quality of the healing tissue could be jeopardized.<sup>18</sup> For nonmuscular injuries, eccentric exercises may not reinjure the part, but the resistance should be limited to a low intensity at this stage to avoid delayed-onset muscle soreness. (This is in contrast to using eccentric exercises to facilitate and strengthen weak muscles when there has been no injury to take advantage of greater tension development with less energy in eccentric contractions, which is described in Chapter 6.)

### Initiation and Progression of Stretching

Restricted motion during the acute stage and adherence of the developing scar usually cause decreased flexibility in the healing tissue and related structures in the region. To increase mobility and stimulate proper alignment of the developing scar, initiate stretching techniques that are specific to the

tissues involved. More than one technique may have to be used to regain the ROM.

**Warm the tissues.** Use modalities or active ROM to increase the tissue temperature and relax the muscles for ease in stretching.

**Muscle relaxation techniques.** Muscles that are not relaxed interfere with joint mobilization and passive stretching of inert tissue. If necessary, utilize hold-relax techniques first to be able to take the tissues to the end of their available range.

**Joint mobilization/manipulation.** If there is decreased joint play restricting range, it is important to begin stretching with specific joint techniques. Use grade III sustained or grade III and IV oscillation techniques to restore some of the joint slide prior to physiological stretching so as to minimize excessive compression of vulnerable cartilage. Joint distraction and gliding techniques are applied to stretch restricting capsular tissue. (See Chapter 5 for the principles and techniques of joint mobilization.)

**Stretching techniques.** Passive stretching techniques, self-stretching, and prolonged mechanical stretching are used to increase the extensibility of inert connective tissue, which permeates every structure in the body. These techniques are interspersed with neuromuscular inhibition techniques to relax and elongate the muscles crossing the joints. (See Chapter 4 for the principles and techniques of stretching.)

**Massage.** Various types of massage can be used for their soft tissue mobilizing effects. For example, cross-fiber friction massage is used to mobilize ligaments and incision sites so they move freely across the joint. Cross-fiber massage is also used at the site of muscle scar tissue or tendon adhesions to gain mobility of the scar tissue. The intensity and duration of the technique is progressively increased as the tissue responds.

**Use of the new range.** The patient must use the new range to maintain any extensibility gained with the stretching maneuvers and to develop control of the new range. Teach home exercises that include light resistance using the agonist in the new range as well as self-stretching techniques. Also encourage the patient to incorporate the new range into his or her daily activities.

### Correction of Contributing Factors

Continue to maintain or develop as normal a physiological and functional state as possible in related areas of the body. Address any postural or biomechanical impairments in stability, connective tissue and muscle flexibility, or strength that may have precipitated the problem or that may prevent full recovery. Resume low-intensity activities as the patient tolerates without exacerbating symptoms. Continue to reassess the patient's progress and understanding of the controlled activities.

## Management During the Chronic Stage

### Tissue Response: Maturation and Remodeling

Scar retraction from activity of the myofibroblasts is usually complete day 21 and the scar stops increasing in size, so from day 21 to day 60, there is a predominance of fibroblasts that are easily remodeled.<sup>27</sup> The process of maturation begins during the late subacute stage and continues for several months. The maturation and remodeling of the scar tissue occur as collagen fibers become thicker and reorient in response to stresses placed on the connective tissue. Remodeling time is influenced by factors that affect the density and activity level of the fibroblasts, including the amount of time immobilized, stress placed on the tissue, location of the lesion, and vascular supply.

#### Maturation of Tissue

The primary differences in the state of the healing tissue between the late subacute and chronic stages are the improvement in quality (orientation and tensile strength) of the collagen and the reduction of the wound size during the chronic stages. The quantity of collagen stabilizes, and there is a balance between synthesis and degradation. Depending on the size of the structure or degree of injury or pathology, healing with progressively increasing tensile quality in the injured tissue may continue for 12 to 18 months.<sup>8,19,28</sup>

#### Remodeling of Tissue

Because of the way immature collagen molecules are held together (hydrogen bonding) and adhere to surrounding tissue, they can be easily remodeled with gentle and persistent treatment. This is possible for up to 10 weeks. If not properly stressed, the fibers adhere to surrounding tissue and form a restricting scar. As the structure of collagen changes to covalent bonding and thickens, it becomes stronger and resistant to remodeling. At 14 weeks, the scar tissue is unresponsive to remodeling. Consequently, an old scar has a poor response to stretch.<sup>5</sup> Treatment under these conditions requires either adaptive lengthening in the tissue surrounding the scar or surgical release.

### Management Guidelines: Minimum to No Protection/Return to Function (Phase III)

The therapist's role during this phase is to design a progression of exercises that safely stresses the maturing connective tissue in terms of both flexibility and strength so the patient can return to his or her regular activities and participate in life situations including work, community mobility, and recreation/sports. Individuals returning to high-intensity work and sport activities require more intense exercises to prepare the tissues to withstand the stresses and train the

neuromuscular system to respond to the demands of the activity (this may be referred to as Phase IV).

Because remodeling of the maturing collagen occurs in response to the stresses placed on it, it is important to use controlled forces that replicate normal stresses on the tissue.<sup>7,15,23</sup> Maximum strength of the collagen develops in the direction of the imposed forces. Pain that the patient now experiences arises

only when stress is placed on restrictive contractures or adhesions or when there is soreness due to increased stress of resistive exercise. To avoid chronic or recurring pain, the contractures must be stretched or the adhesions broken up and mobilized. Excessive or abnormal stress leads to re-injury and chronic inflammation, which can be detrimental to the return of function. The information that follows is summarized in Box 10.4.

### BOX 10.4 MANAGEMENT GUIDELINES— Chronic Stage/Return to Function

#### Impairments of Body Structure and Function:

Soft tissue and/or joint contractures and adhesions that limit normal ROM or joint play  
Decreased muscle performance—weakness, poor endurance, poor neuromuscular control  
Decreased usage of the involved part  
Inability to participate normally in an expected activity

#### Plan of Care

#### Interventions (>3 weeks postinjury)

- |   |  |
|---|--|
| 1. Educate the patient.   | 1. Instruct patient in safe progressions of exercises and stretching. Monitor understanding and compliance. Teach ways to avoid reinjuring the part. Teach safe body mechanics. Provide ergonomic counseling.  |
| 2. Increase soft tissue, muscle, and/or joint mobility.                   | 2. Stretching techniques specific to tight tissue: <ul style="list-style-type: none"> <li>■ Joint and selected ligaments (joint mobilization/manipulation)</li> <li>■ Ligaments, tendons, and soft tissue adhesions (cross-fiber massage)</li> <li>■ Muscles (neuromuscular inhibition, passive stretch, massage, and flexibility exercises)</li> </ul>  |
| 3. Improve neuromuscular <i>control</i> , strength, and muscle endurance. | 3. Progress exercises: <ul style="list-style-type: none"> <li>■ Submaximal to maximal resistance</li> <li>■ Specificity of exercise using resisted concentric and eccentric, weight bearing and nonweight bearing</li> <li>■ Single plane to multiplanar motions</li> <li>■ Simple to complex motions, emphasizing movements that simulate functional activities</li> <li>■ Controlled proximal stability, superimpose distal motion</li> <li>■ Safe biomechanics</li> <li>■ Low repetitions to high repetitions at slow speeds; progress complexity and time; progress speed and time.</li> </ul> |
| 4. Improve cardiopulmonary endurance.                                     | 4. Progress aerobic exercises using safe activities.   |
| 5. Progress activities and participation in life situations.              | 5. Continue using supportive and/or assistive devices until the ROM is functional with joint play and strength in supporting muscles is adequate. Progress functional training with simulated activities from protected and controlled to unprotected and variable. Continue progressive strengthening exercises and advanced training activities until the muscles are strong enough and able to respond to the required demands.   |

**PRECAUTIONS:** There should be no signs of inflammation. Some discomfort will occur as the activity level is progressed, but it should not last longer than a couple of hours. Signs that activities are progressing too quickly or with too great a dosage are joint swelling, pain that lasts longer than 4 hours or that requires medication for relief, a decrease in strength, or fatiguing more easily.

## Patient Education

Unless there is restrictive scar tissue requiring manual techniques for intervention, the patient becomes more responsible for carrying out the exercises in the plan of treatment.

- Instruct the patient in biomechanically safe progressions of resistance and self-stretching and how to self-monitor for detrimental effects and signs of excessive stress (see Box 10.3).
- Establish guidelines for what must be attained to return safely to recreational, sport, or work-related activities.
- Re-examine and evaluate the patient's progress and modify the exercises as progress is noted or if problems develop.
- Recommend modifications in daily living, work, or sport activities if they are contributing to the patient's impairments and preventing return to desired activities.

## Considerations for Progression of Exercises

Free joint play within a useful (or functional) ROM is necessary to avoid joint trauma. If joint play is restricted, joint-mobilization/manipulation techniques should be used. These stretching techniques can be vigorous so long as no signs of increased irritation result.

Adequate muscle support is necessary to protect the joint. If there is weakness, faulty neuromuscular patterns may develop as activities are attempted. Poor support or faulty patterns of movement may result in microtrauma. The criterion for strength should be a muscle test grade of 4 on a 5-point scale in lower extremity musculature before discontinuing use of supportive or assistive devices for ambulation.

- To increase strength when there is a loss of joint play, use multiple-angle isometric exercises in the available range.
- Once joint play within the available ROM is restored, use resistive dynamic exercises within the available range. This does not imply that normal ROM needs to be present before initiating dynamic exercises but that joint play within the available range should be present. (See Chapter 5 for information on joint play.)
- In summary, joint dynamics and muscle strength and flexibility should be balanced as the injured part is progressed to functional exercises.

## Progression of Stretching

Stretching of any restricting contractures or adhesions should be specific to the tissue involved using manual techniques, such as joint mobilization/manipulation, myofascial massage, proprioceptive neuromuscular facilitation stretching, and passive stretching in addition to instruction in self-stretching. (See Chapters 4 and 5 and the self-stretching exercises described in Chapters 16 to 22.) At this stage, progress the intensity and duration of the stretching maneuvers so long as no signs of increased irritation persist beyond 24 hours.

## Progression of Exercises for Muscle Performance: Developing Neuromuscular Control, Strength, and Endurance

As the patient's tissues heal, not only does treatment progress to stimulate proper maturation and remodeling in the healing

tissue, but emphasis is also placed on controlled progressive exercises designed to prepare the patient to meet the outcome goals.

- If the patient is not using some of the muscles because of inhibition, weakness, or dominance of substitute patterns, isolate the desired muscle action or use unidirectional motions to develop awareness of muscle activity and control of the movement.
- Progress exercises from isolated, unidirectional, simple movements to complex patterns and multidirectional movements requiring coordination with all muscles functioning for the desired activity.<sup>30</sup>
- Progress strengthening exercises to simulate specific demands including both weight-bearing and nonweight-bearing (closed- and open-chain) and both eccentric and concentric contractions.<sup>22</sup>
- Progress trunk stabilization, postural control, and balance exercises and combine with extremity motions for effective total body movement patterns.<sup>30</sup>
- Teach safe body mechanics and have the patient practice activities that replicate his or her work environment.
- Often overlooked but of importance in preventing injury associated with fatigue is developing muscular endurance in the prime mover muscles and stabilizing muscles as well as cardiopulmonary endurance.

## Return to High-Demand Activities

Patients who must return to activities with greater than normal demand, such as is required in sports participation and heavy work settings, are progressed further to more intense exercises including plyometrics, agility training, and skill development.

- Develop exercise drills that simulate the work<sup>12</sup> or sport<sup>2,30</sup> activities using a controlled environment with specific, progressive resistance and plyometric drills.
- As the patient demonstrates capabilities, increase the repetitions and speed of the movement.
- Progress by changing the environment and introducing surprise and uncontrolled events into the activity.<sup>1,30</sup>

The importance of proper education to teach a safe progression of exercises and how to avoid damaging stresses cannot be overemphasized. To return to the activity that caused the injury prior to regaining functional pain-free motion, strength, endurance, and skill to match the demands of the task would probably result in recurring injury and pain.

## Cumulative Trauma: Chronic Recurring Pain

### Tissue Response: Chronic Inflammation

When connective tissue is injured, it goes through a healing process of repair, which was described in the preceding sections. However, in connective tissue that is repetitively stressed

beyond the ability to repair itself, the inflammatory process is perpetuated. Proliferation of fibroblasts with increased collagen production and degradation of mature collagen leads to a predominance of new, immature collagen. This has an overall weakening effect on the tissue. In addition, myofibroblastic activity continues, which may lead to progressive limitation of motion.<sup>27</sup>

## Causes of Chronic Inflammation

Prolonged or recurring pain and resulting limitations in activity and function occur as a result of stress being imposed on tissues that are unable to respond to the repetitive or excessive nature of the stress.

**Overuse, cumulative trauma, repetitive strain.** These are terms descriptive of the repetitive nature of the precipitating event.<sup>9</sup> Repetitive microtrauma or repeated strain overload over time results in structural weakening, or fatigue breakdown, of connective tissue, with collagen fiber cross-link breakdown and inflammation. Initially, the inflammatory response from the microtrauma is subthreshold but eventually builds to the point of perceived pain and resulting dysfunction.

Repetitive microtrauma to tendons may lead to tendon degeneration.<sup>29</sup> It has been reported that inflammation occurs in the early stages of tendinopathy, but when tendons become degenerative, inflammation largely disappears, leading some to state that this is not an inflammatory condition.<sup>23,27,29</sup> Histological findings in tendinopathy have shown a poor healing response with collagen degeneration, fiber thinning and disorientation, hypercellularity, and scattered vascular ingrowth.<sup>26,27</sup> The underlying abnormalities resulting in a weakened tendon are not quickly resolved resulting in loss of function.<sup>26</sup>

**Trauma.** Trauma that is followed by superimposed repetitive trauma results in a condition that never completely heals. This may be the result of too early return to high-demand functional activities before the original injury has properly healed. The continued re-injury leads to the symptoms of chronic inflammation and dysfunction.

**Reinjury of an “old scar.”** Scar tissue is not as compliant as surrounding, undamaged tissue. If the scar adheres to the surrounding tissues or is not properly aligned to the stresses imposed on the tissue, there is an alteration in the force transmission and energy absorption. This region becomes more susceptible to injury with stresses that normal, healthy tissue could sustain.

**Contractures or poor mobility.** Faulty postural habits or prolonged immobility may lead to connective tissue contractures that become stressed with repeated or vigorous activity.

## Contributing Factors

By the nature of the condition, there is usually some factor that perpetuates the problem. Not only should the tissue at fault and its stage of pathology be identified, but the *mechanical*

*cause* of the repetitive trauma needs to be defined. Evaluate for faulty mechanics or faulty habits that may be sustaining the irritation. Possibilities include:

- *Imbalance between the length and strength of the muscles* around the joint, leading to faulty mechanics of joint motion or abnormal forces through the muscles
- *Rapid or excessive repeated eccentric demand* placed on muscles not prepared to withstand the load, leading to tissue failure, particularly in the musculotendinous region<sup>18</sup>
- *Muscle weakness* or an inability to respond to excessive strength demands that results in muscle fatigue with decreased contractility and shock-absorbing capabilities and increased stress to supporting tissues<sup>18</sup>
- *Bone malalignment or weak structural support* that causes faulty joint mechanics of force transmission through the joints (poor joint stability as in a flat foot)<sup>20</sup>
- *Change in the usual intensity or demands* of an activity such as an increase or change in an exercise or a training routine or change in job demands<sup>18</sup>
- *Returning to an activity too soon after an injury* when the muscle-tendon unit is weakened and not ready for the stress of the activity<sup>7,10</sup>
- *Sustained awkward postures or motions*, placing parts of the body at a mechanical disadvantage, leading to postural fatigue or injury
- *Environmental factors* such as a work station not ergonomically designed for the individual, excessive cold, continued vibration, or inappropriate weight-bearing surface (for standing, walking, or running), which may contribute to any of the previous factors
- *Age-related factors* such that a person attempts activities that could be done when younger but his or her tissues are no longer in condition to withstand the sustained stress<sup>21</sup>
- *Training errors*, such as using improper methods, intensity, amount, or equipment, or the condition of the participant, which lead to abnormal stresses.<sup>20</sup>
- *A combination of several contributing factors* are frequently seen that cause the symptoms

## Management Guidelines: Chronic Inflammation

When the patient has symptoms and signs of chronic inflammation, it is imperative that treatment begins by controlling the inflammation—in other words, treat it as an acute condition. Once the inflammation is under control, treatment progresses to dealing with the impairments and functional limitations. Management guidelines are summarized in Box 10.5.

### Chronic Inflammation: Acute Stage

When the inflammatory response is perpetuated because of continued tissue irritation, the inflammation must be controlled to avoid the negative effects of continued tissue breakdown and excessive scar formation.

- In addition to the use of modalities and resting the part, it is imperative to identify and then modify the mechanism

**BOX 10.5** MANAGEMENT GUIDELINES—  
**Chronic Inflammation/Cumulative Trauma Syndromes**

**Impairments of Body Structure and Function:**

Pain in the involved tissue of varying degrees:

- Only after doing repetitive activities
- When doing repetitive activities as well as after
- When attempting to do activities; completion of activity is prevented
- Continued and unremitting

Soft tissue, muscle, and/or joint contractures or adhesions that limit normal ROM or joint play

Connective tissue weakness in painful region

Muscle weakness and poor muscular endurance in postural or stabilizing muscles as well as primary muscle at fault

Imbalance in length and strength between antagonistic muscles; biomechanical dysfunction

Faulty position or movement pattern perpetuating the impairment

Decreased use of the region for activities and participation in desired life situation

<b>Plan of Care</b>	<b>Interventions During Chronic Inflammation</b>
1. Educate the patient.	1. Counsel as to cause of chronic irritation and need to avoid stressing the part while inflamed. Adapt the environment to decrease tissue stress. Implement a home exercise program to reinforce therapeutic interventions.
2. Promote healing; decrease pain and inflammation.	2. Cold, compression, massage Rest to the part (stop mechanical stress, orthosis, tape, cast)
3. Maintain integrity and mobility of involved tissue.	3. Nonstressful passive movement, massage, and muscle setting within limits of pain
4. Develop support in related regions	4. Posture training Stabilization exercises

<b>Plan of Care</b>	<b>Interventions—Controlled Motion and Return to Function Phases</b>
1. Educate the patient.	1. Ergonomic counseling in ways to prevent recurrence Home instruction in safe progression of stretching and strengthening exercises. Instruction on signs of too much stress (see Box 10.3)
2. Develop strong, mobile scar.	2. Friction massage Soft tissue mobilization
3. Develop a balance in length and strength of the muscles.	3. Correct cause of faulty muscle and joint mechanics with appropriately graded stretching and strengthening exercises.
4. Progress functional independence.	4. Train muscles to function according to demand; provide alternatives or support if they cannot. Train coordination and timing. Develop endurance.
5. Analyze job/activity.	5. Adapt home, work, and sport environment/tools.

**PRECAUTION:** If there is progressive loss of ROM as the result of stretching, do not continue to stretch. Reevaluate the condition and determine if there is still a chronic inflammation with contracting scar or if there is protective muscle guarding. Emphasize stabilizing the part and training in safe adaptive patterns of motion.

of chronic irritation with appropriate biomechanical counseling. This requires cooperation from the patient. Describe to the patient how the tissue reacts and breaks down under continued inflammation and explain the strategy of intervention.

### CLINICAL TIP

Use of illustrations to help the patient understand the mechanism of tissue breakdown with cumulative trauma syndromes—such as what happens when a person repeatedly hits a thumbnail with a hammer or repeatedly irritates or scrapes a skin area before it heals—helps the patient visualize the repeated trauma occurring in the musculoskeletal problem and understand the need to quit “hitting or irritating the sore.”

- Initially, allow only nonstressful activities.
- Initiate exercises at safe, nonstressful intensities in the involved tissues, as with any acute lesion, and at appropriate corrective intensities in related regions without stressing the involved tissues.

### Subacute and Chronic Stages of Healing Following Chronic Inflammation

Once the constant pain from the chronic inflammation has decreased, progress the patient through an exercise program with controlled stresses until the connective tissue in the involved region has developed the ability to withstand the stresses imposed by the functional activities.

- Locally, if there is a chronic, contracted scar that limits range or continually becomes irritated with microruptures,

mobilize the scar in the tissue using friction massage, soft tissue manipulation, or stretching techniques. If inflammation results from the stretching maneuvers, treat it as an acute injury. Because chronic inflammation can lead to proliferation of scar tissue and contraction of the scar, progressive loss of range is a warning sign that the intensity of stretching is too vigorous.

- Muscle guarding could be a sign that the body is attempting to protect the part from excessive motion. In this case, the emphasis is on developing stabilization of the part and training in safe adaptive patterns of motion.
- Identify the cause of the faulty muscle and joint mechanics. Strengthening and stabilization exercises, in conjunction with working or recreational adaptations, are necessary to minimize the irritating patterns of motion.
- Because chronic irritation problems frequently result from an inability to sustain repetitive activities, muscle endurance is an appropriate component of the muscle re-education program. Consider endurance in the postural stabilizers as well as in the prime movers of the desired functional activity.
- As when treating patients in the chronic stage of healing, progress exercises to develop functional independence. The exercises become specific to the demand and include timing, coordination, and skill.
- Work-conditioning and work-hardening programs may be used to prepare the person for return to work; training in sports-specific exercises is important for returning an individual to sports.

**NOTE:** Specific overuse syndromes are covered in detail in the respective chapters associated with the involved region.

## Independent Learning Activities

### Critical Thinking and Discussion

1. Your patient has experienced an injury to a muscle. Describe the symptoms that he or she will experience during each stage of inflammation and repair and describe the principles of the exercise intervention that should be used during each stage. Once you have identified the principles, choose a commonly injured muscle, such as the hamstrings, and describe the symptoms, test results, goals, treatment plan, and actual interventions that you would use for each stage of intervention.

2. Repeat Activity 1, except use a ligamentous injury, such as strain of the humeroulnar ligament or anterior talofibular ligament.
3. Describe the mechanism of injury for common overuse syndromes, such as lateral epicondylitis or shin splints, and explain the differences between such an injury and an acute traumatic injury.

## Independent Learning Activities 355

General guidelines and principles for developing exercise interventions for patients with soft tissue lesions were presented in the previous chapter. The purpose of this chapter is to present principles of management of selected pathologies that affect joints, connective tissue, and bone. Characteristics of arthritis, fibromyalgia, myofascial pain syndrome, osteoporosis, and fractures are described in conjunction with the effects of therapeutic exercise on impairments associated with these pathological conditions.

## Arthritis: Arthrosis

*Arthritis* is inflammation of a joint. There are many types of arthritis, both inflammatory and noninflammatory, that affect joints and other connective tissues in the body. The most common types treated by therapists are rheumatoid arthritis and osteoarthritis. *Arthrosis* is limitation of a joint without inflammation. Unless the cause of the joint problems is known, such as recent trauma or immobility, medical intervention is necessary to diagnose and medically manage the pathology. Traumatic arthritis may require aspiration if there is bloody effusion.

The therapist examines, integrates, and evaluates the presenting information and then develops a plan of care by selecting interventions to safely meet the goals. Knowledge of the underlying pathology is important in order to understand the prognosis and safely manage the patient's impairments, activity limitations, and participation restrictions.<sup>61,75</sup>

## Clinical Signs and Symptoms

Signs and symptoms common to all types of arthritic conditions generally include the following.

### Impaired Mobility

The patient usually presents with signs typical of joint involvement that include a characteristic pattern of limitation (called a capsular pattern), usually a firm end-feel (unless acute—then the end-feel may be guarded), decreased and possibly painful joint play, and joint swelling (effusion).<sup>79</sup> Additional signs and symptoms may be present depending on the specific disease process. Table 11.1 summarizes the characteristic signs and symptoms of osteoarthritis and rheumatoid arthritis.

Arthrosis may be present if the individual is recovering from a fracture or other problem requiring immobilization. There is limited joint play along with other connective tissue and muscular contractures limiting range of motion (ROM).

### Impaired Muscle Performance

Weakness from disuse or reflex inhibition of stabilizing muscles occurs when there is joint swelling or pain. Muscle weakness or inhibition leads to imbalances in strength and flexibility and poor support for the involved joints. Asymmetry in muscle pull may be a deforming force to the joints, and poor muscle support allows the joint to be more susceptible to trauma; conversely, good muscle support helps protect an arthritic joint.

**TABLE 11.1** Comparison of Osteoarthritis and Rheumatoid Arthritis<sup>6,23,68,140</sup>

Characteristics	Osteoarthritis	Rheumatoid Arthritis
Age of onset	Usually after age of 40	Usually begins between age 15 and 50
Progression	Usually develops slowly over many years in response to mechanical stress	May develop suddenly, within weeks or months
Manifestations	Cartilage degradation, altered joint architecture, osteophyte formation	Inflammatory synovitis and irreversible structural damage to cartilage and bone
Joint involvement	Affects a few joints (usually asymmetrical); typically: —DIP, PIP, 1st CMC of hands —Cervical and lumbar spine —Hips, knees, 1st MTP of feet	Usually affects many joints, usually bilateral; typically: —MCP and PIP of hands, wrists, elbows, shoulders —Cervical spine —MTP, talonavicular and ankle
Joint signs and symptoms	Morning stiffness (usually < 30 min), increased joint pain with weight-bearing and strenuous activity; crepitus and loss of ROM	Redness, warmth, swelling, and prolonged morning stiffness; increased joint pain with activity
Systemic signs and symptoms	None	General feeling of sickness and fatigue, weight loss, and fever; may develop rheumatoid nodules; may have ocular, respiratory, hematological, and cardiac symptoms

### Impaired Balance

Patients may develop balance deficits because of altered or decreased sensory input from joint mechanoreceptors and muscle spindle. This is particularly a problem with weight-bearing joints.<sup>99,155</sup>

### Activity Limitations and Participation Restrictions

The ability to carry out home, community, work-related, or social activities may be minimally to significantly restricted. Adaptive and assistive devices may be used by the patient to improve function or help prevent possible deforming forces. A variety of classification systems and functional instruments have been developed for use in clinical studies as well as routine practice to measure patient function and outcomes in response to interventions.<sup>65</sup>

## Rheumatoid Arthritis

Rheumatoid arthritis (RA) is an autoimmune, chronic, inflammatory, systemic disease primarily of unknown etiology affecting the synovial lining of joints as well as other connective tissue. It is characterized by a fluctuating course, with periods of active disease and remission. The onset and progression vary from mild joint symptoms with aching and stiffness to abrupt swelling, stiffness, and progressive deformity.<sup>4,6,87,97,124</sup> The revised criteria for classification of RA are summarized in Box 11.1. This classification criteria was

### BOX 11.1 Criteria for Diagnosis of Rheumatoid Arthritis<sup>2</sup>

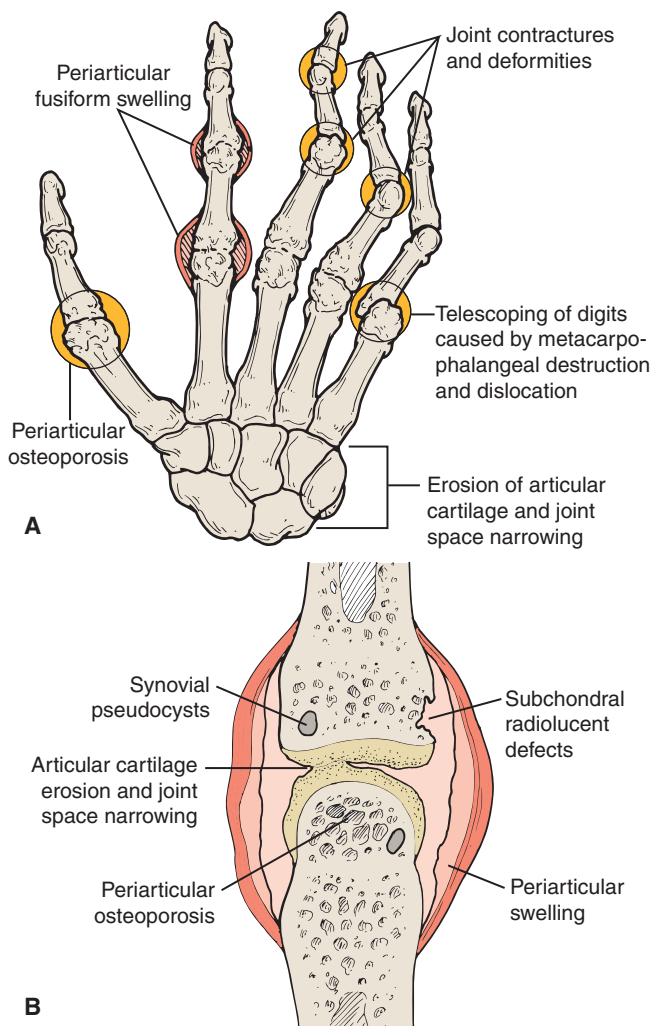

- Confirmed presence of synovitis in at least one joint, absence of an alternative diagnosis
- Achievement of a total score  $\geq 6$  out of 10 from the following 4 domains:
  - Number and site of involved joints.
    - 1 large joint = 0
    - 2–10 large joints = 2
    - 1–3 small joints = 2
    - 4–10 small joints = 3
    - >10 joints (at least 1 small) = 5
  - Serology (at least 1 test result required)
    - Negative RF and negative ACPA = 0
    - Low-positive RF or low-positive ACPA = 2
    - High-positive RF or high-positive ACPA = 3
  - Acute-phase reactants (at least 1 test is needed)
    - Normal CRP and normal ESR = 0
    - Abnormal CRP and abnormal ESR = 1
  - Duration of Symptoms
    - < 6 weeks = 0
    - $\geq 6$  weeks = 1

RF = rheumatoid factor; ACPA = anti-citrullinated protein; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate.

developed in order to focus on identification of the disease at earlier stages rather than features present in late stages of the disease.<sup>2</sup>

### Characteristics of RA

■ This disease is characterized by symmetric, erosive synovitis<sup>4</sup> with periods of exacerbation (flare) and remission.<sup>6,87,97</sup> Joints are characteristically involved with early inflammatory changes in the synovial membrane, peripheral portions of the articular cartilage, and subchondral marrow spaces. In response, granulation tissue (pannus) forms, covers, and erodes the articular cartilage, bone, and ligaments in the joint capsule. Adhesions may form, restricting joint mobility. With progression of the disease, cancellous bone becomes exposed. Fibrosis, ossific ankylosis, or subluxation may eventually cause deformity and disability (Figs. 11.1, 11.2, and 11.3).<sup>6,124</sup>

**FIGURE 11.1** (A) Radiographic hallmarks and typical joint deformities with rheumatoid arthritis in small joints of the wrist and hand. (B) Radiographic hallmarks of rheumatoid arthritis in large joints.

**FIGURE 11.2** Advanced rheumatoid arthritis of the hip joints. Note that the destruction caused by rheumatoid arthritis involves the entire joint space and the bone on both sides of the joint. This causes concentric joint space narrowing. The arrows point to small areas of sclerosis on the weight-bearing superior joint surfaces. Although not a primary characteristic of RA, sclerotic repair (primary in degenerative joint disease) can occur over the years in between episodes of RA exacerbations. (From McKinnis, LN: Fundamentals of Musculoskeletal Imaging, ed. 4. Philadelphia: F.A. Davis, 2014, p 53, with permission.)

- Inflammatory changes also occur in tendon sheaths (tenosynovitis); if subjected to recurring friction, the tendons may fray or rupture.
- Extra-articular pathological changes sometimes occur; they include rheumatoid nodules, atrophy and fibrosis of muscles with associated muscular weakness, fatigue, and mild cardiac changes.
- Progressive deterioration and decline in the functional level of the individual attributed to the muscular changes and progressive muscle weakness is often seen,<sup>35</sup> leading to major economic loss and significant impact on families.<sup>4</sup>
- The degree of involvement varies. Some individuals experience mild symptoms that require minor lifestyle changes and mild anti-inflammatory medications. Others experience significant pathological changes in the joints that require major adaptations in lifestyle. Loss of joint function is irreversible, and often surgery is needed to decrease pain and improve function. Early recognition is essential during the initial stages, with referral to a rheumatologist for diagnosis and

**FIGURE 11.3** Rheumatoid arthritis of the foot. First metatarsophalangeal joint shows severe *erosion* of the joint surface with *subluxation* of the metatarsal (arrow). (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging*, ed. 4. Philadelphia: F.A. Davis, 2014, p 57, with permission.)

medical management to control the inflammation and minimize joint damage.<sup>23</sup>

### Signs and Symptoms: Periods of Active Disease

- With synovial inflammation, there is effusion and swelling of the joints, which cause aching and limited motion. Joint stiffness is prominent in the morning. Usually there is pain on motion, and a slight increase in skin temperature can be detected over the joints. Pain and stiffness worsen after strenuous activity.
- Onset is usually in the smaller joints of the hands and feet, most commonly in the proximal interphalangeal joints. Usually symptoms are bilateral.
- With progression, the joints become deformed and may ankylose or subluxate.
- Pain is often felt in adjoining muscles, and eventually muscle atrophy and weakness occur. Asymmetry in muscle strength and alterations in the line of pull of muscles and tendons add to the deforming forces.
- The person often experiences nonspecific symptoms such as low-grade fever, loss of appetite and weight, malaise, and fatigue.

### Principles of Management: Active Inflammatory Period of RA

Management guidelines are summarized in Box 11.2.

- **Patient education.** Because periods of active disease may last several months to more than a year, begin education in the overall treatment plan, safe activity, and joint protection (Box 11.3) as soon as possible.<sup>100</sup> It is imperative to involve the patient in the management, so he or she learns how to conserve energy and avoid potential deforming stresses during activities and when exercising.
- **Joint protection and energy conservation.** It is important that the patient learns to respect fatigue and, when tired, rests to minimize undue stress to all the body systems. Because inflamed joints are easily damaged and rest is encouraged to protect the joints, teach the patient how to rest the joints in nondeforming positions and to intersperse rest with ROM.
- **Joint mobility.** Use gentle grade I and II distraction and oscillation techniques to inhibit pain and minimize fluid stasis. Stretching techniques are not performed when joints are swollen.
- **Exercise.** The type and intensity of exercise vary depending on the symptoms. Encourage the patient to do active exercises through as much ROM as possible (not stretching). If active exercises are not tolerated owing to pain and swelling, passive ROM is used. Once symptoms of pain and signs of swelling are controlled with medication, progress exercises as if subacute.

### CLINICAL TIP

Therapeutic exercises cannot positively alter the pathological process of RA, but if administered carefully, they can help prevent, retard, or correct the mechanical limitations and deforming forces that occur and, therefore, help maintain function.

### FOCUS ON EVIDENCE

The *Clinical Practice Guidelines (CPGs) for Therapeutic Exercise in the Management of Rheumatoid Arthritis in Adults* recommend therapeutic exercise based on the strength of evidence from comparative controlled trials.<sup>18</sup>

- **Functional training.** Modify any activities of daily living (ADL) needed in order to protect the joints. If necessary, use orthoses and assistive devices to provide protection.

**PRECAUTIONS:** Secondary effects of steroidal medications may include osteoporosis and ligamentous laxity, so use exercises that do not cause excessive stress to bones or joints.

**CONTRAINDICATIONS:** Do not perform stretching techniques across swollen joints. When there is effusion, limited motion is the result of excessive fluid in the joint space. Forcing motion on the distended capsule overstretches it, leading to

### BOX 11.2 MANAGEMENT GUIDELINES— Rheumatoid Arthritis/Active Disease Period

#### Impairments, Activity Limitations, and Participation Restrictions:

Tenderness and warmth over the involved joints with joint swelling  
 Muscle guarding and pain on motion  
 Joint stiffness and limited motion  
 Muscle weakness and atrophy  
 Potential deformity and ankylosis from the degenerative process and asymmetric muscle pull  
 Fatigue, malaise, and sleep disorders  
 Restricted ADLs and IADLs

#### Plan of Care

#### Interventions

- |   |  |
|---|--|
| 1. Educate the patient.                                     | 1. Inform the patient on importance of rest, joint protection, energy conservation, and performance of ROM.<br>Teach home exercise program and activity modifications that conserve energy and minimize stress to vulnerable joints. |
| 2. Relieve pain and muscle guarding and promote relaxation. | 2. Modalities<br>Gentle massage<br>Immobilize in orthoses<br>Relaxation techniques<br>Medications as prescribed by physician   |
| 3. Minimize joint stiffness and maintain available motion.  | 3. Passive or active-assistive ROM within limits of pain; gradual progression as tolerated.<br>Gentle joint techniques using grade I or II oscillations.   |
| 4. Minimize muscle atrophy.                                 | 4. Gentle isometrics in pain-free positions, progression to ROM when tolerated.  |
| 5. Prevent deformity and protect the joint structures.      | 5. Use of supportive and assistive equipment for all pathologically active joints.<br>Good bed positioning while resting.<br>Avoidance of activities that stress the joints.   |

**PRECAUTIONS:** Respect fatigue and increased pain; do not overstress osteoporotic bone or lax ligaments.

**CONTRAINDICATIONS:** Do not stretch swollen joints or apply heavy resistance exercise that cause joint stress or place deforming forces on the joint.

subsequent hypermobility (or subluxation) when the swelling abates. It may also increase the irritability of the joint and prolong the joint reaction.

#### Principles of Management: Subacute and Chronic Stages of RA

As the intensity of pain, joint swelling, morning stiffness, and systemic effects diminish, the disease is considered subacute. Often medications can decrease the acute symptoms, so the patient can function as if in the subacute stage. The chronic stage occurs between exacerbations. This may be very short in duration, or it may last many years.

- *Treatment approach.* The treatment approach is the same as with any subacute and chronic musculoskeletal disorder, except appropriate precautions must be taken because the pathological changes from the disease process make the tissues more susceptible to damage.
- *Joint protection and activity modification.* Continue to emphasize the importance of protecting the joints by adapting the environment, and by modifying activity, using orthoses, and assistive devices.
- *Flexibility and strength.* To improve function, exercises should be aimed at improving flexibility, muscle strength, and muscle endurance within the tolerance of the joints.<sup>35</sup>
- *Cardiopulmonary endurance.* Nonimpact or low-impact conditioning exercises—such as aquatic exercise, cycling, aerobic dancing, and walking/running—performed within the tolerance of the individual improve aerobic capacity and physical activity and decrease depression and anxiety.<sup>10,105,132,159</sup> Group activities, such as water aerobics, also provide social support in conjunction with the activity. One randomized review suggested that aerobic training also has a positive impact on the cardiovascular status of patients with RA.<sup>104</sup>

**BOX 11.3 Principles of Joint Protection and Energy Conservation<sup>88,123</sup>**

- Monitor activities and stop when discomfort or fatigue begins to develop.
- Use frequent but short episodes of exercise (three to five sessions per day) rather than one long session.
- Alternate activities to avoid fatigue.
- Decrease level of activities or omit provoking activities if joint pain develops and persists for more than 1 hour after activity.
- Maintain a functional level of joint ROM and muscular strength and endurance.
- Balance work and rest to avoid muscular and total body fatigue.
- Increase rest during flares of the disease.
- Avoid deforming positions.
- Avoid prolonged static positioning; change positions during the day every 20 to 30 minutes.
- Use stronger and larger muscles and joints during activities whenever possible.
- Use appropriate adaptive equipment.

**PRECAUTIONS:** The joint capsule, ligaments, and tendons may be structurally weakened by the rheumatic process (also as a result of using steroids), so the dosage of stretching and joint mobilization techniques used to counter any contractures or adhesions must be carefully graded.

**CONTRAINDICATIONS:** Vigorous stretching or high-velocity thrust manipulative techniques.

**FOCUS ON EVIDENCE**

Several systematic reviews looking at best evidence for the use of therapeutic exercise in the treatment of RA have been published.<sup>18,34,38,104</sup> Although there are few randomized well-controlled studies looking at the outcome of exercise, studies of various strength do support that therapeutic exercise, including functional strengthening and aerobic exercise, is beneficial for patients with RA, demonstrating relief of pain, improved muscle strength, and functional status. In one of the reviews,<sup>38</sup> investigators found that moderate- or high-intensity exercise in patients with RA had a minimal effect on disease activity and radiological evidence of damage in the hands and feet, and that there is insufficient radiological evidence to determine the effect in large joints. The reviewers also reported that long-term moderate- or high-intensity exercises (individualized to protect radiologically damaged joints) improve aerobic capacity, muscle strength, functional ability, and psychological well-being in patients with RA.<sup>38</sup> A more recent systematic review of randomized research studies on the effect of aerobic exercise in adults with RA found that aerobic exercise improved the quality of life, decreased pain, increased function, and did not exacerbate the disability or radiologic indicators.<sup>136</sup>

**Osteoarthritis: Degenerative Joint Disease**

Osteoarthritis (OA) is a chronic degenerative disorder primarily affecting the articular cartilage of synovial joints, with eventual bony remodeling and overgrowth at the margins of the joints (spurs and lipping) (Fig. 11.4). There is also progression of synovial and capsular thickening and joint effusion. The impairments from OA lead to activity limitations and participations restrictions in a substantial number of people with a significant social and financial impact as a result of surgical and medical interventions.<sup>19</sup>

**FIGURE 11.4** Radiographic hallmarks of osteoarthritis. (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging*, ed. 4. Philadelphia: F.A. Davis, 2014, p 60, with permission.)

Although the etiology of OA is not known, mechanical injury to the joint due to a major stress or repeated minor stresses and poor movement of synovial fluid when the joint is immobilized are possible causes. Rapid destruction of articular cartilage occurs with immobilization because the cartilage is not being bathed by moving synovial fluid and is thus deprived of its nutritional supply.<sup>66,87</sup>

OA is also genetically related, especially in the hands and hips and, to some degree, in the knees.<sup>42</sup> Other risk factors that show a direct relationship to OA are obesity, weakness of the quadriceps muscles, joint impact, sports with repetitive impact and twisting (e.g., soccer, baseball pitching, and football), and occupational activities such as jobs that require kneeling and squatting with heavy lifting.<sup>42</sup>

The perception of pain in OA is complex in that it is influenced not only by local factors, but also activation of central pain-producing pathways and psychological fear avoidance behaviors in some individuals.<sup>84,146</sup>

### Characteristics of OA

- With degeneration, there may be capsular laxity as a result of bone remodeling and capsule distention, leading to hypermobility or instability in some ranges of joint motion. With pain and decreased willingness to move, contractures eventually develop in portions of the capsule and overlying muscle, so as the disease progresses, motion becomes more limited.<sup>42,68</sup>
- The cartilage splits and thins out, losing its ability to withstand stress. As a result, crepitation or loose bodies may occur in the joint. Eventually, subchondral bone becomes exposed. There is increased density of the bone along the joint line, with cystic bone loss and osteoporosis in the adjacent metaphysis. During the early stages, the joint is usually asymptomatic because the cartilage is avascular and aneural, but pain becomes constant in later stages.
- Affected joints may become enlarged. Heberden's nodes (enlargement of the distal interphalangeal joints of the fingers) and Bouchard's nodes (enlargement of the proximal interphalangeal joints) are common.
- Most commonly involved are weight-bearing joints (hips and knees), the cervical and lumbar spine, and the distal interphalangeal joints of the fingers and carpometacarpal joints of the thumbs (Figs. 11.5 and 11.6).

**FIGURE 11.5** Osteoarthritis of the knees in a 66-year-old woman. This film was made with the patient weight-bearing. At the patient's right knee, osteoarthritis is evidenced by narrowed joint space (white arrows), osteophyte formation at the joint margins (large white arrowhead), and sclerotic subchondral bone (small black arrowheads) of both the medial and lateral tibial plateaus. At the patient's left knee, it is interesting to note that in the area of minimal weight-bearing stress, the subchondral bone has lost density, and rarefaction is present on the medial aspect of the joint. (From McKinnis, LN: Fundamentals of Musculoskeletal Imaging, ed. 4. Philadelphia: F.A. Davis, 2014, p 60, with permission.)

**FIGURE 11.6** Severe osteoarthritis of the hip with pseudocysts. The radiolucent cyst-like areas (*ovals*) are caused by intrusion of synovial fluid into areas of subchondral bone that have become weakened by microfractures. (From McKinnis, LN: Fundamentals of Musculoskeletal Imaging, ed. 4. Philadelphia: F.A. Davis, 2014, p 61, with permission.)

### Principles of Management: OA

Pain, joint stiffness, decreased muscle performance, and decreased aerobic capacity affect the quality of life and increase the risk for disability for the individual with OA.<sup>43</sup> Therapeutic exercise and manual therapy interventions are important in the comprehensive management of OA.<sup>116</sup> Management guidelines are summarized in Box 11.4.

- *Patient instruction.* Education includes teaching the patient about the disease of OA, how to protect the joints while remaining active, and how to manage the symptoms. Instruct the patient in a home program of safe exercises to improve muscle performance, ROM, and endurance.
- *Pain management—early stages.* Pain and feelings of “stiffness” are common complaints during the early stages. Pain usually occurs because of excessive activity and stress on the involved joint and is relieved with rest. Brief periods of stiffness occur in the morning or after periods of inactivity. This is due to gelling of the involved joints after periods of inactivity.<sup>3</sup> Movement relieves the stasis and feelings of stiffness. Help the patient find a balance between activity and rest and correct biomechanical stresses in order to prevent, retard, or correct the mechanical limitations.
- *Pain management—late stages.* During the late stages of the disease, pain is often present at rest. The pain may be from

### BOX 11.4 MANAGEMENT GUIDELINES— Osteoarthritis

#### Impairments, Activity Limitations, and Participation Restrictions:

Pain with mechanical stress or excessive activity  
Pain at rest in the advanced stages  
Stiffness after inactivity  
Limitation of motion  
Muscle weakness  
Decreased proprioception and balance  
Functional limitations in ADLs and IADLs

Plan of Care	Intervention
1. Educate the patient.	1. Teach about deforming forces and prevention. Teach home exercise program to reinforce interventions and minimize symptoms.
2. Decrease effects of stiffness.	2. Active ROM Joint-play mobilization techniques
3. Decrease pain from mechanical stress and prevent deforming forces.	3. Orthoses and/or assistive equipment to minimize stress or to correct faulty biomechanics, strengthen supporting muscles. Alternate activity with periods of rest.
4. Increase ROM.	4. Stretch muscle, joint, or soft tissue restrictions with specific techniques.
5. Improve neuromuscular control, strength, and muscle endurance.	5. Low-intensity resistance exercises and muscle repetitions.
6. Improve balance.	6. Balance training activities.
7. Improve physical conditioning.	7. Nonimpact or low-impact aerobic exercise.

**PRECAUTIONS:** When strengthening supporting muscles, increased pain in the joint during or following resistive exercises probably means that too great a weight is being used or stress is being placed at an inappropriate part of the ROM. Analyze the joint mechanics and at what point during the range the greatest compressive forces are occurring. Maximum resistance exercise should not be performed through that ROM.

involvement of subchondral bone, synovium, and the joint capsule with local inflammatory and molecular stimuli or from psychological or neurophysiological influences.<sup>84,146</sup> In the spine, if bony growth encroaches on the nerve root, there may be radicular pain (see Chapter 15). Emphasize activity modification and use of assistive devices and/or orthoses to minimize joint stress. Pain that cannot be managed with activity modification (as described in the following bullet) and analgesics is usually an indication for surgical intervention.

- *Assistive and supportive devices and activity.* With progression of the disease, the bony remodeling, swelling, and contractures alter the transmission of forces through the joint, which further perpetuates the deforming forces and creates joint deformity. Functional activities become more difficult. Adaptive or assistive devices, such as a raised toilet seat, cane, or walker, may be needed to decrease painful stresses and maintain function. Shock-absorbing footwear may decrease the stresses in OA of the knees.<sup>42</sup> Aquatic therapy and

group-based exercise in water decreases pain and improves physical function in patients with lower extremity OA.<sup>36,154</sup>

- *Resistance exercise.* Progressive weakening in the muscle occurs either from inactivity or from inhibition of the neuronal pools. Weak muscles may add to the joint dysfunction.<sup>3</sup> Strong muscles protect the joint. Use resistance exercises, within the tolerance of the joint, as part of the patient's exercise program. Avoid deforming forces and heavy weights that the patient cannot control or that cause joint pain. Adaptations include the use of multiple-angle isometrics in pain-free positions, applying resistance only through arcs of motion that are not painful, and use of a pool to decrease weight-bearing stresses and improve functional performance.<sup>52</sup>
- *Stretching and joint mobilization.* Use stretching and joint mobilization techniques to increase mobility. Teach the patient self-stretching/flexibility exercises and the importance of movement through the full available ROM to counteract the developing restrictions.

### FOCUS ON EVIDENCE

In a single-blind, randomized clinical trial of 109 patients with OA of the hip, specific manipulations and mobilizations of the hip joint were reported to have a greater success rate than active exercise for improving muscle function and joint motion. Outcomes measured were perceived improvement after treatment (81% vs. 50%), pain, stiffness, hip function, and ROM.<sup>69</sup>

- **Balance activities.** Joint position sense may be impaired.<sup>155</sup> (See Chapter 8 for principles and description of balance exercises.) Nontraditional forms of exercise, such as tai chi, have been found to be effective for improving balance in patients with OA.<sup>147</sup>
- **Aerobic conditioning.** Instruct the patient in exercises designed to improve cardiopulmonary function.<sup>17</sup> It is also proposed that aerobic exercise be used to improve pain and treat underlying depression and anxiety that may be comorbidities in OA.<sup>120,146</sup> The choice of exercise should have low impact on the joints, such as walking, biking, or swimming. Avoid activities that cause repetitive intensive loading of the joints, such as jogging and jumping.

### FOCUS ON EVIDENCE

The *CPGs for Therapeutic Exercises and Manual Therapy in the Management of Osteoarthritis*, which is based on a systematic review of randomized controlled and observational studies, highlight the importance of therapeutic exercise and physical activity to increase strength, manage pain, and improve aerobic capacity and functional status in patients with OA.<sup>19</sup>

The *CPGs for the Management of Osteoarthritis in Adults Who Are Obese or Overweight* identified that diet programs combined with physical activity (both aquatic and land-based exercises that include endurance, strength, ROM, and aerobic training) are more beneficial showing improved clinical outcomes of pain relief, improved strength, functional status, and quality than physical activity alone or diet alone and therefore recommends that physical therapists work with an interdisciplinary team that includes dietitians when treating this population.<sup>20</sup>

Two systematic reviews of studies designed to examine evidence of the effects of exercise in the management of hip and knee OA describe support for aerobic exercise and strengthening exercises to reduce pain and disability.<sup>127,128</sup> The consensus of expert opinion cited by Roddy<sup>123</sup> is that there are few contraindications and that exercise is relatively safe in patients with OA but that exercise should be individualized and patient-centered with consideration for age, comorbidity, and general mobility.

A systematic review of 15 randomized controlled trials that looked at therapies to improve balance and reduce falls in older individuals with OA of the knee concluded that strength training, tai chi, and aerobic exercises improved balance and reduced

the risk of falls in this population and that balance outcomes were not significantly improved with water-based exercises.<sup>99</sup>

In another study that followed 285 patients with knee OA for 3 years, investigators found that factors that protected the individuals from poor functional outcomes included strength and activity level, as well as factors such as mental health, self-efficacy, and social support.<sup>138</sup>

## Fibromyalgia and Myofascial Pain Syndrome

Fibromyalgia (FM) and myofascial pain syndrome (MPS) are chronic pain syndromes that are often confused and interchanged. Each has a distinct proposed etiology. Individuals with FM process nociceptive signals differently from individuals without FM,<sup>131,148</sup> and individuals with MPS have localized changes in the muscle.<sup>45,56,57,137,141,148</sup> Although there are some similarities, the differences are significant and determine the method of treatment. They are summarized in Table 11.2.

### Fibromyalgia

FM, as defined by the American College of Rheumatology in 1990,<sup>158</sup> is a chronic condition characterized by widespread pain that affects multiple body regions (right or left side, upper or lower half of the person) plus the axial skeleton and that has lasted for more than 3 months. Additional symptoms include 11 of 18 tender points at specific sites throughout the body (Fig. 11.7), nonrestorative sleep, and morning stiffness. A final common problem is fatigue with subsequent diminished exercise tolerance.

**TABLE 11.2** Similarities and Differences Between Fibromyalgia and Myofascial Pain Syndrome

Similarities	
Pain in muscles	
Decreased ROM	
Postural stresses	
Differences	
Fibromyalgia	Myofascial Pain Syndrome
Tender points at specific sites	Trigger points in muscle
No referred patterns of pain	Referred patterns of pain
No tight band of muscle	Tight band of muscle
Fatigue and waking unrefreshed	No related fatigue complaints

**FIGURE 11.7** Fibromyalgia tender points.

### FOCUS ON EVIDENCE

In 2010, Wolfe and associates<sup>157</sup> developed preliminary diagnostic criteria to complement the ACR-specific criteria, including the measurement of symptom severity. The authors recommend the following: widespread pain index (WPI)  $\geq 7$  *and* symptom severity (SS) scale  $\geq 5$ , *OR* WPI 3 to 6 *and* SS  $\geq 9$ . These criteria correctly classified 88.1% of individuals with FM determined from the ACR classification without tender point palpation. The SS scale includes items such as somatic symptoms, not feeling refreshed after sleeping, fatigue, and cognition.

### Prevalence of FM

It is estimated that 2% of the population—nearly 5 million adults 18 years old or older—have FM, with women affected far more than men (3.4% to 0.5%). In addition, the prevalence increases with age, with 7.4% of women ages 70 to 79 affected.<sup>86</sup> While women have also been shown to have greater pain intensity, men report a longer duration of symptoms of FM.<sup>30</sup>

### Characteristics of FM

The characteristics of FM include the following:<sup>148</sup>

- The first symptoms of FM can occur at any age but usually appear during early to middle adulthood.
- For many of those diagnosed, the symptoms develop after physical trauma such as a motor vehicle accident or a viral infection.

- Although the symptoms vary from individual to individual, there are several hallmark complaints. Pain is usually described as muscular in origin and is predominantly reported in the scapula, head, neck, chest, and low back.
- Another common report is a significant fluctuation in symptoms. Some days an individual may be pain free, whereas other days the pain is markedly increased. Most individuals report that when they are in a cycle in which the symptoms are diminished, they try to do as much as possible. This is usually followed by several days of worsening symptoms and an inability to carry out their normal daily activities. This is often the response to exercise.
- Individuals with FM have a higher incidence of tendonitis, headaches, irritable bowel, temporal mandibular joint dysfunction, restless leg syndrome, mitral valve prolapse, anxiety, depression, and memory problems.

### Factors Contributing to a Flare

Although FM is a noninflammatory, nondegenerative, nonprogressive disorder, several factors may affect the severity of symptoms. These factors include environmental stresses, physical stresses, and emotional stresses. FM is not caused by these various stresses, but it is aggravated by them.

- Environmental stresses include weather changes, especially significant changes in barometric pressure, cold, dampness, fog, and rain.
- Physical stresses include repetitive activities, such as typing, playing piano, vacuuming; prolonged periods of sitting and/or standing; and working rotating shifts.
- Emotional stresses are any normal life stresses.

### Principles of Management: FM

Individuals with FM typically have lower tolerance for activities and exercise. People often report “good” and “bad” days in which they have more or less energy, respectively. Learning to pace activities throughout the day so as to not push too hard or too little is an important component of the intervention plan.

### CLINICAL TIP

The Fibromyalgia Impact Questionnaire (FIQ), originally developed in 1991,<sup>24</sup> includes 10 items that assess the patient’s overall function status. A higher score is correlated with lower function. It has been used in many studies to report progress<sup>90, 96,152</sup> and predict successful outcomes.<sup>121,152</sup> The FIQ has been modified in 1997, 2002, and 2009 and has been shown to be valid and reliable. The minimal clinically important difference has been estimated to be 14%.

- *Exercise.* Research supports the use of exercise, particularly aerobic exercise, to reduce the most common symptoms associated with FM.<sup>21,22,25,26,41,95</sup>

## FOCUS ON EVIDENCE

The *CPGs for Aerobic Fitness Exercises in the Management of Fibromyalgia: Part 1*<sup>21</sup> and the *CPGs for Strengthening Exercises in the Management of Fibromyalgia: Part 2*<sup>22</sup> show emerging evidence that aerobic fitness and strengthening exercises are beneficial in the overall management of FM for pain relief, muscle strength, quality of life, self-efficacy, and decreased depression and that progressive strengthening programs do not cause an exacerbation of exercise-induced FM symptoms. The guidelines also recommend individualized programs with multiple treatment regimens be used due to the variability in FM symptoms.<sup>22</sup>

An updated evidence report from the Cochrane Collaborative<sup>27</sup> summarized the findings of five randomized trials related to FM and exercise. The reviewers concluded that while moderate-intensity and moderate- to high-intensity resistance training can improve function, pain, strength, and tenderness in people with FM, an 8-week aerobic program has even better outcomes. Furthermore, the authors reported that a 12-week low-intensity exercise program was superior to flexibility training for improving pain and function.

While these findings are supported elsewhere in the literature,<sup>28</sup> some evidence suggests aerobic activity is sufficient.<sup>62,76,78</sup> In a randomized controlled trial, 199 participants with FM tracked their daily steps. It was determined that people averaging at least 5,000 steps each day had better functional outcomes after 12 weeks as compared with those individuals with less than 5,000 steps a day.<sup>78</sup> Still other research promotes a combination of strength and flexibility training for improved functional outcomes and decreased pain.<sup>55,58,71,82,134,135</sup>

### Additional interventions<sup>64</sup>

- Prescription medication
- Over-the-counter medication
- Instruction in pacing activities, in an attempt to avoid fluctuations in symptoms
- Cognitive behavior therapy
- Avoidance of stress factors
- Decreasing alcohol and caffeine consumption
- Diet modification
- Manual therapy<sup>29,160</sup>

## CLINICAL TIP

When beginning any type of exercise with individuals with FM, it is best to begin at lower levels than recommended by the American College of Sports Medicine<sup>5</sup> for aerobic and strengthening and to slowly increase the activity. If the exercise leads to an increase in FM symptoms, reduce the intensity, while encouraging continued participation in the exercise.<sup>21,22,25,70</sup>

## Myofascial Pain Syndrome

Myofascial pain syndrome (MPS) is defined as a chronic, regional pain syndrome.<sup>56,141</sup> The hallmark classification of MPS comprises the myofascial trigger points (MTrPs) in a muscle that have a specific referred pattern of pain (Fig. 11.8), along with sensory, motor, and autonomic symptoms.<sup>40,45,56,142,143</sup>

The *trigger point* is defined as a hyperirritable area in a tight band of muscle.<sup>45,48,49,56,74</sup> The pain from these points is described as dull, aching, and deep.

**FIGURE 11.8** Composite pattern of pain (dark red) referred from trigger points (TrPs) (Xs) in the right piriformis muscle (medium red). The lateral X (TrP<sub>1</sub>) indicates the most common TrP location. The red stippling locates the spillover part of the pattern that may be felt as less intense pain than that of the essential pattern (solid red). The spillover pain may be absent. (From Travell, JG, Simmons, DG: *Myofascial Pain and Dysfunction: The Trigger Point Manual: The Lower Extremities*, Vol 2. Baltimore: Williams & Wilkins, 1992, p 188, with permission.)

## Possible Causes of Trigger Points

Although the etiology of trigger points is not completely understood, some potential causes are:<sup>56,141-143</sup>

- Chronic overload of the muscle that occurs with repetitive activities or that maintain the muscle in a shortened position.
- Acute overload of muscle, such as slipping and catching oneself, picking up an object that has an unexpected weight, or following trauma such as in a motor vehicle accident.
- Poorly conditioned muscles compared to muscles that are exercised on a regular basis.

- Postural stresses such as sitting for prolonged periods of time, especially if the workstation is not ergonomically correct, and leg length differences.
- Poor body mechanics with lifting and other activities.

### FOCUS ON EVIDENCE

Recently researchers have looked at the contribution of MTrPs as a contributing factor in chronic headaches,<sup>133</sup> tension type headaches,<sup>46,47</sup> mechanical neck pain,<sup>31,44,122,161</sup> and shoulder disorders.<sup>31,67,92,133</sup> Additionally, Iglesias-Gonzalez and associates<sup>74</sup> compared active and latent trigger points (LTrPs) in participants with non-specific low back pain. The authors reported direct correlation with increased number of trigger points and high pain intensity ( $p < 0.001$ ) and worse quality of sleep ( $p = 0.03$ ).

Lucas and associates<sup>91</sup> investigated the muscle activation pattern (MAP) of scapular muscles during arm elevation in pain-free individuals without trigger points and pain-free individuals with LTrPs. The LTrP group had a significant difference in MAP ( $p < 0.05$ ). These individuals were then treated with either a placebo or active intervention to deactivate the trigger point, and the MAP was reassessed. There was a significant difference ( $p < 0.05$ ) in MAP after deactivation of the LTrPs.

### Principles of Management: Myofascial Pain Syndrome

Pain from trigger points is described as dull, aching, and deep. Additional impairments from the trigger points include decreased ROM when the muscle is being stretched, decreased strength in the muscle, and increased pain with muscle stretching. The trigger points may be active (producing a classic pain pattern) or latent (asymptomatic unless palpated).

Treatment consists of three main components:<sup>1,16,45,80,94,141-143,150</sup>

- **Correct chronic overload.** Correct contributing factors that cause chronic overload of the muscle, such as faulty posture, repetitive activity, or poor lifting techniques. The correction is often done with education including stressing the importance of taking intermittent mini-breaks. If indicated, an ergonomic assessment of the work environment is performed.
- **Eliminate the trigger point.** Several techniques are used to eliminate trigger points
  - Contract-relax-passive stretch done repeatedly until the muscle lengthens
  - Contract-relax-active stretch also done in repetition
  - Trigger point release
  - Spray and stretch
  - Modalities
  - Dry needling or injection
- **Strengthen muscle.** Exercise prescription, using a muscle endurance protocol, is typically indicated for core and

scapular stabilizing muscle groups to improve overall muscle performance.

### FOCUS ON EVIDENCE

Dry needling (DN) has been shown to be a low-risk intervention that can decrease pain severity and pain pressure threshold as well as improve functional outcomes in people with MTrPs.<sup>16,83,125,149,161</sup> In a recent randomized controlled trial, Ziaefar and associates found that DN significantly decreased pain intensity when compared with trigger point compression technique of the upper trapezius.<sup>161</sup> Additionally, a meta-analysis showed both an immediate and 4 week follow-up improvement in pain in the cervicothoracic region when using DN as the intervention.<sup>83</sup>

### CLINICAL TIP

If the cause of the trigger point in myofascial pain syndrome is a chronic overload of the muscle, eliminate the contributing factor prior to addressing the trigger point. Initiate muscle strengthening when ROM is restored and the trigger point has been addressed.

## Osteoporosis

*Osteoporosis* is a disease of bone that leads to decreased mineral content and weakening of the bone. This weakening may lead to fractures, especially of the spine, hip, and wrist. Approximately 10 million Americans have osteoporosis, 80% of them women, and an additional 34 million individuals are at increased risk due to decreased bone mass.<sup>109</sup> The diagnosis of osteoporosis is determined by the T-score of a bone mineral density (BMD) scan. The T-score is the number of standard deviations above or below a reference value (young, healthy Caucasian women). The World Health Organization has established the following criteria:<sup>110,151</sup>

- Normal:  $-1.0$  or higher
- Osteopenia:  $-1.0$  to  $-2.4$
- Osteoporosis:  $-2.5$  or less

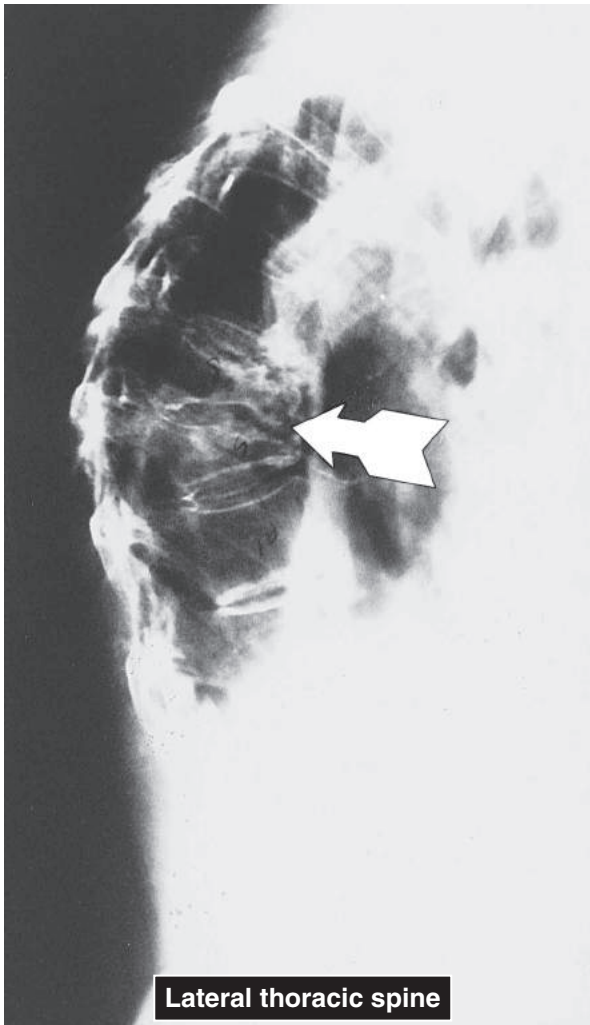

A decrease of 1 standard deviation represents a 10% to 12% loss of BMD.

### Risk Factors

**Primary osteoporosis.** Risk factors for developing primary osteoporosis include being postmenopausal, Caucasian or Asian descent, family history, low body weight, little or no physical activity, diet low in calcium and vitamin D, and

smoking.<sup>51,59,111</sup> Additional risk factors include prolonged bed rest and advanced age. (Refer to Chapter 24 for additional information on osteoporosis in the older population.)

**Secondary osteoporosis.** Secondary osteoporosis develops owing to other medical conditions (i.e., gastrointestinal diseases, hyperthyroidism, chronic renal failure, and excessive alcohol consumption) and the use of certain medications such as glucocorticoids.<sup>51,112,151</sup> Regardless of etiology, osteoporosis is detected radiographically by cortical thinning, osteopenia (increased bone radiolucency), trabecular changes, and fractures (Figs. 11.9 and 11.10).<sup>102</sup>

**FIGURE 11.9** Osteoporosis of the spine with multiple compression fractures. The arrow points to the T8-T9 disc space, which is deformed by the collapse of these two vertebrae from multiple compression fractures. This 94-year-old woman has severe kyphosis of the thoracic spine (also known as a gibbous deformity) accentuated by vertebral collapse at multiple levels. The whitish area of the lower half of this lateral radiograph is the combined radiodensities of the pelvis and the abdominal organs. (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging, ed. 4. Philadelphia: F.A. Davis, 2014, p 63, with permission.*)

**FIGURE 11.10** Osteoporosis is evident in this knee by the accentuation of the remaining trabeculae. The trabeculae have diminished in number and thickness, and the remaining vertically oriented trabeculae stand out as thin, delicate line images. (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging, ed. 4. Philadelphia: F.A. Davis, 2014, p 63, with permission.*)

## Prevention of Osteoporosis

The National Osteoporosis Foundation (NOF) recommends four ways to prevent osteoporosis.<sup>113</sup>

- Eating foods that are good for bone health, such as fruits and vegetables
- Maintaining a balanced diet that is rich in calcium and vitamin D
- Performing regular weight-bearing exercise
- Following a healthy lifestyle with moderate alcohol consumption (limit 2-3 drinks per day) and no smoking

Bone is living tissue that is continually replacing itself in response to the daily demands placed on it. Normally, this continual replacement keeps our bone at its optimum strength.

Cells in bone called osteoclasts resorb bone, especially if calcium is needed for particular body functions and not enough is obtained in the diet. Another type of cell, the osteoblast, builds bone. This cycle is usually kept in balance with bone resorption equaling bone replacement until the third decade of life. At this point, peak bone mass should be reached. With increasing age, there is a shift to greater resorption. For women, resorption is accelerated during menopause owing to the decrease in estrogen.<sup>114,116,117,151</sup> Both exercise and pharmacological therapy have been shown to be effective in the prevention of decreased bone mass density.<sup>54,72,89</sup> Bleicher et al<sup>11</sup> tracked the bone density of 1,100 men, aged 70 to 97 years, for 2 years. They concluded that walking, improved balance, and the use of beta blockers were found to retard the bone absorption process.

### Physical Activity

Physical activity has been shown to have a positive effect on bone remodeling. In children and adolescents, this activity may increase the peak bone mass. In adults, it has been shown to maintain or increase bone density; in the elderly, it has been shown to reduce the effects of age-related or disuse-related bone loss.<sup>51,115</sup> Maintenance of, or an increase in, bone density is important for preventing fractures associated with osteoporosis. Weak bones due to osteoporosis have been attributed to causing more than 1.5 million fractures per year at a cost of \$19 billion dollars. Many of these individuals never return to their previous functional level.<sup>151</sup>

### Effects of Exercise

Muscle contraction (e.g., strengthening exercises and resistance training) and mechanical loading (weight bearing) deform bone. This deformation stimulates osteoblastic activity and improves BMD.<sup>144</sup>

### FOCUS ON EVIDENCE

Martyn-St James and Carroll<sup>98</sup> completed a meta-analysis of prescribed walking programs on BMD at the hip and spine in postmenopausal women. Results reported no increase in BMD at the spine, but a significant increase at the femoral neck.

Huntoon, Schmidt, and Sinaki<sup>73</sup> completed a retrospective analysis of medical records comparing the refracture rate following vertebral compression fractures in patients instructed in a back extension program following percutaneous vertebroplasty to those who did not perform the exercises. The nonexercise group refractured within an average of 4.5 months, whereas the exercise group average time to refracture was 20.4 months.

An evidence report from the Cochrane Collaborative<sup>14</sup> summarized the findings of 18 randomized trials related to exercise and osteoporosis in women. The reviewers concluded that exercise, particularly fast walking, was effective on the BMD of the spine and hip. Resistance and weight-bearing exercises were also beneficial on the BMD of the spine.

In a meta-analysis, it was concluded that lower extremity exercises decreased bone loss in postmenopausal women. Those participants that exercised for either longer duration

(12 months) or early postmenopause showed the most significant changes.<sup>126</sup>

## Recommendations for Exercise

The NOF recommends weight-bearing exercise in the prevention of osteoporosis but does not specify what type of exercise or how often it should be done. Based on current research, the following recommendations are made.\*

- Weight-bearing exercise, such as walking, jogging, climbing stairs, and jumping
- Nonweight-bearing exercise, such as with a bicycle ergometer
- Resistance (strength) training of 8 to 10 exercises that target major muscle groups

### Mode: Aerobic

**Frequency.** Five or more days per week.

**Intensity.** Thirty minutes of moderate intensity (fast walking) or 20 minutes of vigorous intensity (running). Doing three short bouts per day of 10 minutes of activity is acceptable.

### Mode: Resistance

**Frequency.** Two to three days per week with a day of rest in between each bout of exercise.

**Intensity.** Eight to 12 repetitions that lead to muscle fatigue.

### FOCUS ON EVIDENCE

Weighted vests or backpacks have been shown to improve bone mass density.<sup>129,156</sup> The increased weight has been shown to alter the spinal muscle imbalance and focus more weight bearing to the osseous structures of the spine.<sup>156</sup> If there is a history of vertebral fracture, recommendations are that up to 1 kg can be carried on the back or up to 2 kg on the front.<sup>156</sup> A study by Roghani et al<sup>125</sup> followed three groups of women for 6 weeks that exercised 3 times per week. The groups included a control population and two exercise groups; one with and one without a weighted vest (4%-8% of body weight). It was reported that while both exercise groups had increased bone synthesis and decreased bone resorption, the weighted exercise group also demonstrated improved balance. (See Fig 24.10A & B for pictures of a weighted vest.)

## Precautions and Contraindications

- Because osteoporosis changes the shape of the vertebral bodies (they become more wedge shaped), leading to kyphosis, flexion activities and exercise, such as supine curl-ups and sit-ups, as well as the use of sitting abdominal machines, should be avoided. Stress into spinal flexion increases the risk of a vertebral compression fracture.

\*8,9,12,13,14,14,32,33,50,51,53,60,63,73,77,81,85,98,103,107,108,115,118,119,130,139,145,151

- Avoid combining flexion and rotation of the trunk to reduce stress on the vertebrae and the intervertebral discs.
- When performing resistance exercise, it is important to increase the intensity progressively but within the structural capacity of the bone.

**NOTE:** Refer to Chapter 6 for a discussion of pathological fractures and precautions that should be taken during resistance exercise, identified in Box 6.14.

**CLINICAL TIP**

Utilizing a multimodal program of weight-bearing exercise, balance activities, and strengthening may help reduce the risk of falls and subsequent hip fractures in individuals with osteoporosis.<sup>39,106,141</sup> Walking has good cardiopulmonary benefits, but an exercise program that involves only walking does not

appear to have a significant effect on increasing bone density in people that have been diagnosed with osteoporosis.<sup>93,157</sup>

## Fractures and Posttraumatic Immobilization

A fracture is a structural break in the continuity of a bone, an epiphyseal plate, or a cartilaginous joint surface.<sup>132</sup> When there is a fracture, some degree of injury also occurs to the soft tissues surrounding the bone. Depending on the site of the fracture, the related soft tissue injury could be serious if a major artery or peripheral nerve is also involved. If the fracture is more central, the brain, spinal cord, or viscera could be involved. Causes and types of fractures are summarized in Table 11.3 and are illustrated in Figures 11.11, 11.12, and 11.13.

**TABLE 11.3** Causes and Types of Fractures<sup>132</sup>

Force	Effect on Bone	Type of Fracture
Bending (angulatory)	Long bone bends causing failure on convex side of bend	Transverse or oblique fracture; Greenstick fracture in children
Twisting (torsional)	Spiral tension failure in long bone	Spiral fracture
Straight pulling (traction)	Tension failure from pull of ligament or muscle	Avulsion fracture
Crushing (compression)	Usually in cancellous bone	Compression fracture; Torus (buckle) fracture in children
Repetitive microtrauma	Small crack in bone unaccustomed to the repetitive/rhythmic stress	Fatigue fracture or stress fracture
Normal force on abnormal bone	Such as with osteoporosis, bony tumor, or other diseased bone	Pathological fracture

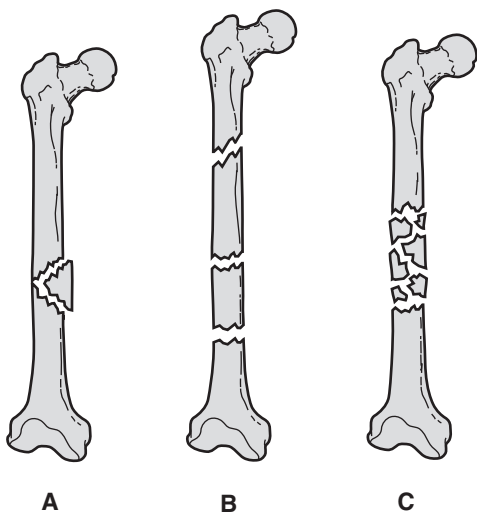

**FIGURE 11.11 (A–F)** The *position* of fracture fragments may be described by how the *distal* fragment displaces in relationship to the *proximal* fragment. (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging*, ed. 4. Philadelphia: F.A. Davis, 2014, p 82, with permission.)

**FIGURE 11.12 (A–D)** Directions of fracture lines are described in reference to the longitudinal axis of the bone. (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging*, ed. 4. Philadelphia: F.A. Davis, 2014, p 83, with permission.)

**FIGURE 11.13** Comminuted fractures are fractures with more than two fragments. Some frequently occurring comminuted fracture patterns are (A) the wedge-shaped or butterfly pattern and (B) a two- or three-segmented level fracture. (C) Other fractures with multiple fragments, be it several or several hundred, are still described as comminuted. (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging*, ed. 4. Philadelphia: F.A. Davis, 2014, p 83, with permission.)

A fracture is identified by:<sup>132</sup>

- **Site:** diaphyseal, metaphyseal, epiphyseal, intra-articular
- **Extent:** complete, incomplete
- **Configuration:** transverse, oblique or spiral, comminuted (two or more fragments)
- **Relationship of the fragments:** undisplaced, displaced
- **Relationship to the environment:** closed (skin intact), open (fracture or object penetrated the skin)
- **Complications:** local or systemic; related to the injury or to the treatment

The diagnosis, reduction, alignment, and immobilization for healing of a fracture are medical procedures and are not discussed in this text. There are times, though, when the therapist provides the initial screening following a traumatic event or examines a patient following repetitive microtrauma; moreover, a patient may sustain an injury while at a therapy session. Hence, the therapist must be aware of symptoms and signs of a potential fracture. If a fracture is suspected, refer the patient for radiographic examination, medical diagnosis, and management. Box 11.5 summarizes the typical symptoms and signs of a possible fracture.

## Risk Factors

Risk factors for fracture include:<sup>66</sup>

- Sudden impact (e.g., trauma, accidents, abuse, or assault)
- Osteoporosis (women more than men)
- History of falls (especially with increased age, low body mass index, and low levels of physical activity)
- Repetitive stress (repeated microtrauma)
- Pathology (abnormal fragile bone from neoplastic, poor health, or disease conditions)

(See Chapter 24 for additional information on risk factors in the older population.)

## Bone Healing Following a Fracture

Fracture healing has (1) an *inflammatory phase* in which there is hematoma formation and cellular proliferation, (2) a *repairative phase* in which there is callous formation uniting the breach and ossification, and (3) a *remodeling phase* in which there is consolidation and remodeling of the bone.<sup>87</sup>

## Cortical Bone Healing

### Inflammatory Phase

When the dense cortical bone of the shaft of a long bone is fractured, the tiny blood vessels are torn at the site, resulting in internal bleeding followed by normal clotting. The amount of bleeding depends on the degree of fracture displacement and amount of soft tissue injury in the region.

### BOX 11.5 Symptoms and Signs of a Possible Fracture

The following should alert the therapist to a possible fracture.

- History of a fall, direct blow, twisting injury, or accident
- Localized pain aggravated by movement and on weight bearing
- Muscle guarding with passive movement
- Decreased functional use of the part
- Swelling, deformity, or abnormal movement (may or may not be obvious)
- Sharp, localized tenderness at the site

### Reparative Phase

The early stages of healing take place in the hematoma. Osteogenic cells proliferate from the periosteum and endosteum to form a thick callus, which envelops the fracture site. At this stage, the callus does not contain bone and is therefore radiolucent.

As the callus starts to mature, the osteogenic cells differentiate into osteoblasts and chondroblasts. Initially, the chondroblasts form cartilage near the fracture site, and the osteoblasts form primary woven bone.

### Remodeling Phase

- *Stage of clinical union.* When the fracture site is firm enough that it no longer moves, it is clinically united. This occurs when the temporary callus consisting of the primary woven bone and cartilage surrounds the fracture site. The callus gradually hardens as the cartilage ossifies (endochondral ossification). On radiographic examination, the fracture line is still apparent, but there is evidence of bone in the callus. Usually at this stage, immobilization is no longer required. Movement of the related joints is allowed with the caution of avoiding deforming forces at the site of the healing fracture. When assessing the site, no movement of the fracture site or pain should be felt by the patient or therapist.
- *Stage of radiological union.* The bone is considered radiographically healed, or consolidated, when the temporary callus has been replaced by mature lamellar bone. The callus is resorbed, and the bone returns to normal.

### Rigid Internal Fixation

Sometimes it is necessary to surgically apply an internal fixation device, such as a rod or a plate with screws, to protect a healing bone. This allows the bone to be kept stable as it heals, but disuse osteoporosis of the bone under the device occurs because normal stresses are transmitted through the device and bypass the bone. Usually the fixation device is removed once the fracture is united in order to reverse the osteoporosis. Following removal of the rod or plate, the bone must be protected from excessive stress for several months until the osteoporosis is reversed.

### Healing Time

Healing time varies with age of the patient, the location and type of fracture, whether it was displaced, whether surgical repair was needed, amount of soft tissue injury, and the blood supply to the fragments. Healing is assessed by the physician using radiological and clinical examinations. The prognosis for healing is influenced by many factors including health of the individual, age, and use of tobacco. Generally, children heal within 4 to 6 weeks, adolescents within 6 to 8 weeks, and adults within 10 to 18 weeks.<sup>66</sup> Several types of abnormal healing may occur. These are summarized in Box 11.6.

### Cancellous Bone Healing

When the sponge-like lattice of the trabeculae of cancellous bone fractures (in the metaphysis of long bones and bodies of short bones and flat bones), healing occurs primarily

### BOX 11.6 Types of Abnormal Healing of Fractures<sup>66</sup>

*Malunion:* The fracture heals in an unsatisfactory position resulting in a bony deformity.

*Delayed union:* The fracture takes longer than normal to heal.

*Nonunion:* The fracture fails to unite with a bony union. There may be a *fibrous union* or a *pseudarthrosis*.

through formation of an internal callus (endosteal callus). There is a rich blood supply and a large area of bony contact, so union is more rapid than in dense cortical bone.

Cancellous bone is more susceptible to compression forces, resulting in crush or compression fractures. If the surfaces of the fracture are pulled apart, which may occur during reduction of the fracture, healing is delayed.

### Epiphyseal Plate Healing

If a fracture involves the epiphyseal plate, there may be growth disturbances and bony deformity as the skeleton continues to mature. The prognosis for growth disturbances depends on the type of injury, age of the child, blood supply to the epiphysis, method of reduction, and whether it is a closed or open injury.

## Principles of Management: Period of Immobilization

### Local Tissue Response

With immobilization, there is connective tissue weakening, articular cartilage degeneration, muscle atrophy, and contracture development as well as sluggish circulation.<sup>37,66,101</sup> In addition, there is soft tissue injury with bleeding and scar formation.<sup>132</sup> Because immobilization is necessary for bone healing, the soft tissue scar cannot become organized along lines of stress as it develops (described in Chapter 10). Early, nondestructive motion within the tolerance of the fracture site is ideal but usually not feasible unless there is some type of internal fixation to stabilize the fracture site. It is important to keep structures in the related area in a state as near normal as possible by using appropriate exercises without jeopardizing alignment of the fracture site while it is healing. The therapist must be alert to complications that can occur following a fracture (summarized in Box 11.7).

### Immobilization in Bed

If bed rest or immobilization in bed is required, as with skeletal traction, secondary physiological changes occur systematically throughout the body. General exercises for the uninvolved portions of the body are initiated to minimize these problems.

### Functional Adaptations

If there is a lower extremity fracture, alternative modes of ambulation, such as the use of crutches or a walker, are taught to the patient who is allowed out of bed. The choice of device

**BOX 11.7 Complications of Fractures<sup>66</sup>**

- *Swelling* that is contained within a compartment (fascial compartment or tight cast) leading to nerve and circulatory compromise.
- *Fat embolism* (may occur with fracture in bones with the most marrow, such as long bones and the pelvis) that migrates to the lungs and blocks pulmonary vessels. This is potentially life-threatening.
- *Skin ulceration, nerve injury, or vascular compromise*
- *Problems with fixation devices* such as displacement of screws and breakage of wires
- *Infection* that occurs locally or systemically
- *Refracture*
- *Delayed union or malunion*

and gait pattern depends on the fracture site, the type of immobilization, and the functional capabilities of the patient. The patient’s physician should be consulted to determine the amount of weight bearing allowed. Management guidelines are summarized in Box 11.8.

**Postimmobilization**

**Impairments**

- Decreased ROM, joint play, and muscle flexibility.
- Muscle atrophy with weakness and poor muscle endurance.

- Initially, the patient experiences pain as movement begins, but it should progressively decrease as joint movement, muscle strength, and ROM improve.
- If there was soft tissue damage at the time of the fracture, an inelastic scar restricts tissue mobility in the region of the scar.

**Management: Postimmobilization**

Management guidelines are summarized in Box 11.9.

Consultation with the referring physician is necessary to determine if there is clinical or radiological healing. Until the fracture site is radiologically healed, care should be used any time stress is placed across the fracture site, such as when applying resistance or a stretch force or during weight-bearing activities. Once radiologically healed, the bone has normal structural integrity and can withstand normal stress.

The patient is examined to identify impairments and determine the current functional status, activity level, and desired outcome. ROM, joint mobility, and muscle performance, as well as any other impairments, are measured and documented. Usually all of the joint and periarticular tissues are affected in the region that was immobilized.

Typical interventions include:

- **Joint mobilization.** Joint mobilization techniques are effective for regaining lost joint play without traumatizing the articular cartilage or stressing the fracture site.<sup>79</sup> Intervention begins with grade I and II techniques and progresses to more aggressive grades as joint reaction becomes predictable and progresses in intensity as joint reaction becomes predictable.

**BOX 11.8 MANAGEMENT GUIDELINES—  
Postfracture/Period of Immobilization**

**Impairments, Activity Limitations, and Participation Restrictions:**

Initially, inflammation and swelling

Progressive muscle atrophy, contracture formation, cartilage degeneration, and decreased circulation in the immobilized area

Potential overall body weakening/complications if confined to bed (deep vein thrombosis, pulmonary embolism, pneumonia)

Limited activity and restricted participation in ADLs, IADLs, and work imposed by the fracture site and method of immobilization used

Plan of Care	Intervention
1. Educate the patient.	1. Teach functional adaptations. Teach safe ambulation, bed mobility.
2. Decrease effects of inflammation during acute period.	2. Ice, elevation
3. Decrease effects of immobilization.	3. Intermittent muscle setting. Active ROM to joints above and below immobilized region.
4. If patient is confined to bed, maintain ROM and strength in major muscle groups.	4. ROM activities to all areas not immobilized Resistive exercises to major muscle groups not immobilized, especially in preparation for future ambulation

**BOX 11.9 MANAGEMENT GUIDELINES—  
Postfracture/Postimmobilization**
**Impairments:**

Pain with movement, which progressively decreases  
 Decreased ROM  
 Decreased joint play  
 Scar tissue adhesions  
 Decreased strength and endurance

**Plan of Care**
**Interventions**

1. Educate the patient.	1. Inform patient of limitations until fracture site is radiologically healed. Teach home exercises that reinforce interventions.
2. Provide protection until radiologically healed.	2. Use partial weight bearing in lower extremity and nonstressful activities in the upper extremity.
3. Initiate active exercises.	3. Active ROM, gentle multi-angle isometrics
4. Increase joint and soft tissue mobility.	4. Initiate joint play stretching techniques (using grades III and IV) with the force applied proximal to the healing fracture site. For muscle stretching, apply the force proximal to the healing fracture site until radiologically healed.
5. Increase strength and muscle endurance.	5. As the ROM increases and the bone heals, initiate resistive and repetitive exercises.
6. Improve cardiorespiratory fitness.	6. Initiate safe aerobic exercises that do not stress the fracture site until it is healed.

**PRECAUTIONS:** No stretch or resistive forces distal to the fracture site until the bone is radiologically healed. No excessive joint compression or shear for several weeks after the period of immobilization. Use protected weight bearing until the site is radiologically healed.

- **PNF Stretching.** Hold-relax and agonist-contraction techniques are used during the postimmobilization period because the intensity can be controlled by the patient. It is important to monitor the intensity of contraction and to not apply the resistive or stretch force beyond the fracture site until there is radiological healing of the bone in order to avoid a bending force across the fracture site. Once the bone is radiologically healed, the stretch force can be applied beyond the fracture site.
- **Functional activities.** The patient can resume normal activities with caution. During the early postimmobilization period, it is important to not traumatize the weakened muscle, cartilage, bone, and connective tissue. Partial weight bearing must be continued for several weeks after a lower extremity fracture until the fracture site is completely healed and able to tolerate full weight bearing.
- **Muscle performance: Strengthening and muscle endurance.** For 2 to 3 weeks following immobilization, because neither the bone nor cartilage can tolerate excessive compressive or bending forces, exercises are initiated with light isometrics. As joint play and ROM improve, progression is made to light resistance through the available range. The resistive force should be applied proximal to the fracture site until the bone is radiologically healed. Once healed, PRE and other more intense dynamic exercises can be initiated.
- **Scar tissue mobilization.** If there is restricting scar tissue, manual techniques to mobilize the scar are used. The choice of technique depends on the tissue involved.

## Independent Learning Activities

### Critical Thinking and Discussion

1. Your patient sustained a traumatic knee joint injury in an automobile accident. There is joint effusion, limited ROM, and decreased joint play 2 days after the accident. X-rays have cleared the area of any fractures. The patient guards against motion as you approach the end of the available range. Identify the principles of treatment, the goals, and plan of care for this patient. Describe and practice specific therapeutic techniques that you would use for intervention and describe how you would progress the techniques through the stages of healing.
2. Develop a program of interventions for a patient with OA in the knees who has pain when ascending and descending steps and has difficulty standing up from a chair. What examination procedures do you want to do? What functional tests do you want to document? How would the program differ for an individual with symptoms of RA during a period of active disease (the acute phase)? During a period of remission (the chronic phase)?
3. Describe your plan of care and list specific interventions for a 55-year-old woman who is postmenopausal and has early signs of osteoporosis. What patient instructions would be important to include?
4. An individual sustained a fracture 6 weeks ago, and the limb was just removed from the cast. How does treatment differ from that of other traumatic conditions 6 weeks post injury? Describe what precautions you will follow and why they are important.
5. Your patient was involved in a motor vehicle accident 6 months ago. You saw her 3 months ago, but now she has returned with a diagnosis of FM. Her physician recommends exercise. Describe your treatment program, taking into consideration the characteristics of FM and the benefits and problems of exercise in this population.
6. Your new patient is a secretary who presents with upper back and neck pain. She describes a gradual onset. She reports sitting at a computer for 6 to 8 hours each day and having to take phone calls on a regular basis as well. You examine the patient and find several active MTrPs. Describe your course of treatment for this patient. How will you address the effect her work has on her problem?

Joint Procedures 373

Extra-articular Bony Procedures 377

Independent Learning Activities 379

Many injuries, diseases, and disorders of the musculoskeletal system can be associated with levels of impairment so significant that surgical intervention is required. These impairments can affect all musculoskeletal tissues—muscles, tendons, ligaments, cartilage, fascia, joint capsules, or bones—of the upper or lower extremities or spine. Ideally, surgery is preceded by a comprehensive examination and evaluation of the patient's impairments and functional status, coupled with preoperative patient education. Following surgery, a planned course of postoperative rehabilitation is usually warranted.

This chapter provides an overview of the indications for surgical intervention for musculoskeletal pathology, describes considerations for preoperative management, notes factors that influence the outcomes of surgery, provides general rehabilitation guidelines following surgery, and identifies potential complications that may interfere with the achievement of optimal functional outcomes. The chapter concludes with an overview of several orthopedic surgical procedures that may be undertaken for the management of musculoskeletal conditions

Descriptions of selected surgical procedures for common injuries or disorders of each region of the extremities are provided in Chapters 17 through 22. In these chapters, guidelines and progressions for postoperative management of specific surgeries are presented that are based on the principles of tissue healing and exercise prescription addressed in Chapter 10, rather than adherence to specific protocols. These principles can be applied by the therapist when designing exercise interventions for patients undergoing current surgical procedures and can also be applied as a

foundation for future rehabilitation strategies as surgical interventions change and evolve.

## Indications for Surgical Intervention

Many acute, recurring, and chronic musculoskeletal conditions are managed successfully with conservative measures, such as rest, protection with splinting or use of assistive devices, medication, therapeutic exercise, manual therapy, functional training, and the use of physical agents or electrotherapy. However, surgical intervention is the best treatment option when a conservative program has not been successful in adequately modifying impairments or restoring function, or if the severity of a patient's condition is beyond the level that is appropriate for conservative management. Indications for a variety of musculoskeletal surgeries are identified in Box 12.1.<sup>11,13,16,62</sup>

## Guidelines for Preoperative and Postoperative Management

Although surgical intervention can correct or reduce the adverse conditions and impairments associated with musculoskeletal pathology, a carefully planned and progressed

### BOX 12.1 Indications for Surgery for Musculoskeletal Disorders of the Extremities and Spine

- Incapacitating pain at rest or with functional activities
- Marked limitation of active or passive motion
- Gross instability of a joint or bony segments
- Joint deformity or abnormal joint alignment
- Significant structural degeneration
- Chronic joint swelling
- Failed conservative (nonsurgical) or prior surgical management
- Significant loss of function leading to disability as the result of any of the preceding factors

rehabilitation program is essential for the patient to achieve optimal functional outcomes after surgery. Ideally, rehabilitation begins with patient education and “prehabilitation” exercises or functional skill development before surgery and continues with direct intervention from a therapist and long-term self-management by the patient after surgery.

## Considerations for Preoperative Management

Direct communication with the patient prior to pre-planned, elective surgery is advisable, preferably on a one-to-one basis between therapist and patient, but a group setting can also be used. In the current health-care environment, authorization for reimbursable preoperative consultations with individual patients is often difficult. However, preoperative contact with a group of patients scheduled for similar surgeries may be possible. The benefits of preoperative communication and instruction with a patient include the ability to assess their preoperative functional status, to discuss their goals and expectations following surgery, to establish rapport, and to educate the patient regarding postoperative rehabilitation.

There are several elements of preoperative management, including a comprehensive examination and evaluation of a patient’s preoperative status, patient education, an opportunity for the patient to ask questions about the procedure, instruction regarding postoperative care, and providing a preoperative exercise program if appropriate.

## Preoperative Examination and Evaluation

When a preoperative visit is approved for an individual patient, the therapist can perform a comprehensive examination to determine the patient’s impairments and functional status prior to surgery.<sup>61,74</sup> The therapist can evaluate the findings of the examination to identify the patient’s needs and goals, document the pre-surgical level of function, and generate a prognosis regarding the expected functional outcomes following surgery.

Examination of specific factors is particularly important for developing realistic goals and estimating functionally relevant outcomes of surgery and postoperative rehabilitation.<sup>74</sup> These factors are also emphasized in the postoperative examination and in subsequent evaluations during rehabilitation.

- *Pain.* Quantitatively measure the patient’s level of pain with a visual analog scale or a scale that identifies the degree of pain with specific functional activities.
- *Range of motion and joint integrity.* Measure both active and passive range of motion (ROM) of the involved joint or extremity and compare it to the ROM of the uninvolved areas. Evaluate the quality of active joint motion. Assess joint stability using passive accessory mobility testing and special tests specific to passive restraints.
- *Skin integrity.* Note the presence of scars from previous injuries or surgeries, particularly those that are adherent and restrict mobility of skin or underlying connective tissue and joints.
- *Muscle performance.* Evaluate muscle strength of the affected areas, recognizing that pain adversely affects strength. Assess the functional strength of unaffected body segments in anticipation of postoperative needs such as ambulation with assistive devices, transfers, and activities of daily living (ADLs).
- *Posture.* Identify the patient’s preferred positions for comfort and any postural abnormalities that may affect ROM and function.
- *Gait analysis.* Analyze the gait characteristics, type of supportive or protective devices currently used, and degree of weight bearing tolerated during ambulation.
- *Functional status.* Identify the patient’s preoperative functional activity limitations and functional abilities and his or her perception of disability associated with participation restrictions using a quantitative, self-report measurement tool. A valid and reliable outcome measure should be used if available and specific to the body region.

## Preoperative Patient Education: Methods and Rationale

Patient education can begin preoperatively during an individual instruction session with a patient or in a group setting with patients planning to undergo similar surgeries. Some large, acute-care facilities have education programs for patients scheduled for joint replacement surgery that use group instruction by team members from several disciplines, including nursing, physical therapy, and occupational therapy.<sup>28,46,52</sup> The group programs may also include a tour of the operating and recovery rooms. Programs such as these may help a patient understand what to expect the day of surgery and during the early postoperative phase, possibly alleviating some of a patient’s anxiety about the surgery and hospital experience.

Preoperative instruction gives a patient an opportunity to learn about factors associated with surgery such as wound care, special precautions that must be followed after surgery, and the use of assistive or supportive equipment such as crutches, an immobilizer, or a sling.<sup>61,74</sup> Of equal importance, the patient can

learn and practice early postoperative exercises without being hampered by postoperative pain or the side effects of pain medication, such as disorientation and drowsiness.<sup>61,74</sup> If surgery is scheduled as an outpatient procedure, preoperative instruction teaches the patient skills needed to be safe at home and the postoperative exercises they can perform at home before formal rehabilitation with the therapist begins.

### Components of Preoperative Patient Education

- *Overview of the plan of care.* Explain the overall plan of care the patient can expect during the postoperative period.
- *Postoperative precautions.* Advise the patient of any precautions or contraindications to positioning, movement, or weight bearing that must be followed postoperatively.
- *Bed mobility and transfers.* Teach the patient how to move in bed or perform wheelchair transfers safely, incorporating the necessary postoperative precautions.
- *Initial postoperative exercises.* Teach the patient any exercises that will be started during the very early postoperative period. These exercises often include:
  - *Deep-breathing and coughing exercises.* Explain the rationale for periodically performing deep-breathing exercises throughout the day.
  - *Active ankle exercises (pumping exercises).* Teach the patient how to reduce postoperative venous stasis and decrease the risk of deep vein thrombosis (DVT).
  - *Gentle muscle-setting exercises of immobilized joints.*
- *Gait training.* Teach the patient to use supportive devices that may be needed for protected weight bearing during ambulation after surgery, such as crutches or a walker.
- *Wound care.* Explain or reinforce postoperative care of the incision for optimal wound healing.
- *Pain management.* Educate on the correct use of cryotherapy for postoperative pain management.

### FOCUS ON EVIDENCE

Although preoperative education is considered a valuable component of the preparation and recovery from surgery, evidence supporting its effectiveness is limited. McDonald et al reviewed 18 randomized or quasi-randomized trials evaluating the effectiveness of preoperative patient education prior to hip or knee arthroplasty and found no added benefit with respect to reducing anxiety, or for improved surgical outcomes like pain, function, or number of adverse events.<sup>58</sup>

### An Extended Preoperative Exercise Program

The rationale for implementing an exercise program prior to a planned surgical procedure is to limit further progression of impairments, such as long-standing strength and ROM deficits, that have developed as the result of the musculoskeletal condition requiring surgery, to improve the likelihood that learning will carry over and exercises will be performed correctly

following surgery, and to increase the likelihood of achieving optimal postoperative functional outcomes.<sup>47,75</sup>

A preoperative exercise program may be particularly beneficial if a prolonged period of immobilization or reduced weight bearing is necessary after surgery.

### FOCUS ON EVIDENCE

Studies evaluating the effectiveness of an exercise program initiated prior to a planned orthopedic surgical procedure have reported mixed results. Kean and colleagues<sup>47</sup> studied the functional impact of a strengthening program initiated prior to high tibial osteotomy in a relatively young, active group of patients with medial compartment osteoarthritis. Fourteen individuals (13 men and 1 woman, mean age 48 years) participated in a supervised isokinetic resistance training program for the quadriceps and hamstrings muscle groups 3 times a week for 12 weeks prior to surgery, leading to significant gains in strength. They also participated in postoperative rehabilitation. The functional status of the experimental group was compared with a matched control group of patients who also had undergone high tibial osteotomy and postoperative rehabilitation, but no preoperative resistance training. At 6 months postsurgery, the preoperative resistance training group scored significantly better than the control group on ADL and recreational/sports participation subscales of a quantitative measurement tool assessing function in individuals with knee arthritis.

In contrast, Rooks and associates<sup>75</sup> found that despite a 20% increase in lower extremity strength as the result of a preoperative exercise program in a group of patients scheduled to undergo total hip or knee arthroplasty, there were no significant improvements in postoperative functioning compared with that of a control group. Key differences in these studies were the type of preoperative resistance training programs, the mean ages of the participants, and degree of joint arthritis.

A recent systematic review of seventeen studies that provided prehabilitation prior to surgery demonstrated no benefit to patients over usual care at any time point following surgery. Prehabilitation programs consisted of aerobic exercises, strength training, and/or functional task training, and main outcome measures included quality of life, pain, hospital readmission, and nursing home placement. The majority of studies (13) included patients planning hip or knee arthroplasty. The lone positive finding was that a dose of over 500 hours of prehabilitation minimized the need for postoperative rehabilitation.<sup>15</sup>

### Considerations for Postoperative Management

A well-planned rehabilitation program, composed of a carefully progressed sequence of therapeutic exercise, functional training, and ongoing patient education, is fundamental to

the patient's postoperative care. Appropriate rehabilitative management must consider many factors, all of which will affect the components, the progression, and the outcomes of a patient's postoperative program. These factors are noted in Box 12.2. Ultimately, the success of the surgical procedure is closely linked with the effectiveness of the postsurgical rehabilitation.

To design a safe, effective, efficient rehabilitation program for a patient, the therapist must understand the indications and rationale for a particular surgical procedure; become familiar with the procedure itself; be aware of special precautions related to the surgery; and communicate effectively with the patient, surgeon, and other members of the rehabilitation team.<sup>31</sup>

### Postoperative Examination and Evaluation

Every postoperative rehabilitation program must be based on initial and ongoing examinations of the individual patient. In addition to the components of a preoperative examination noted previously in this section, an assessment of integumentary integrity is important after surgery. The incision should be inspected before and after each exercise session to identify any evidence of wound infection or delayed healing. Inspection of the surgical site includes the items noted in Box 12.3.

### Phases of Postoperative Rehabilitation

Postoperative rehabilitation is most often divided into phases, with each phase containing goals and suggested interventions. Phases can be distinguished in several ways: by the transitional sequences of tissue healing (acute/inflammatory, subacute/proliferative, chronic/remodeling), by the permitted level activity (initial, intermediate, advanced), by the degree of protection of healing tissues (maximum, moderate,

#### BOX 12.3 Inspection of the Surgical Incision

- Check for signs of redness or tissue necrosis along the incision(s) and around sutures.
- Palpate along the incision and note signs of tenderness and edema.
- Palpate to determine evidence of increased heat.
- Check for signs of drainage; note color and amount of drainage on the dressing.
- Note the integrity of an incision across a joint *during and after* exercise.
- As the incision heals, check the mobility of the scar.

minimum protection), or simply by sequential numbering (e.g., I, II, III).

As with non-operative management of musculoskeletal pathology, the phase descriptions all reflect to some extent the stages of healing of involved soft tissue and bone. In addition, phases of postoperative rehabilitation must account for particular elements of the surgical procedure, such as the type of surgical approach or tissue fixation.

In general, the goals and interventions across the phases of postoperative rehabilitation are established to safely progress the patient toward functional recovery. Early after surgery, the emphasis of management focuses on minimizing pain, preventing postoperative complications, and resuming a safe level of functional mobility while protecting the surgical site. Later, as tissues heal and the patient recovers from surgery, interventions are directed toward restoring or improving range of motion (ROM), strength, neuromuscular control, stability, balance, and muscular and cardiopulmonary endurance, as well as the patient's ability to perform all necessary and desired functional activities.

Phases of postoperative rehabilitation do not take into account the individual qualities, needs, and abilities of each patient, nor do they consider how a modification to the normal surgical procedure may impact care. Therefore, the phases are intended as general guidelines for management rather than prescriptive programs. To develop an individualized rehabilitation program for the patient, the suggested guidelines for each phase should be modified based on the results of ongoing postoperative examination of the patient.

Recognizing the differences among various surgical procedures and the fact that each patient's recovery after surgery is unique, guidelines for postoperative rehabilitation in this section are divided into three broad, overlapping phases based on the degree of protection of operated structures. The characteristics of these three phases are as follows.

- **Maximum protection phase.** This is the initial postoperative period when protection of operated tissues is paramount in the presence of tissue inflammation and pain. After some surgeries, immobilization of the operated area is necessary during this phase. After other surgeries, it is advisable to

#### BOX 12.2 Factors That Influence the Components, Progression, and Outcomes of a Postoperative Rehabilitation Program

- Extent of tissue pathology or damage
  - Size or severity of the lesion
- Type and unique characteristics of the surgical procedure
- Patient-related factors
  - Age, extent of preoperative impairments, and functional limitations
  - Health history, particularly use of medications and diabetes
  - Lifestyle history, including use of tobacco
  - Needs, goals, expectations, and social support
  - Level of motivation and ability to adhere to an exercise program
- Stage of healing of involved tissues
- Characteristics of types of tissues involved
  - Response to immobilization and remobilization
  - Integrity of structures adjacent to involved tissues
- Philosophy of the surgeon

place low-level stresses on operated tissues soon after surgery, making early passive or assisted ROM within a protected range or within a patient's tolerance permissible. In both situations, muscle-setting exercises to prevent muscle disuse atrophy also are indicated. The time frame for maximum protection ranges from a few days to 6 weeks depending on the type of surgery and the tissues involved.

- **Moderate protection phase.** This is the intermediate phase of rehabilitation when inflammation has subsided, pain and tenderness are minimal, and tissues are able to withstand gradually increasing levels of stress. Criteria for progression to this phase often include the absence of pain at rest and the availability of at least limited pain-free movement of the operated extremity. There is an emphasis on restoring ROM and normal arthrokinematics while tissues continue to heal and remodel, improving neuromuscular control and stability, and gradually increasing strength during this phase. Depending on the healing characteristics of the operated tissues, this phase typically begins around 4 to 6 weeks postoperatively and continues for an additional 4 to 6 weeks.
- **Minimum protection/return to function phase.** During this advanced phase, little to no protection of operated tissues is

required. To progress to this phase, full (or almost full) pain-free active ROM should be available and the joint capsule (if involved) should be clinically stable. Strength requirements to begin this phase vary widely depending on the procedure. Rehabilitation focuses on restoring functional strength and gradually progressing the patient's functional activities. This phase begins anywhere from 6 to 12 weeks postoperatively and may continue until 6 months postoperatively or beyond.

Box 12.4 summarizes general management guidelines for postoperative rehabilitation, including the common structural and functional impairments that must be addressed and a plan of care with suggested goals and interventions for each phase of rehabilitation. Postsurgical guidelines for specific surgeries at each region are provided in Chapter 15 and Chapters 17 through 22.

### Time-Based and Criterion-Based Progression

Time frames for each phase of rehabilitation can vary dramatically depending on the procedure. For example, immediately after an arthroscopic meniscectomy, the maximum protection phase during which movement of the operated

#### BOX 12.4 MANAGEMENT GUIDELINES— Postoperative Rehabilitation

##### Structural and Functional Impairments:

- Postoperative pain because of disruption of soft tissue
- Postoperative swelling
- Potential circulatory and pulmonary complications
- Joint stiffness or limitation of motion because of injury to soft tissue and necessary postoperative immobilization
- Muscle disuse atrophy because of immobilization
- Loss of strength for functional activities
- Limitation of weight bearing
- Potential loss of strength and mobility of non-operated joints

##### Maximum Protection Phase

Plan of Care	Interventions
1. Educate the patient in preparation for self-management.	1. Instruction in safe positioning and limb movements and special postoperative precautions or contraindications.
2. Decrease postoperative pain, muscle guarding, or spasm.	2. Relaxation exercises. Use of modalities such as transcutaneous electrical nerve stimulation (TENS), cold, or heat. Continuous passive motion (CPM) during the early postoperative period.
3. Prevent wound infection.	3. Instruction or review of proper wound care (cleaning and dressing the incision).
4. Minimize postoperative swelling.	4. Elevation of the operated extremity. Active muscle pumping exercises at the distal joints. Use of compression garment. Gentle distal-to-proximal massage.

**Plan of Care**
**Interventions**

- |   |   |
|---|---|
| 1. Continue patient education.  | 1. Emphasize gradual but progressive incorporation of improved muscle performance, mobility, and balance into functional activities.  |
| 2. Prevent re-injury or postoperative complications.                          | 2. Reinforce self-monitoring and review the signs and symptoms of excessive use; identify unsafe activities.  |
| 3. Restore full joint and soft tissue mobility, if possible.                  | 3. Joint stretching (mobilization) and self-stretching techniques.  |
| 4. Maximize muscle performance, dynamic stability, and neuromuscular control. | 4. Progressive strengthening exercises using higher loads and speeds and combined movement patterns.<br>Integrate movements and positions into exercises that simulate functional activities. |

### BOX 12.4 MANAGEMENT GUIDELINES— Postoperative Rehabilitation—cont'd

#### Plan of Care

5. Restore balance and coordinated movement.

6. Acquire or relearn specific motor skills.

#### Interventions

5. Progressive balance and coordination training.

6. Apply principles of motor learning (appropriate practice and feedback during task-specific training).

**PRECAUTIONS:** In addition to the precautions already addressed that relate to the stages of tissue repair and healing, there are several additional precautions that are of particular importance to the postoperative patient.

- Avoid positions, movements, or weight bearing that could compromise the integrity of the surgical repair.
- Keep the wound clean to avoid postoperative infection. Monitor for wound drainage and signs of systemic or local infection, such as elevated temperature.
- Avoid vigorous/high-intensity stretching or resistance exercises with soft tissues, such as muscles, tendons, or joint capsules that have been repaired or reattached for at least 6 weeks to ensure adequate healing and stability.
- Modify level and selection of physical activities, if necessary, to prevent premature wear and tear of repaired or reconstructed soft tissues and joints.

joint is limited to passive or assisted motion within a protected range may extend for only 1 day postoperatively. However, after a complex tendon repair in the hand, maximum protection may be required for several weeks.

Although published descriptions of postoperative rehabilitation typically include estimated time frames for each phase of a program, these time periods must be considered general guidelines. Determining the patient's readiness to advance from one phase of postoperative rehabilitation to the next should not be based solely on time but also on the patient's attainment of predetermined criteria, such as the absence of pain or restoration of a particular amount of ROM or level of strength. However, at this time most published guidelines and protocols are time based and provide little or no information for making criterion-based decisions.

### Putting Postoperative Rehabilitation Into Perspective

Postoperative rehabilitation after an orthopedic surgical procedure is often a lengthy process. Given the limited number of justifiable therapy sessions available for postoperative management, it is highly unlikely for a therapist to have direct, ongoing contact with a patient through all phases of a rehabilitation program. Consequently, the key to successful postoperative outcomes is effective, long-term patient self-management. This approach includes therapist-directed, early postoperative patient education, followed by a home program of selected interventions—in particular, a progression of exercises that have been carefully taught and are periodically monitored and modified by the therapist during each phase of rehabilitation.<sup>38</sup>

### Potential Postoperative Complications and Risk Reduction

There are a number of serious complications that a patient may encounter after surgery, any one of which can adversely affect the outcomes of surgery and postoperative rehabilitation. Complications can manifest early (within 6 months after surgery) and/or late, and some aspects of preoperative patient education and postoperative interventions are included to reduce the risk of developing complications. Potential complications are described here and noted in Box 12.5.<sup>3,13,45,79</sup>

#### Pulmonary Complications

The risk of pneumonia or atelectasis (collapse of the lung caused by bronchial obstruction) is highest during the early postoperative period. General anesthesia and use of pain medication increase the risk of these complications, as does extended confinement to bed. Deep breathing exercises initiated on the day of surgery and early standing and ambulation following surgery may reduce this risk.

#### DVT and Pulmonary Embolism

Although there is an increased risk of development of a DVT and a subsequent pulmonary embolism in all patients who have undergone surgery, this risk is particularly increased after total joint replacement surgery of the hip or knee.<sup>21,89</sup> A therapist must be familiar with signs and symptoms and risk factors for these complications, as well as interventions for prevention or management. The next section of this chapter contains more detailed information about DVT and pulmonary embolism.

### BOX 12.5 Potential Postoperative Complications

- Pulmonary dysfunction, including pneumonia or atelectasis
- Local or systemic infection
- Deep vein thrombosis or pulmonary embolism
- Delayed wound healing
- Muscle function deficits secondary to tourniquet compression and resulting ischemia or nerve compression
- Failure, loosening, or displacement of internal fixation devices
- Delayed union of bone after fracture, osteotomy, or joint fusion
- Rupture of incompletely healed soft tissue after repair or reconstruction
- Subluxation or dislocation of joint surfaces or implants
- Nerve entrapment from scar tissue formation resulting in pain or sensory changes
- Adhesions and scarring leading to contractures of soft tissues and joint hypomobility
- Loosening of joint implants secondary to periprosthetic osteolysis or infection

### Joint Subluxation or Dislocation

If a joint capsule has been incised during surgery, as is the case for total joint replacement or an open labrum repair, there is an increased risk of postoperative joint dislocation. This risk can be reduced through patient education and exercise instruction. For example, a preoperative or postoperative program typically includes teaching a patient proper use of a removable immobilization device, such as a splint or sling, and the joint positions to avoid during exercises and ADL so that the incision site is protected from increased loading.

### Restricted Motion From Adhesions and Scar Tissue Formation

Postoperative contractures can develop as incised or repaired tissues progress through the healing process. Movement of the operated area as early as possible after surgery with ROM exercises or continuous passive motion (CPM) within a safe range is directed at maintaining the extensibility of soft tissues and preventing contractures.

### Failure, Displacement, or Loosening of Internal Fixation Device

Excessive or premature weight bearing prior to bony healing after open reduction and internal fixation of a fracture can cause loss of bone-to-bone apposition of the fracture site. Heavy lifting or strong muscle recruitment after a soft tissue repair in the upper extremity can cause rupture of sutured, but incompletely healed, tissues. Proper use of supportive devices, such as crutches or a walker, to control weight bearing during ambulation and appropriate progression of exercises

and functional activities can reduce the risk of these postoperative complications.

## Deep Vein Thrombosis and Pulmonary Embolism: A Closer Look

A thrombosis is a bolus of coagulated blood in the circulatory system. Lower extremity venous thrombosis can occur in the superficial or deep vein systems (Fig. 12.1).<sup>35</sup> A thrombus in one of the superficial veins in the calf usually is small and resolves without serious consequences.<sup>73</sup> In contrast, thrombus formation in a deep vein in the calf, thigh, or pelvic region, known as DVT, tends to be larger and can cause serious complications. When a clot breaks away from the wall of a vein and travels proximally, it is called an *embolus*. When an embolus affects pulmonary circulation, it is called a *pulmonary embolism*, which is a potentially life-threatening disorder.<sup>35,73</sup>

FIGURE 12.1 Veins of the lower extremity.

## Risk Factors for DVT

A lower extremity DVT is a common complication after musculoskeletal injury or surgery, prolonged limb immobilization, or bed rest and is attributed to venous stasis, injury to and inflammation of the walls of a vein, or a hypercoagulable state of the blood.<sup>39,87</sup> Risk factors for DVT are listed in Box 12.6.<sup>32,35,39,73</sup>

## DVT: Signs and Symptoms

During the early stages of a DVT, only 25% to 50% of cases can be recognized by clinical manifestations, such as dull aching or severe pain, swelling, or changes in skin temperature and color, specifically heat and redness.<sup>2,35,39,73</sup>

The Wells Criteria<sup>88</sup> provide the clinician with a tool to establish the likelihood of a lower extremity DVT when the condition is suspected. The criteria include both patient history and physical signs, and the presence of two or more clinical features indicate that a DVT is likely, while fewer than two suggests a DVT is unlikely.<sup>88</sup> Box 12.7 lists the Wells criteria. When a DVT is likely based on the clinical features present, medical testing should be initiated to confirm or rule out the condition. Only diagnostic imaging, such as ultrasonography, venous duplex screening, or venography, can confirm a DVT.<sup>2,87</sup>

## Pulmonary Embolism: Signs and Symptoms

As described previously, pulmonary embolism is a possible consequence of DVT. Risk factors for pulmonary embolism are similar to those already identified for DVT (see Box 12.6).

The signs and symptoms of pulmonary embolism vary considerably depending on the size of the embolus, the extent of lung involvement, and the presence of coexisting cardiopulmonary conditions.<sup>93</sup> The hallmark signs and symptoms are a sudden onset of shortness of breath (dyspnea), rapid and shallow breathing (tachypnea), and chest pain located at the lateral aspect of the chest that intensifies with

### BOX 12.7 Wells Criteria for Likelihood of Deep Vein Thrombosis<sup>88</sup> (A score of 2 or more points indicates a DVT is likely)

Clinical Feature	Points
Active cancer (treatment ongoing, within 6 months, or palliative care)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bedridden for 3 days or longer, or major surgery requiring general or regional anesthesia within 12 weeks	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than asymptomatic side	1
Pitting edema confined to symptomatic leg	1
Collateral superficial veins	1
Previously documented DVT	1
Alternative diagnosis at least as likely as DVT	-2

deep breathing and coughing. Other signs and symptoms include swelling in the lower extremities, anxiety, fever, excessive sweating (diaphoresis), a cough, and blood in the sputum (hemoptysis).<sup>93</sup>

If a patient presents with signs or symptoms of possible pulmonary embolism, immediate medical referral is warranted for a definitive diagnosis and management.

## Reducing the Risk of DVT

Every effort should be made to reduce the risk of a DVT and subsequent thrombophlebitis in patients who have undergone a surgical procedure, particularly a lower extremity procedure. The following medical/pharmacological and exercise-related interventions are implemented for risk reduction.<sup>21,43,87,89</sup>

### BOX 12.6 Risk Factors for Deep Vein Thrombosis and Thrombophlebitis

- Postoperative or postfracture immobilization
- Prolonged bed rest
- Sedentary lifestyle or extended episode of sitting
- Prolonged standing (>6 hours)
- Trauma to venous vessels
- Limb paralysis
- Active malignancy (within past 6 months)
- History of deep vein thrombosis or pulmonary embolism
- Advanced age
- Obesity
- Congestive heart failure
- Use of oral contraceptives
- Pregnancy

- Prophylactic use of anticoagulant therapy (high molecular weight heparin) for the high-risk patient because of a lower extremity surgery or extended bed rest
- Elevating the legs when lying supine or when sitting
- No prolonged periods of sitting, especially for the patient with a long-leg cast
- Initiating ambulation as soon as possible after surgery, preferably no more than a day or two postoperatively
- Active “pumping” exercises (active dorsiflexion, plantarflexion, and circumduction of the ankle) regularly throughout the day when lying supine
- Use of compression stockings to support the walls of the veins and minimize venous pooling
- Use of a sequential pneumatic compression unit for patients on bed rest

### CLINICAL TIP

In addition to medical/pharmacological management with administration of early postoperative, anticoagulant drugs,<sup>21,89</sup> 1 minute of active ankle pumping exercises performed at regular intervals during the day has been shown to increase venous blood flow (for up to 30 minutes after exercise) and decrease venous stasis in the calf after total hip replacement surgery.<sup>60</sup> Therefore, ankle pumping exercises are thought to decrease the risk of developing a DVT. Early ambulation (before day 2) after surgery also promotes circulation and reduces the risk of a DVT.<sup>89</sup>

### Management of DVT

**Acute care management.** If the presence of DVT and resulting thrombophlebitis is confirmed, immediate medical intervention is essential to reduce the risk of pulmonary embolism. Initial management includes administering anticoagulant medication, placing the patient on bed rest, elevating the involved extremity, and using graduated compression stockings. The reported time frame for bed rest varies from 2 days to more than a week.<sup>1</sup> Box 12.8 summarizes the guidelines for management of acute DVT and thrombophlebitis.<sup>1,54</sup>

### FOCUS ON EVIDENCE

A **clinical practice guideline** (CPG) for management of individuals at risk for or diagnosed with venous thromboembolism, developed by the APTA, provides 14 key action statements for therapists to consider in making decisions regarding care of patients with this condition.<sup>42</sup> The overall main points are that physical therapists:

- Are an integral part of the health care team in identifying those at risk for venous thromboembolism and lower extremity DVT;
- Should advocate for preventive measures in those determined to be at risk; should use the Wells criteria for assessing the degree of DVT risk;
- Should mobilize patients with a confirmed lower extremity DVT once therapeutic levels of anticoagulation medication are reached; and
- Can minimize future complications for patients after DVT through education, mechanical compression, and exercise.<sup>42</sup>

During the period of bed rest, exercises usually are contraindicated because movement of the involved extremity may cause pain and is thought to increase congestion in the venous channels when tissues are inflamed. It is currently suggested that ambulation can begin after anticoagulant therapy reaches

## BOX 12.8 MANAGEMENT GUIDELINES— Deep Vein Thrombosis and Thrombophlebitis

### Structural and Functional Impairments

Dull ache or pain usually in the calf  
Tenderness, warmth, and swelling with palpation

### Plan of Care

1. Relieve pain during the acute inflammatory period.
2. Begin mobility when therapeutic levels of anticoagulant medication have been administered.
3. As acute symptoms subside, regain functional mobility.
4. Prevent recurrence of the acute disorder.

### Interventions

1. Bed rest, pharmacological management (systemic anticoagulant therapy); elevation of the affected lower extremity, maintaining slight knee flexion.
2. Progressively increasing ambulation and functional activity training while graded compression stockings are worn by patient.
3. Continue graded ambulation with legs in pressure-gradient support stockings.
4. Continuation of appropriate medical and pharmacological management. Use of strategies to prevent DVTs.

**CONTRAINDICATIONS:** Passive or active motion or application of moist heat; use of a sequential pneumatic compression pump.

**PRECAUTIONS:** Following discharge but while continuing anticoagulant medication, avoid contact sports and high fall risk physical activities.

therapeutic levels, and the therapist should consult the medical team regarding the timing of initiating this intervention.<sup>42</sup>

### FOCUS ON EVIDENCE

Aldrich and colleagues<sup>1</sup> conducted a systematic review of the literature to determine when a patient with DVT should be allowed to begin walking. The review revealed a limited number of studies (a total of five, three of which were randomized, controlled trials) that addressed this issue. Results of these studies suggest that early ambulation, begun within the first 24 hours after initiating anticoagulant therapy, does not increase the incidence of pulmonary embolism in patients without an existing pulmonary embolism and who have adequate cardiopulmonary reserve. However, if a patient has a known pulmonary embolism, an ambulation program must be initiated more cautiously. It is important to note that in the studies reviewed all patients who participated in an early ambulation program wore compression garments.

The results also revealed that early ambulation is associated with more rapid resolution of pain and swelling. The authors of the review were unable to identify studies that investigated the initiation and progression of other forms of exercise for patients with DVT.

**Posthospitalization precautions.** Following discharge, a patient typically continues on an anticoagulant medication for about 6 months. During that time period, the patient must avoid contact sports, running, and skiing; however, treadmill walking or jogging and use of an elliptical trainer is permitted. Mandatory helmet use also is advisable during participation in high “fall risk” activities.<sup>32</sup>

## Overview of Common Orthopedic Surgeries and Postoperative Management

Surgical management of musculoskeletal conditions encompasses a wide variety of procedures. Orthopedic surgery procedures can be divided into several broad categories, including repair, reattachment, reconstruction, stabilization, replacement, realignment, transfer, release, resection (excision), fixation, and fusion.<sup>17,33,77</sup> Examples of specific procedures in these categories are identified in Table 12.1.

The purpose of this final chapter section is to provide brief descriptions of some surgical procedures in these categories and a broad overview of the place of therapeutic exercise in postoperative rehabilitation. Factors such as duration of immobilization following surgery and the timing, intensity and progression of exercise will vary based on the surgical techniques used, the surgeon’s philosophy, and patient’s response to surgery and postoperative therapy. Chapters 17 through 22

contain more extensive descriptions of selected surgical procedures and progressions of postoperative management for each region of the upper and lower extremities. For more detailed descriptions of specific surgeries and operative techniques for musculoskeletal conditions from the orthopedic surgeon’s perspective, many textbooks and journals are available for reference.<sup>17,33,37,59,66,80,90</sup> The specific aspects of an individual patient’s surgical procedure should be known prior to designing and implementing a safe and effective postoperative exercise program and this information is available in the operative report in the patient’s medical record and through communication with the surgeon.

## Surgical Approaches

### Open Procedures

An open surgical procedure involves an incision of adequate length and depth through the necessary superficial and deep layers of skin, fascia, muscles, and joint capsule that allows the operative field to be fully visualized by the surgeon during the procedure.<sup>57,77</sup> The term *arthrotomy* is used to describe an open procedure in which the joint capsule is incised to expose joint structures. Open approaches are necessary for surgeries such as joint replacement, arthrodesis, or internal fixation of fractures and for some soft tissue repairs and reconstruction such as tendon or ligament tears. Open procedures result in extensive disturbance of soft tissues and require a lengthy period of rehabilitation to allow soft tissue healing.

### Arthroscopic Procedures

Arthroscopy is used as a diagnostic tool and as a means of treating a variety of intra-articular disorders.<sup>29,59,72,82</sup> Arthroscopic procedures are typically performed on an outpatient basis and often under local anesthesia.

Arthroscopy involves several very small incisions (portals) in the skin, muscle, and joint capsule for insertion of an endoscope to visualize the interior of the joint by means of a camera, and of miniature, motorized surgical tools used for the procedures. Arthroscopic techniques are most often used for surgical procedures at the shoulder and knee<sup>57,59,72,82</sup> but are being used increasingly more frequently for hip joint disorders.<sup>20,29</sup>

Arthroscopic procedures include ligament, tendon, and capsule repairs or reconstruction, joint débridement, meniscectomy, articular cartilage repair, and synovectomy. Because the incisions for the portals are so small, there is minimal disturbance of soft tissues during arthroscopic procedures. Therefore, rehabilitation usually—but not always—can proceed more quickly than after an open procedure.

### Arthroscopically Assisted Procedures

An arthroscopically assisted procedure uses arthroscopy for a portion of the procedure but also requires an open surgical field for selected aspects of the operative procedure.<sup>57,59</sup> This approach is sometimes referred to as a “mini-open” procedure.<sup>31</sup>

**TABLE 12.1** General Methods and Examples of Musculoskeletal Surgeries

Surgical Methods	Examples of Procedures
Repair	Tenorrhaphy, tendon repair; meniscus or ligament repair; articular cartilage repair
Release or decompression	Myotomy, tenotomy, fasciotomy; capsulotomy; tenolysis; muscle-tendon lengthening; retinacular release; arthroscopic subacromial decompression
Resection or removal	Synovectomy, meniscectomy, capsulectomy; débridement and lavage; laminectomy; excision of soft tissue or bony neoplasms
Realignment or stabilization	Tendon transfer, tenodesis; extensor mechanism realignment; capsulorrhaphy, capsular shift; osteotomy
Reconstruction or replacement	Tenoplasty; capsulolabral reconstruction; ligamentous reconstruction; chondroplasty; arthroplasty
Fusion or fixation for bony union	Arthrodesis; open reduction with internal fixation

## Tissue Grafts

In a number of orthopedic procedures to repair damaged structures, tissue grafts are implanted during the repair process. For example, soft tissue grafts are routinely used to reconstruct ligaments of the knee or ankle. Grafts are also used in articular cartilage repair procedures and many bony procedures.

### Types of Grafts

Tissue grafts can be placed into several categories: autografts, allografts, and synthetic grafts.<sup>51</sup>

**Autograft.** An autograft, also referred to as an autogenous or autologous graft, uses a patient's own tissue harvested from a donor site in the body. Patellar tendon grafts, for example, have been used for more than 4 decades for intra-articular anterior or posterior cruciate ligament reconstruction.<sup>69</sup> More recently, autografts have been used for osteochondral implantation for repair of small, localized femoral condyle articular defects.<sup>19</sup> Risks associated with autografts include the need for two surgical procedures and the potential for negative consequences at the donor site.

**Allograft.** An allograft uses fresh or cryopreserved tissue that comes from a source other than the patient, typically from a cadaveric donor. This type of graft is used when an autograft in a previous surgery has failed or when an appropriate autograft is not available. Allografts are associated with several risks, such as disease transmission from the donor, compromised graft strength resulting from sterilization, and failure secondary to immunological rejection. Allograft is not an option for articular cartilage implantation because cryopreservation destroys articular chondrocytes.

**Synthetic grafts.** Materials such as Gore-Tex® and Dacron offer an alternative to human tissue and have been used on a limited basis for ligament reconstruction in the knee. However, synthetic ligaments, to date, have had a high rate of failure and

have not maintained their integrity over time.<sup>19</sup> Implantation of synthetic ligaments has also been associated with chronic synovitis of the knee.

## Repair, Reattachment, Reconstruction, Stabilization, or Transfer of Soft Tissues

Surgical repair, reattachment, or reconstruction of soft tissues may be necessary after severe injury of a muscle, tendon, or ligament.<sup>37,48,55,62</sup> Surgical reconstruction and stabilization of a joint capsule may be indicated to reduce excessive capsular laxity contributing to instability of the joint.<sup>56,91</sup> Transfer of a muscle-tendon unit may be required to improve stability of an unstable joint or to enhance neuromuscular control and function.

Although there are numerous surgeries that fall into this category, a therapist must always consider the effects of immobilization and remobilization and the healing characteristics of the soft tissues involved when designing a postoperative exercise program.

### Muscle Repair

A complete tear or rupture of a muscle is unusual but may occur if a muscle that is in a state of contraction takes a direct blow or is forcibly stretched.<sup>17</sup>

#### Procedure

Immediate surgical repair of a severe tear or even complete rupture of a muscle is uncommon because inflammation affects the texture of muscle tissue, making it difficult to hold sutures in place. A patient can achieve a more satisfactory outcome with a late repair (approximately 48 to 72 hours after injury) after acute symptoms have decreased. For repair, the muscle is re-opposed, sutured, and immobilized in a shortened position as healing begins.<sup>62,77</sup>

### Postoperative Management

- Gradual muscle-setting exercise of the sutured muscle may be initiated immediately after surgery.
- When the immobilization is removed, active ROM, emphasizing controlled motion within a protected range, may begin to restore joint mobility and prevent contractures.
- Weight bearing is partially restricted until the patient achieves a functional level of strength and flexibility in the repaired muscle.
- Low-load, high-repetition resistance exercises should not elicit pain and be progressed very gradually to protect the healing muscle.
- Vigorous stretching or the return to full activity level are contraindicated until soft tissue healing is complete—as long as 6 to 8 weeks postoperatively.

### Tendon Repair

When a tendon tears or ruptures in a young person, it is usually the result of severe trauma.<sup>68</sup> In an elderly person, tears are usually the result of progressive deterioration of a tendon coupled with a sudden and unusual or forceful motion.<sup>6</sup> Tendons usually rupture at musculotendinous or tendo-osseous junctions.<sup>68</sup> Common sites of acute tear or rupture are the bicipital tendon at the shoulder and the Achilles tendon.<sup>49</sup>

In patients with chronic tenosynovitis of the hand and wrist, the extensor tendons can erode over time and may eventually rupture along the dorsum of the hand.<sup>7,13</sup> The superficial tendons of the hand and foot also are vulnerable to lacerations that may require surgical repair. The flexor tendons of the fingers, for example, are commonly severed as the result of a deep laceration to the palm of the hand.

Aside from the acute pain that occurs at the time of injury, a complete tendon tear, rupture, or laceration causes an inability to generate tension in the muscle-tendon unit and results in weakness but little pain. With a partial tear, there is significant pain during an active muscle contraction or stretch of the muscle-tendon unit.

### Procedure

A complete tear or laceration of a tendon should be repaired immediately or within a few days after injury. If not repaired within this time the tendon begins to retract, making reattachment difficult. After the tendon is sutured, the repaired muscle-tendon unit is maintained in a shortened position, as with a complete tear of a muscle. A longer immobilization period may be required for a repaired tendon than for a repaired muscle because the vascular supply to tendons is poor.<sup>26,24</sup> However, remobilization involving a limited degree of tensile forces on the repaired tendon is initiated as early as possible to prevent or minimize adhesions that can hinder tendon gliding.

### Postoperative Management

- Muscle setting is begun immediately after surgery to prevent adhesions of the tendon to the sheath or surrounding tissues and to promote alignment of healing tissue. If it is possible to remove the immobilization for brief periods of

exercise, passive motion or active contraction of a muscle group that is an antagonist of the repaired muscle tendon within a protected range also may be permissible within a few days after surgery.<sup>7,14</sup>

- Controlled antigravity motions are initiated after the repaired tendon has had several weeks to heal.
- Weight bearing may be restricted after an upper or lower extremity tendon repair, and heavy lifting activities are often contraindicated for as long as 6 to 8 weeks after an upper extremity repair.
- Because the muscle-tendon unit must be held in a shortened position for several weeks, regaining full range may be difficult. However, vigorous stretching and high-intensity resistance exercise should not be initiated for at least 8 weeks after repair, when healing of the tendon has occurred.<sup>14</sup>

**NOTE:** For detailed information on postoperative rehabilitation after repair of tendons in the shoulder, fingers, or ankle, refer to Chapters 17, 19, and 22, respectively.

### Ligament Repair or Reconstruction

After a large or complete ligament tear or when a ligament cannot be approximated for healing through closed reduction, surgical intervention through repair or reconstruction is warranted. Repair involves approximating and suturing the torn ligament, whereas reconstruction is accomplished with a tissue graft taken from a donor site. The knee, ankle, and elbow joints are the more common sites of ligament injury and surgical intervention.<sup>33,48,50,90</sup>

### Procedure

There are many surgical procedures that involve ligamentous repair or reconstruction. What is common to these surgeries is that, postoperatively, the joint is held in a position that places a safe level of tension on the sutured or reconstructed ligament during the healing process.<sup>50,55</sup> The duration of immobilization varies with the site and severity of injury and the type of repair or reconstruction that was done.<sup>11,16,77,90</sup>

### Postoperative Management

Rehabilitation after ligament surgery emphasizes early but protected motion and progressive strengthening and weight-bearing activities to load the healing tissues consistently but safely.<sup>50,69,90</sup> The rate of progression depends on many factors, such as the type of repair or reconstruction that was done. For example, rehabilitation after anterior cruciate ligament reconstruction utilizing a patellar tendon graft and bone-to-bone fixation can be progressed more rapidly than after a soft tissue stabilization procedure involving a hamstring graft.<sup>16,27,55</sup> The rate of advancement also depends on the site of the repair or reconstruction. For example, if the repair is at a potentially unstable joint, external support such as a brace should be worn and weight bearing restricted until muscular control can adequately protect the joint.

Generally, postoperative rehabilitation after ligamentous surgery is a lengthy process. For patients wishing to return to high-demand work or sports activities, it may take at least 6 months or as long as a year of rehabilitation until they are ready.<sup>27,55</sup>

**NOTE:** Rehabilitation after reconstruction of ligaments of the knee and ankle is addressed in Chapters 21 and 22.

### Capsule Stabilization and Reconstruction

A joint capsule with excessive laxity loses the capacity to provide passive stability to the joint. Hypermobility of the capsule can therefore be an underlying cause of symptomatic joint instability ranging from subluxation to gross instability and recurrent dislocation. Joints particularly vulnerable to instability are those with minimal inherent stability, most notably the glenohumeral joint.

In some instances, an individual is predisposed to instability at many joints because capsular laxity and joint hypermobility are congenital.<sup>76</sup> More often, joint instability results from an acute capsular injury suffered during a traumatic dislocation or from repetitive stresses applied to the capsule with the joint in extreme positions.<sup>56</sup> The latter is seen most often in athletes participating in sports such as baseball and tennis that involve repetitive, end-range shoulder motions.<sup>84</sup>

Surgical stabilization or reconstruction of a joint capsule is indicated for a patient with traumatic dislocation with associated capsular or labral avulsion or fracture, recurrent dislocation or symptomatic subluxation despite a course of nonoperative treatment, or an irreducible (fixed) dislocation.<sup>56,72,84,94</sup>

#### Procedure

Surgical procedures designed to reduce capsular laxity and joint volume and restore or improve joint stability fall into several categories and are performed using open or arthroscopic approaches. An open procedure with arthrotomy is used if an open reduction of the joint is required or if there is extensive damage to the labrum, avulsion of the capsule, or a fracture. An arthroscopic approach is most often used to reduce capsular laxity and for some reconstructive procedures.<sup>56,94</sup>

Examples of stabilization and reconstruction procedures at the glenohumeral joint used for anterior, posterior, inferior, or multidirectional instabilities are described here.

**Capsulorrhaphy (capsular shift).** For capsulorrhaphy using an arthroscopic or open approach, a specific portion of the capsule is incised and tightened by imbrication/plication (overlapping and then suturing) of the redundant tissue.

**Capsulolabral reconstruction.** Capsulolabral reconstruction involves arthroscopic or open repair of a capsular lesion and labral tear by reattaching the labrum to the rim of the glenoid in combination with capsule stabilization.

**Electrothermally assisted capsulorrhaphy.** For electrothermally assisted capsulorrhaphy using an arthroscopic approach, thermal energy (laser or radiofrequency) is delivered to the capsule to shrink identified regions of laxity.<sup>91</sup>

#### Postoperative Management

After any joint stabilization or reconstruction procedure, the emphasis of postoperative management is to restore the balance among joint stability and functional motion while protecting the joint capsule and other repaired tissues during healing. The duration of the immobilization period and the selection and

progression of postoperative exercises and functional activities depend on factors such as the preoperative direction of the instability, the surgical approach, the type of stabilization or reconstruction procedure and tissue fixation used, and the quality of the patient's tissue.

Postoperative exercises focus on the following:

- Restoring ROM, emphasizing active motions within a protected range during early rehabilitation. Movements that place stress on the portion of the capsule that was tightened or repaired are progressed cautiously.
- Strengthening exercises, when permissible, emphasizing the function of the dynamic joint stabilizers.

**NOTE:** Detailed progressions of postoperative exercises after surgical stabilization of the shoulder are presented in Chapter 17.

### Tendon Transfer or Realignment

The transfer or realignment of a muscle-tendon unit alters the line of pull, potential force generation, and excursion of the muscle.<sup>71</sup> Transfers may be indicated, for example, to improve the stability of an unstable shoulder joint or to stabilize a chronically dislocating patella. Although a realignment procedure alters the line of pull, it does not change the action of the muscle-tendon unit. For instance, after realignment of the extensor mechanism for recurrent patellar dislocation, the quadriceps muscle remains a knee extensor.

A tendon transfer from one bony surface to another is sometimes indicated for the patient with a significant neurological deficit to prevent deformity and improve functional control.<sup>71</sup> With this type of procedure, not only is the line of pull of the muscle-tendon unit altered, but the action of the muscle is also changed. For example, transfer of the distal attachment of the flexor carpi ulnaris to the dorsal surface of the wrist changes the action of the muscle-tendon unit from a wrist flexor to a wrist extensor. This procedure may be indicated for a child with cerebral palsy to prevent wrist flexion contracture and improve active wrist extension for functional grasp.<sup>71</sup>

#### Procedure

During a typical tendon transfer or realignment procedure, the distal attachment of the muscle-tendon unit is removed from its bony insertion and reattached to a different bone, to a different location on the same bone, or to adjacent soft tissues.<sup>62,71,77</sup> The realigned muscle-tendon unit is then immobilized in a shortened position for a period of time.

#### Postoperative Management

- As with a tendon repair, early muscle setting and protected motion are important to maintain tendon gliding. Resisted movements are progressed cautiously and gradually to protect the reattached tendon.
- If the purpose of the transfer was to change the function of the muscle, biofeedback and electrical muscle stimulation are often used to help a patient learn to control the new actions of the transferred muscle-tendon unit.<sup>77</sup>

**NOTE:** Rehabilitation after tendon transfer for rheumatoid arthritis of the hand and wrist is described in Chapter 19. Chapter 21

contains information on rehabilitation after realignment of the patellar tendon for chronic patellofemoral dysfunction.

## Release, Lengthening, or Decompression of Soft Tissues

Soft tissues may be incised or sectioned to improve ROM, prevent or minimize progressive deformity, or relieve pain. Procedures include myotomy, tenotomy, or fasciotomy.<sup>11,62,77</sup>

Surgical release of soft tissues may be indicated for a young patient with severe arthritis and resulting contractures in whom joint replacement is not advisable or as a preliminary procedure in adults prior to joint replacement.<sup>13</sup> Releases are also performed in patients with myopathic and neuropathic diseases, such as muscular dystrophy and cerebral palsy, to improve functional mobility.<sup>77</sup> Release of soft tissues to achieve decompression of tissues and relieve pain may be indicated for a patient with an impingement or compartmental syndrome, such as shoulder impingement or carpal tunnel syndrome.<sup>11,62</sup>

### Procedure

During release or lengthening of a shortened muscle group, a portion of the muscle-tendon unit is surgically sectioned and fibrotic tissues are incised. A tendon also can be partially incised, as in a Z-lengthening to allow greater extensibility. The incised structures are then immobilized in a lengthened position except during exercise.<sup>62,77</sup> Some form of splinting or bracing in the corrected position in conjunction with exercise is always used postoperatively to maintain the ROM gained by the procedure.

During decompression procedures, fasciae that are compressing muscles, tendons, or nerves may be released or removed. Some decompression procedures also involve removal of osteophytes or alteration of bony structures that are contributing to the excessive pressure on soft tissues.

### Postoperative Management

- CPM and/or active-assistive ROM is typically initiated within a day or two after surgery. As soft tissue healing progresses, this is followed by active ROM through the gained ranges.<sup>11,77</sup>
- Strengthening of the antagonists of the lengthened muscle and functional use within the available ROM are also started early to maintain active control of movement within the newly gained range.

## Joint Procedures

Orthopedic surgery involving the joints of the upper and lower extremities is most frequently used for pain management and for dysfunction associated with arthritis or acute injury. Surgical interventions for arthritis range from arthroscopic joint débridement and lavage or repair of a small chondral lesion to total joint replacement arthroplasty or joint fusion. An overview of these procedures follows.

## Arthroscopic Débridement and Lavage

Joint débridement and lavage involves arthroscopic removal of fibrillated cartilage, unstable chondral flaps, and fragments of cartilage or bone from a joint.<sup>13</sup> Osteophytes also may be excised. This procedure is most often indicated to relieve joint pain and “clicking,” “ratcheting,” or “catching” during joint movement.

### Synovectomy

Synovectomy involves removal of the synovial lining of the joint in the presence of chronic joint inflammation. Typically, it is performed in patients who have rheumatoid arthritis with chronic proliferative synovitis but minimal articular changes.<sup>13,41,61,92</sup> It is indicated when medical management has failed to alleviate joint inflammation for 4 to 6 months.

### Procedure

Synovectomy is usually performed using an arthroscopic approach and is most commonly performed on the knee, elbow, wrist, and metacarpophalangeal (MCP) joints.<sup>7,13,41,61,92</sup> When synovium proliferates in the synovial sheaths of tendons, it is referred to as tenosynovitis. Removal of excessive synovium from tendon sheaths is known as a tenosynovectomy. This procedure is most often done for chronic synovitis of the wrist to clear synovium from the extensor tendons of the hand and is also called a dorsal clearance procedure.<sup>13,61,92</sup>

Although synovium tends to regenerate, resection of the inflamed synovium temporarily relieves pain and swelling and is thought to protect articular cartilage or tendons from enzymatic damage secondary to the tenosynovitis.<sup>13,41</sup>

### Postoperative Management

- If an arthroscopic approach is used, passive or assisted ROM exercises (or CPM) and muscle-setting exercises are begun immediately or within 24 hours after surgery. Exercises quickly progress to active ROM. After synovectomy of the knee, for example, partial weight bearing as tolerated during ambulation progresses to full weight bearing by 10 to 14 days. After wrist or elbow synovectomy, lifting heavy objects is restricted for several weeks.
- After open synovectomy, progression of exercises and ADLs proceeds more slowly than after arthroscopic synovectomy.
- Progression of the rehabilitation program is based on the patient’s response to exercise combined with their response to medication for the primary inflammatory disease. Every effort should be made to avoid excessive exercise or activity that could increase joint pain or swelling.<sup>7,61,92</sup>

## Articular Cartilage Procedures

Surgical intervention for repair of articular cartilage defects, or osteochondral lesions, has proven to be particularly challenging because of the limited capacity of this type of connective tissue to heal.<sup>19,64</sup> However, several procedures for a symptomatic extremity joint have been developed. Selection criteria for one procedure over another are based on the size of the chondral lesion and patient-related factors, such as age and the ability to participate in the rehabilitation process.

### Procedure

**Abrasion arthroplasty, subchondral drilling, and microfracture.** Several arthroscopic procedures are used to promote healing of small chondral defects in symptomatic joints. These procedures stimulate a bone marrow-based response that leads to local ingrowth of fibrocartilage.<sup>19,64,82</sup> Lesions of the medial femoral condyle and the posterior aspect of the patella are most often treated with these procedures.

Abrasion arthroplasty, also known as abrasion chondroplasty, and subchondral drilling involve mechanical disruption of the articular surface down to the superficial layer of subchondral bone using a motorized, arthroscopic burr or drill. The positive effects of these procedures have been questionable, at best, and possibly no more effective for symptom relief than arthroscopic débridement alone.<sup>19</sup>

### FOCUS ON EVIDENCE

A long-term assessment of abrasion arthroplasty for full-thickness medial femoral condyle cartilage lesions noted that at 20 years' post procedure, 68% of the patients reported Knee Society Scores  $\geq 70$  or no secondary operation on their knee. All patients had CPM until hospital discharge, 6 to 8 hours of CPM per day following discharge, and protected weight bearing for a minimum of 6 weeks.<sup>78</sup> Outcomes at a mean of 38.1 months for subchondral drilling of the talus demonstrated improvements in pain and two separate standardized outcome measures. Weight bearing in a walking boot was limited to tolerance for 2 weeks, followed by full weight-bearing and active exercises.<sup>18</sup>

**NOTE:** Despite evidence supporting long-term functional outcomes after abrasion arthroplasty or subchondral drilling,<sup>18,78</sup> the local, tissue-specific benefits may be short-lived. Because the fibrocartilage replacement tissue lacks the qualities of the original hyaline cartilage, the new tissue tends to deteriorate readily after ingrowth.<sup>11,19</sup>

A newer technique, microfracture of articular cartilage, is designed to repair osteochondral defects smaller than 1.5 cm<sup>2</sup>. This procedure involves the use of a nonmotorized arthroscopic awl to systematically penetrate the subchondral bone and expose the bone marrow. Initial studies of this procedure suggested that microfracture relieved symptoms more effectively than abrasion arthroplasty or subchondral drilling, possibly because using the nonmotorized instrument reduces the potential for tissue damage due to thermal necrosis.<sup>19,64</sup> However, a recent comparison of microfracture and subchondral drilling for talus osteochondral defects did not find long-term differences in outcomes between the two procedures.<sup>18</sup> A recent systematic review of level I and II studies of microfracture suggests that this procedure provides good short-term benefit for younger patients and those with small defects but that osteoarthritis and failures requiring additional surgical procedures were frequently reported at long-term follow-up.<sup>36</sup>

**Chondrocyte transplantation.** Chondrocyte transplantation, also known as autologous chondrocyte implantation (ACI),<sup>34,64</sup> is designed to stimulate growth of hyaline cartilage for repair of articular cartilage focal defects and to prevent progressive deterioration of joint cartilage leading to osteoarthritis.<sup>12,19,34,63,64</sup> It was introduced during the mid-1990s as an alternative to abrasion arthroplasty for full-thickness, symptomatic focal chondral and osteochondral defects (2.5 to 4.0 cm<sup>2</sup>) of the knee, specifically lesions of the femoral condyles or patella.<sup>12</sup>

Chondrocyte transplantation occurs in two stages. First, healthy articular cartilage is harvested arthroscopically from the patient. Chondrocytes are extracted from this articular cartilage, cultured for several weeks, and processed in a laboratory to increase the volume of healthy tissue. The second stage, currently an open procedure, involves débridement of the defect sites, covering the site with a periosteal patch, and injecting millions of autologous chondrocytes into the covered defect.<sup>19</sup> Long-term success for function and patient satisfaction have been reported in up to 82% of patients following ACI.<sup>70</sup>

**Osteochondral autografts and allografts.** Unlike transplantation of chondrocytes, osteochondral grafts involve transplantation of intact articular cartilage along with some underlying bone, resulting in a bone-to-bone graft.<sup>64</sup> An autogenous osteochondral graft procedure harvests a patient's own articular cartilage and bone from a donor site.<sup>19</sup> As noted previously (see Box 12.10), a drawback to this type of articular graft is damage to the donor site, specifically the creation of an osteochondral defect. To minimize damage to the patient's donor site, osteochondral mosaicplasty was developed where small-diameter osteochondral plugs are retrieved from a donor site and press-fit into the chondral defect.<sup>9</sup>

In contrast, an osteochondral allograft procedure transplants intact articular cartilage and bone from a cadaveric donor. However, only fresh, intact grafts, which are in limited supply and can be stored for only a few days, can be used. This is because freezing the graft material prior to storage for later use destroys the articular chondrocytes and results in graft failure.

### Postoperative Management

Rehabilitation after all of the articular cartilage procedures described in this section, with the exception of arthroscopic débridement, is a slow and arduous process.<sup>12,19,34,44,63,64</sup> Exercise is an important aspect of postoperative management at each stage of rehabilitation. Early passive motion, sometimes with CPM, and protected weight bearing are essential to promote the maturation and maintain the health of implanted chondrocytes or an osteochondral graft. Full weight bearing is allowable by 8 to 9 weeks. A well-controlled program of progressive exercises continues for 6 months to a year to achieve optimal functional outcomes.<sup>33,44</sup>

**NOTE:** More detailed information on rehabilitation after procedures to repair articular cartilage and osteochondral lesions is presented in Chapter 21.

## Arthroplasty

Any reconstructive joint procedure designed to relieve pain and improve function is referred to broadly as arthroplasty. This definition encompasses excision, interposition, and replacement arthroplasty, procedures that may or may not include a joint implant.

### Procedure

**Excision arthroplasty.** Excision arthroplasty, also known as resection arthroplasty, involves removing periarticular bone from one or both articular surfaces. A space is maintained between the new surfaces that is filled with fibrotic scar tissue during the healing process.<sup>13,61</sup> Excision arthroplasty is performed to relieve pain in many joints, including the hip, elbow, wrist, and foot. Although an older and less frequently used procedure, this type of arthroplasty is still considered appropriate in select cases. Resection of the head of the radius for late-stage arthritis of the humeroradial joint<sup>22</sup> or a severe comminuted fracture of the radial head<sup>65</sup> and resection of the distal ulna (Darrach procedure) for late-stage arthritis of the distal radioulnar joint<sup>24</sup> are still used as primary excision procedures to reduce pain. However, excision arthroplasty of the hip (Girdlestone procedure) is only used now as a salvage procedure after a failed total hip replacement when revision arthroplasty is not feasible.<sup>13</sup>

Despite the usefulness of excision arthroplasty, there are also a number of disadvantages:

- Possible joint instability
- In the hip, significant leg length discrepancy and poor cosmetic result because of shortening of the operated extremity
- Persistent muscular imbalance and weakness

**NOTE:** Rehabilitation after excision arthroplasty of the radial head is discussed in Chapter 18.

**Excision arthroplasty with implant.** For excision arthroplasty with implant, an artificial implant is inserted to help in the remodeling of a new joint. This is sometimes called implant resection arthroplasty.<sup>22,61</sup> The implant usually is made of a flexible silicone material that becomes encapsulated by fibrous tissue as the joint reforms.

**Interposition arthroplasty.** Interposition arthroplasty is biological resurfacing of a joint to provide a new articulating surface. After the involved joint surfaces are débrided, a foreign material is placed, or interposed, between the two joint surfaces.<sup>5,61</sup> A variety of materials including fascia tendon, silicone material, or metal may be inserted between the joint surfaces.

This type of arthroplasty is used most often in young patients with incapacitating pain and loss of function from severe articular surface deterioration who are not appropriate for replacement arthroplasty. Some examples of interpositional arthroplasty are resurfacing of the glenoid fossa with fascia<sup>5</sup> and tendon interposition arthroplasty of the carpometacarpal (CMC) joint of the thumb.<sup>23</sup>

**Joint replacement arthroplasty.** Joint replacement arthroplasty includes total joint replacement arthroplasty and

hemireplacement arthroplasty. Total joint replacement is a common reconstructive procedure to relieve pain and improve function in patients with severe joint degeneration associated with late-stage arthritis (Fig. 12.2).<sup>13,57,61,66</sup>

Total joint replacement arthroplasty involves resecting both articular surfaces and replacing them with artificial components. Hemireplacement arthroplasty involves resection and replacement of only one of the articular surfaces.<sup>13,61,66</sup> Hemireplacement is used when only one articulating surface of a joint has deteriorated and is also an option after femoral neck and proximal humeral fractures.<sup>13</sup>

- **Materials, designs, and methods of fixation.** Prosthetic components have been developed and refined for almost every extremity joint but are used more frequently and successfully at the hip and knee than at the smaller joints of the foot and hand.<sup>13,61,66</sup> The materials, designs, and fixation methods used for replacement arthroplasty are summarized in Box 12.9. Prosthetic implants are made of inert materials, specifically metal alloys, high-density polyethylenes (plastics), and sometimes ceramics. Component designs range from unconstrained (resurfacing) with no inherent stability to semiconstrained and fully constrained (articulated) designs that provide stability to the joint. In almost all designs, one articular surface is metal and the other is plastic. The choice of fixation is based in part on the anticipated loading that will be normally placed on the components over time. Cemented fixation, using an acrylic-based

**FIGURE 12.2** Total hip replacement arthroplasty. Both the acetabular and femoral portions of the joint have been replaced with prosthetic components. (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging*, ed. 4. Philadelphia: F.A. Davis, 2014, p 387, with permission.)

### BOX 12.9 Materials, Designs, and Methods of Fixation for Joint Replacement Arthroplasty

#### Implant Materials

- Rigid: inert metal (cobalt-chrome alloy, titanium alloy, or ceramic)
- Semirigid: plastic (high-density polymers such as polyethylene)

#### Implant Designs

- Unconstrained (resurfacing): no inherent stability
- Semiconstrained
- Fully constrained (articulated): inherent stability

#### Methods of Fixation

- Cemented
  - Acrylic cement (polymethylmethacrylate)
- Noncemented
  - Biological fixation (microscopic ingrowth of bone into a porous-coated prosthetic surface)
  - Macrointerlock between a nonporous component and bone with a bioactive compound applied to the component to improve osseous integration
  - Press fit (tight fit between bone and implant)
  - Screws, bolts, or nails
- Hybrid
  - Noncemented component for one joint surface and cemented component for opposing joint surface

cement (polymethylmethacrylate), tends to eventually break down at the bone-cement interface, resulting in mechanical loosening of the implant and pain.<sup>13,66,79</sup> Therefore, cemented fixation is used primarily for older or sedentary patients who are unlikely to place high stresses on the implants. Bio-ingrowth fixation, a form of cementless fixation, is achieved by growth of bone into the porous-coated exterior surface of an implant. It is thought that this form of fixation, which is advocated for younger, more active patients, is less likely to loosen over time.<sup>13,66,79</sup> Most recently, a nonporous, cementless prosthetic implant has been developed that is used with a bioactive compound that stimulates bone growth. Fixation is achieved by a macrointerlock between the implant and adjacent bone.<sup>66</sup>

**NOTE:** Descriptions of implants are reviewed, joint by joint, in Chapters 17 through 22.

- **Minimally invasive versus traditional arthroplasty.** A recent advance in joint replacement arthroplasty that may have a significant impact on postoperative rehabilitation and outcomes is the development of minimally invasive surgical techniques with less soft tissue disruption than traditional arthroplasty. Currently, minimally invasive procedures are being used for total hip and total knee replacement.<sup>4,10,85</sup> Although traditional hip and knee replacement procedures have provided excellent results for several decades,<sup>13,67,79</sup>

they impose substantial trauma to skin, muscles, and joint capsule, leading to significant postoperative pain and prolonged postoperative recovery. Compared to surgical techniques for traditional hip and knee replacement, minimally invasive procedures use smaller skin incisions, less muscle splitting to expose the joint, and less capsule disruption in preparation for insertion of prosthetic implants. For example, a minimally invasive hip replacement surgery uses one or two small incisions (<10 cm in length) rather than a single longer incision (15 to 30 cm long involving extensive muscle splitting).<sup>10</sup> A 2-year follow-up study indicates that patients who underwent minimally invasive total knee replacement had less pain, better early motion, and a shorter hospital stay than patients who had standard knee replacement surgery.<sup>85</sup> These early patient benefits of minimally invasive surgery for knee arthroplasty have not translated to improved functional performance, pain, ROM, or surgical outcomes at either 8 or 12 weeks when compared to those having a conventional open technique.<sup>81,86</sup>

- **Contraindications to joint replacement arthroplasty.** Despite the positive functional outcomes after joint replacement arthroplasty, not every patient with advanced joint disease is a candidate for these procedures. Contraindications are noted in Box 12.10.<sup>13,61,66</sup> Although opinions vary as to which of these contraindications are absolute versus relative, there is general agreement that infection is of the utmost concern.

### Postoperative Management

Postoperative management, including therapeutic exercise interventions, after selected types of joint replacement arthroplasty of major joints of the extremities is described in detail in Chapters 17 through 22.

### Arthrodesis

Arthrodesis is surgical fusion of the joint surfaces. It is indicated as a primary surgical intervention in cases of severe joint pain associated with late-stage arthritis and joint instability in which mobility of the joint is a lesser concern.<sup>8,83</sup> Arthrodesis of the extremity joints is also reserved for patients with significant weakness of muscles surrounding a joint as the result of neurological abnormalities, such as a peripheral neuropathy of the ankle or a severe brachial plexus injury.<sup>62,77</sup> In addition,

### BOX 12.10 Contraindications to Total Joint Arthroplasty

- Active infection in the joint
- Chronic osteomyelitis
- Systemic infection
- Substantial loss of bone or malignant tumors that prohibit adequate implant fixation
- Significant paralysis of muscles surrounding the joint
- Neuropathic joint
- Inadequate patient motivation

it may be the only salvage procedure available for a patient with a failed total joint arthroplasty when revision arthroplasty is not an option.<sup>53</sup>

Arthrodesis is used most frequently in the cervical or lumbar spine, wrist, thumb, and ankle but also has been used in the shoulder and hip joints. For example, arthrodesis of one or more joints of the ankle and foot (Fig. 12.3) is the procedure most often used to relieve pain associated with severe arthritis.<sup>83</sup>

The optimal joint position for arthrodesis is somewhat dependent on the functional needs or goals of each patient and may vary slightly in some joints, such as the elbow and ankle. For example, the optimal position for elbow fusion in the dominant upper extremity usually is between 70° and 90°. However, in the nondominant limb, the elbow must be in more extension for assistive activities.<sup>8</sup> For a woman, the optimal position for arthrodesis of the ankle might be in slightly greater plantarflexion than for a man to allow a woman to wear shoes with a slightly higher heel height.<sup>77</sup> Optimal positions for arthrodesis are listed in Table 12.2.

Although arthrodesis eliminates pain and creates stability in the involved joint, it is not without disadvantages. Because loads and motions needed for functional activities are transferred to joints above and below the fused joint, there is the potential that excessive stresses may lead to pain and hypermobility at these joints over time.

### Procedure

Fusion of joint surfaces in the position of maximum function is achieved with internal fixation (i.e., pins, nails, screws, plates, and bone grafts). Initially, the joint is immobilized in

**FIGURE 12.3** Arthrodesis (surgical fusion with internal fixation of the ankle). (From Logerstedt, DS, Smith, HL: Postoperative Management of the Foot and Ankle. Independent Study Course 15.2. Postoperative Management of Orthopedic Surgeries. Orthopedic Section. La Crosse, WI: APTA, Inc., 2005, with permission.)

**TABLE 12.2** Optimal Positions for Arthrodesis

Joint	Position
Shoulder	At 15°–30° of abduction and flexion and 45° of internal rotation: a position so the hand can reach the mouth
Elbow	Dominant upper extremity: 70°–90° of flexion and midposition of forearm pronation/supination; Nondominant limb: greater elbow extension than the dominant extremity
Wrist	Slight extension
MCP of the thumb	At 20° of flexion
Hip	At 10°–15° of flexion to allow ambulation and comfortable sitting
Ankle	
Tibiotalar joint	Neutral (90°) or slight equinus for women who wear low heels
Subtalar joint	Neutral to valgus
Spine	Neutral so normal lordosis or kyphosis is maintained

a cast above and below the site of arthrodesis for 6 to 12 weeks postoperatively. Later, an orthotic device is used until complete bony healing and joint ankylosis has occurred.<sup>8</sup>

### Postoperative Management

- Because no movement is possible in the fused joint, ROM and strength must be maintained above and below the operated joint.
- Weight bearing is restricted until there is evidence of bony healing.

### Extra-articular Bony Procedures

Two of the more common reasons for surgical intervention involving bony structures outside a joint are fractures that require open reduction combined with internal fixation and deformity or malalignment of bone, sometimes associated with arthritis.

### Open Reduction and Internal Fixation of Fractures

Fractures are managed with either closed or open reduction. The process of bone healing and fracture management, addressed in Chapter 11, applies regardless of the method of reduction. In most instances in which open reduction is required, some type of internal fixation device is used to stabilize and maintain the alignment of the fracture site as it heals.

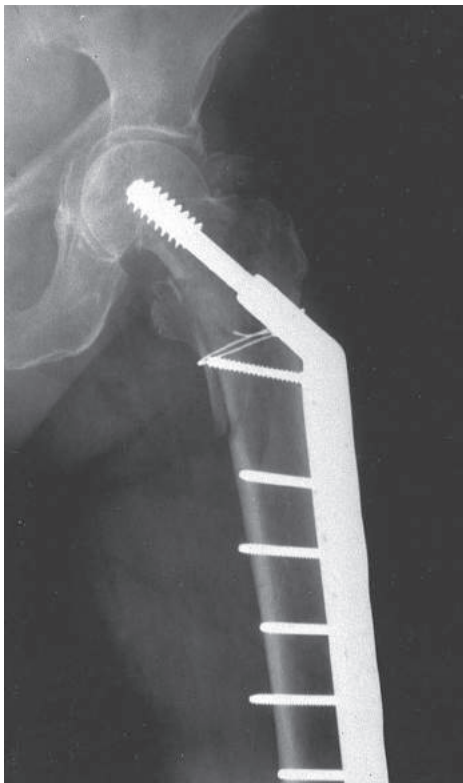

### Procedure

After exposing the fracture site during surgery, any number of internal fixation devices such as pins, nails, screws, plates, or rods, may be used to align and stabilize the bone fragments.<sup>17,77</sup> Intertrochanteric fracture of the femur, for example, is commonly stabilized with a compression plate and screws, as shown in Figure 12.4. After the fracture has healed, a second surgery may be necessary to remove some or all of the internal fixation devices because they tend to migrate over time.

### Postoperative Management

Maintaining stability of the fracture site so bony healing can occur and getting the patient up and out of bed as early as possible are the main postoperative priorities. The progression of rehabilitation after surgical stabilization of a fracture is dependent not only on factors such as the type and severity of fracture and the patient's age and health status but also on the method(s) of internal fixation used.

Some fixation methods eliminate the need for additional external stabilization of the fracture site thereby enabling the patient to begin assisted or active movement of the involved limb and protected weight bearing shortly after surgery. With other fractures, however, external stabilization and restricted weight bearing are necessary even with the use of internal fixation.<sup>17,77</sup>

**FIGURE 12.4** Intertrochanteric fracture of the left femur, fixed with compression plate and screws. (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging*, ed. 4. Philadelphia, FA Davis, 2014, p 64, with permission.)

During postoperative management, not only must the fracture site be protected as it heals, soft tissues injuries associated with the fracture or the surgery must also be managed appropriately as they heal.

**NOTE:** Surgical interventions and postoperative management after hip fracture are discussed in Chapter 20.

### Osteotomy

Osteotomy—the surgical cutting and realignment of bone—is an extra-articular procedure indicated for the management of impairments associated with a number of musculoskeletal disorders. It is most often performed at the knee or hip.<sup>13</sup> For example, osteotomy is used to reduce pain and correct deformity in a young adult with moderate, focal articular degeneration in the medial compartment and a varus deformity of the knee as the result of osteoarthritis<sup>40,61</sup> or in a child with severe hip joint deterioration and pain secondary to congenital dysplasia or Legg-Calvé-Perthes disease (avascular necrosis of the head of the femur).<sup>62</sup>

Cutting and realigning bone near the involved joint shifts weight-bearing loads to intact joint surfaces, reducing joint pain and preventing further deterioration of the involved articular cartilage.<sup>13,77</sup> It is also thought that redistributing loads on joint surfaces may stimulate the growth of fibrocartilage in the unloaded compartment of the joint.<sup>25</sup> A successful osteotomy delays the need for total joint replacement in patients who will most likely require revision arthroplasty sooner than the average patient with degenerative arthritis.

Osteotomy is also used to correct angular or rotational deformities of bone occurring in congenital or developmental disorders, such as congenital dislocation of the hip, acquired hip dislocation in cerebral palsy, or congenital foot deformities.<sup>77</sup> Osteotomy is also used when surgically shortening or lengthening a bone to correct a severe leg length discrepancy.<sup>17,77</sup>

### Procedure

Numerous procedures are classified as osteotomies. Several examples are:

- High tibial, medial or lateral opening, wedge osteotomy with screw-plate fixation, which is a procedure to correct varus or valgus deformities, change the mechanical axis of the knee, and shift the load on joint surfaces in a patient with unicompartmental degenerative arthritis of the knee.<sup>40,47</sup>
- Medial wedge osteotomy of the distal femur to correct a valgus deformity of the knee and shift weight-bearing loads away from the deteriorated cartilage in the lateral compartment of the knee.<sup>61</sup>
- Intertrochanteric osteotomy of the proximal femur, which repositions the femoral head to change the area in which weight bearing occurs for a patient with arthritis or avascular necrosis of the hip.<sup>61</sup>
- Periacetabular osteotomy, which repositions the acetabulum, to improve coverage of the head of the femur for a patient with congenital dysplasia of the hip and recurrent

dislocation that could not be managed effectively by non-operative methods, such as splinting.<sup>77</sup>

During an osteotomy, muscles and other soft tissues may have to be reflected to expose the operative field and then reattached or repositioned. As with any type of soft tissue repair, muscle-tendon units disturbed during surgery must be protected from excessive stress postoperatively.

### Postoperative Management

The primary concern of postoperative management is maintaining bone-to-bone apposition for healing of the osteotomy site. Some procedures allow early joint motion and protected weight bearing because internal fixation maintains apposition of the osteotomy fragments. Others require additional external (cast) stabilization of the joints above and below the osteotomy site until bony union occurs, which may take as

long as 8 to 12 weeks.<sup>25,61</sup> Full functional recovery after osteotomy may take as long as 6 months.

Postoperative exercises, when permissible, include the following:

- If cast stabilization is necessary, the patient can begin active ROM of the joints above and below the site of the osteotomy to prevent joint stiffness and muscle weakness.
- When motion and weight bearing are allowed, either immediately after surgery or when the cast is removed, active-assistive and active exercise progressing to light resistive exercise is performed to restore joint ROM and strength. (See the discussion of management of fractures after immobilization in Chapter 11.)
- Weight bearing is typically protected for 4 to 6 weeks or more.

## Independent Learning Activities

### Critical Thinking and Discussion

1. You have been asked to develop two preoperative patient education programs for groups of individuals scheduled for surgery—a total hip arthroplasty group and a total knee arthroplasty group. What topics should be covered in your presentations? Why are these topics important for prospective patients to understand? How will the two programs be similar? How will the programs differ?
2. You are treating an elderly patient for the first time who underwent an open reduction with internal fixation of a proximal femur fracture 24 hours ago. What are the priorities of your initial examination of this patient? What is the general emphasis of postoperative management, including goals and interventions, during the maximum, moderate, and minimum protection phases of recovery?
3. What is the role of the physical therapist in the overall prevention or management of a lower extremity DVT? What are the signs and symptoms of DVT that a patient at risk

for this problem must learn to recognize? If you suspect that a patient you are treating has developed a DVT following lower extremity orthopedic surgery, what questions should you ask the patient? What should you do before contacting the patient's physician?

4. Briefly describe the various surgical interventions for repair of articular cartilage. Describe the pros and cons of each intervention and the long-term results.
5. Differentiate among the following types of soft tissue or bony surgeries primarily used in the management of arthritis: arthrodesis, arthroplasty, articular cartilage repair, débridement, and osteotomy. Briefly describe each surgery and compare and contrast the postoperative management with respect to the use of therapeutic exercise.
6. Discuss the similarities and differences of postoperative management for the following soft tissue surgeries: muscle repair, tendon repair, tendon transfer, ligament reconstruction, repair of a joint capsule, tenotomy or myotomy, and decompression.

## Independent Learning Activities 413

Therapeutic exercise and related manual therapy techniques would not be possible without the nervous system and all its components activating, controlling, and modifying motor responses as well as receiving and interpreting feedback from the variety of sensory receptors throughout the body. Because of their intimate proximity to all the structures in the trunk and extremities, nerves may become stressed or injured with various musculoskeletal conditions, postures, and repetitive microtraumas, resulting in neurological symptoms, structural and functional impairments, activity limitations, and participation restrictions. Highlights of the anatomy and results of injury to the peripheral nervous system are reviewed in the first section of this chapter for the purpose of laying the

foundation for management guidelines, including therapeutic exercise and manual therapy interventions, that are described in the remainder of the chapter. In the treatment of patients with musculoskeletal impairments, often the therapist does not think of the components of the central nervous system. Even though this chapter primarily deals with the peripheral nervous system, acknowledgment that the central nervous system plays a key role in the initiation and control of movement is a must. The reader is referred to Chapter 8 for consideration of motor control in the total rehabilitation of the individual with musculoskeletal involvement.

The development of a plan of care and intervention techniques differs for patients with impairments due to nerve

involvement. Nerve injuries may result in significant activity limitations and participation restrictions due to paralysis and resulting deformity. Utilizing the principles presented in this chapter, along with the knowledge and skills of examination and evaluation of the neural, muscular, and skeletal systems, the reader should be able to design therapeutic exercise programs for patients with limitations due to injury or mobility restrictions of the peripheral nervous system. Several peripheral nerve entrapment conditions are described in order to illustrate therapeutic interventions, including thoracic outlet syndrome and carpal tunnel syndrome. Also included in this chapter is a section on complex regional pain syndrome (CRPS).

## Review of the Peripheral Nervous System

### Nerve Structure

Peripheral components of the neuromuscular system include the alpha and gamma motor neurons, their axons, and the skeletal muscles they innervate; the sensory neurons and their receptors located in the connective tissues, joints, and blood vessels; and the neurons of the autonomic nervous system. Connective tissue surrounds each axon (endoneurium) as well as fascicles (perineurium) and entire nerve fibers (epineurium).<sup>3,78</sup> The axolemma is the surface membrane of an axon. Schwann cells lie between the axolemma and endoneurium; they form myelin, which functions to insulate the axon as well as speed the conduction of action potentials along the nerve fiber. The exceptions are very small fibers that are unmyelinated. A peripheral nerve may consist of a single fascicle or consist of several fascicles. The structure of a peripheral nerve with its connective tissue and vascular layers is illustrated in Figure 13.1, and the location of their cell bodies and structures innervated are summarized in Box 13.1.

### Mobility Characteristics of the Nervous System

In 1991, David Butler,<sup>15</sup> one of the original therapists to study neurodynamics, described the peripheral and central nervous systems as a continuous tissue tract; simply stated, the tract is like an H on its side. Structurally and functionally, there is continuity of the connective tissues, the impulse transmission between the neurons, and the chemical flow of neurotransmitters. The nervous system is designed to move as well as withstand mechanical forces, while at the same time conduct impulses.

Nerves slide and glide relative to the adjacent tissue, both longitudinally and transversely. Excursion of the nerve is critical to neural function because it serves to dissipate tension within the neural system. Initially, excursion occurs adjacent to the moving joint, but excursion of the nerve progresses more distally from the moving joint as limb movement continues.<sup>61,71,79</sup>

FIGURE 13.1 Peripheral nerve and its connective tissue coverings.

#### BOX 13.1 Content of Peripheral Nerves and Location of Their Cell Bodies

Peripheral nerves contain a mix of motor, sensory, and sympathetic neurons.

- *Alpha motor neurons (somatic efferent fibers)*: cell bodies located in anterior column of spinal cord; innervate skeletal muscles
- *Gamma motor neurons (efferent fibers)*: cell bodies located in lateral columns of spinal cord; innervate intrafusal muscle fibers of the muscle spindle
- *Sensory neurons (somatic afferent fibers)*: cell bodies located in the dorsal root ganglia; innervate sensory receptors
- *Sympathetic neurons (visceral afferent fibers)*: cell bodies located in sympathetic ganglia; innervate sweat glands, blood vessels, viscera, and glands

Substantial mobility in the nervous system is needed for an individual to move during functional activities. With movement of an extremity, before there is increased tension in the nerve itself, the whole peripheral nerve moves, and there is movement between connective tissues and neural

tissues. This mobility is allowed without undue stress on the nerve tissue because:

- The arrangement of the spinal cord, nerve roots, and plexes allows mobility. If any part of the nervous system is placed under tension, the force can be dissipated throughout the system and neural ischemia is avoided.
- The connective tissue around the individual nerves and bundles of nerves (epineurium, perineurium, and endoneurium) absorb tensile forces before the nerve itself stretches.
- The perineurium specifically, the primary guard against excessive tension, allows for 18% to 22% strain before failure due to its longitudinal strength and elasticity.

Cadaveric and in vivo ultrasound studies of median nerve mobility and strain have shown nerve movement of 0.1 and 12.5 mm depending on the position and motion of each of the joints in the upper extremity and neck, 0.1 and 4.0 mm for the ulnar nerve, 0.7 and 5.2 mm for the tibial nerve, and 0.1 and 3.5 mm for the sciatic nerve, as well as a wavy appearance when on a slack (unloaded) and a straightening of the nerve when under tension.<sup>19,25,72</sup> Strain calculated in the stretch position (see upper limb neurodynamic test for the median nerve described in the section on peripheral nerve impairments later in this chapter) was 2.5% to 3.0%.<sup>25,72</sup>

## Common Sites of Injury to Peripheral Nerves

Compression and/or injury to the nerves of the peripheral nervous system can occur anywhere along the pathway from the nerve roots to their termination in the tissues of the trunk and extremities. As each nerve courses from the intervertebral foramina to its peripheral destination, there are sites that increase its susceptibility to either tension or compression. Symptoms and signs of nerve impairments are sensory changes or loss and motor weakness in the distribution of the involved nerve fibers. Because nerves are composed of innervated connective tissue and because blood vessels surround the axons, ischemic pain or tension pain may occur when these tissues are stressed. Also, because peripheral nerves include sympathetic fibers, autonomic responses might occur. Whenever neurological symptoms and signs are present, the entire nerve should be tested for mobility and signs of compression at key points along its pathway.

In this section, primary sites of compression, stress, or injury are identified for the peripheral nerves in the upper and lower quarter regions including their origins at the nerve roots and pathways through each of the plexuses.

### Nerve Roots

Nerve roots emerge from the spinal canal and traverse the foramina of the spine, where they can become impinged as a result of various pathologies of the spine that reduce the space in the foramina, such as degenerative disc disease, degenerative joint disease, disc lesions, and spondylolisthesis. With reduced spinal canal or foraminal space (stenosis), extension, side bending, or rotation of the vertebra to the side of the stenosis

further decreases the space where the nerve root courses and may cause or perpetuate symptoms. If adhesions place compression or stress on a nerve root, nerve mobility tests (described later in this chapter) can reproduce symptoms when the spine is side-bent (laterally flexed) away from the side causing the symptoms. When involved, symptoms and signs include sensory changes and/or loss of motor function in the respective dermatome and myotome patterns (Fig. 13.2 and Box 13.2). Nerve roots of the upper quarter include C5 through T1 and those of the lower quarter L1 through S3. Management guidelines for individuals with nerve root symptoms are described in Chapter 15.

### Brachial Plexus

After emerging from the foramina, the nerve fibers divide into anterior and posterior primary rami. Vasomotor fibers from the sympathetic trunk join the anterior primary rami to course within the brachial plexus and peripheral nerves to the extremities. The brachial plexus is formed by the anterior primary divisions of the C5–T1 nerve roots (Fig. 13.3). The plexus functions as the distribution center for organizing the contents of each peripheral nerve. In addition, Butler<sup>16</sup> suggested that the weave pattern in the brachial plexus contributes to the mobility of the nerves such that when tension is placed on any one peripheral nerve, the tension is transmitted to several cervical nerve roots rather than just one nerve root.

The brachial plexus courses through the region known as the thoracic outlet. There are three primary sites for compression or entrapment of the neurovascular structures in this region (see Fig. 13.19 later in this chapter).

- *Interscalene triangle*: bordered by the anterior and middle scalene muscles and first rib. It contains the subclavian artery and the upper, middle, and lower trunks of the brachial plexus.
- *Costoclavicular space*: between the clavicle, the subclavius muscle, and the costocoracoid ligament anteriorly and the first rib and the anterior and middle scalene muscles posteriorly. This space contains the subclavian vessels and the divisions of the brachial plexus.
- *Retropectoralis minor space*: inferior to the coracoid process, anterior to the second through fourth ribs, and posterior to the pectoralis minor. This space contains the cords of the brachial plexus and the axillary artery and vein.
- Structural anomalies, such as a cervical rib, an elongated C7 transverse process, or malunion of a clavicular fracture, may compress or entrap a portion of the plexus as well.

When vascular and/or neurological symptoms are caused by compression in the thoracic outlet, it is commonly referred to as thoracic outlet syndrome. Characteristics of this syndrome and management guidelines are described later in the chapter.

Other injuries to the brachial plexus include:

- **Upper plexus injuries (C5, 6)**: The most common injury to the plexus involves compression or tearing of the upper trunk. The mechanism involves shoulder depression and lateral flexion of the neck to the opposite side. There is loss

FIGURE 13.2 Dermatomes—anterior and posterior views.

### BOX 13.2 Key Muscles for Testing Upper and Lower Quarter Myotomes<sup>52</sup>

#### Upper Quarter

C1–2	Cervical flexion
C3	Cervical side flexion
C4	Scapular elevation
C5	Shoulder abduction
C6	Elbow flexion and wrist extension
C7	Elbow extension and wrist flexion
C8	Thumb extension
T1	Finger abduction

#### Lower Quarter

L1–2	Hip flexion
L3	Knee extension
L4	Ankle dorsiflexion
L5	Big toe extension
S1	Ankle eversion and plantar flexion, hip extension
S2	Knee flexion
S3	No specific test action; intrinsic foot muscles (except abductor hallucis)

of abduction and lateral rotation of the shoulder and weakness in elbow flexion and forearm supination (waiter's tip position). Erb's palsy occurs with birth injuries when the shoulder is stretched downward, although Benjamin<sup>5</sup> cautioned that there are maternal and infant factors that could contribute to this injury in addition to the forces applied during delivery. A "stinger" occurs with injuries that might be sustained when a football player lands on the upper torso and shoulder with the head/neck laterally flexed in the opposite direction.

- **Middle plexus injuries (C7):** Rarely seen alone.
- **Lower plexus injuries (C8, T1):** Usually due to compression by a cervical rib or stretching the arm overhead. Klumpke's paralysis (paralysis of the intrinsic of the hand) occurs in birth injuries when the baby presents with its arm overhead.<sup>5</sup>
- **Complete or total injury of the plexus:** Complete paralysis from a total brachial plexus injury may occur as a complication of birth; it is known as Erb-Klumpke's paralysis and is associated with Horner's syndrome in one-third of those severely affected.<sup>5</sup>

**FIGURE 13.3** Brachial plexus.

### Peripheral Nerves in the Upper Quarter

The brachial plexus terminates in five primary peripheral nerves that are responsible for innervating the tissues of the upper extremity: (1) musculocutaneous, (2) axillary, (3) median, (4) ulnar, and (5) radial nerves. Common sites for compression or tension injuries for each of the nerves are described in this section. The patterns of muscle weakness and primary impairments with peripheral nerve injuries in the upper quarter are summarized in a table that is available on the FA Davis web site associated with this text (see ONL Table 13.1)

#### Axillary Nerve: C5, 6

The axillary nerve (Fig. 13.4) emerges from the posterior cord of the brachial plexus; it passes laterally through the axilla, sends a branch to the teres minor muscle, courses behind the surgical neck of the humerus, and innervates the deltoid muscle and overlying skin. The axillary nerve is vulnerable to injury with dislocation of the shoulder and fractures of the surgical neck of the humerus. If the upper trunk of the brachial plexus is stretched or injured, it affects the function of the axillary nerve. Shoulder abduction and lateral rotation are impaired when this nerve is affected.

#### Musculocutaneous Nerve: C5, 6

The musculocutaneous nerve (Fig. 13.4) emerges from the lateral cord of the brachial plexus and crosses the axilla with the median nerve; it pierces and innervates the coracobrachialis and then travels distally to innervate the biceps and brachialis muscles. It continues between these muscles to the flexor surface of the elbow; after emerging from the deep fascia at the elbow, it becomes the lateral cutaneous nerve of the forearm. Isolated impingement of this nerve is not common; injury to the lateral cord or the upper trunk of the brachial

plexus affects the musculocutaneous nerve. When affected, the patient is unable to flex the elbow with the forearm supinated and may have some instability in the shoulder.

#### Median Nerve: C6–8

Bundles from the medial and lateral cords of the brachial plexus unite in the uppermost part of the arm to form the median nerve (Fig. 13.5). The median nerve courses the medial aspect of the humerus to the elbow, where it is deep in the cubital fossa under the bicipital aponeurosis, medial to the tendon of the biceps and brachial artery; it then moves into the forearm between the two heads of the pronator teres muscle. Hypertrophy of this muscle can compress the median nerve, producing symptoms that mimic carpal tunnel syndrome except that the forearm muscles (pronator teres, wrist flexors, extrinsic finger flexors) are involved in addition to the intrinsic muscles.

To enter the hand, the median nerve passes through the carpal tunnel at the wrist with the flexor tendons. The carpal tunnel is covered by the thick, relatively inelastic transverse carpal ligament. Entrapment of the median nerve in the tunnel, called carpal tunnel syndrome, causes sensory changes and progressive weakness in the muscles innervated by the median nerve distal to the wrist. Characteristics of this syndrome and management guidelines are described later in the chapter.

#### Ulnar Nerve: C8, T1

The ulnar nerve (Fig. 13.6) emerges from the medial cord of the brachial plexus at the lower border of the pectoralis minor and descends the arm along the medial side of the humerus. It passes posterior to the elbow joint in the groove between the medial epicondyle of the humerus and the olecranon of the ulna. The groove is covered by a fibrous sheath that forms

**FIGURE 13.4** Sensory and motor innervations of the axillary (C5, 6) and musculocutaneous (C5, 6) nerves.

the cubital tunnel. The nerve possesses considerable mobility to stretch around the elbow as it flexes, although the nerve can be easily irritated or entrapped at the elbow owing to its superficial location and anatomic arrangement.<sup>28</sup> It then passes between the humeral and ulnar heads of the flexor carpi ulnaris muscle, another site where impingement could occur.<sup>28</sup> The extrinsic muscles innervated by the ulnar nerve are the flexor carpi ulnaris and ulnar half of the flexor digitorum profundus.

The ulnar nerve enters the hand through a trough formed by the pisiform bone and hook of the hamate bone and is covered by the volar carpal ligament and palmaris brevis muscle, forming the tunnel of Guyon. Trauma or entrapment in this region causes sensory changes and progressive weakness of muscles innervated distal to the site, resulting in a partial claw-hand deformity. Injury to the nerve after it bifurcates leads to partial involvement, depending on the site of injury.<sup>27,28</sup> Characteristics of ulnar nerve impingement in the tunnel and management guidelines are described later in the chapter.

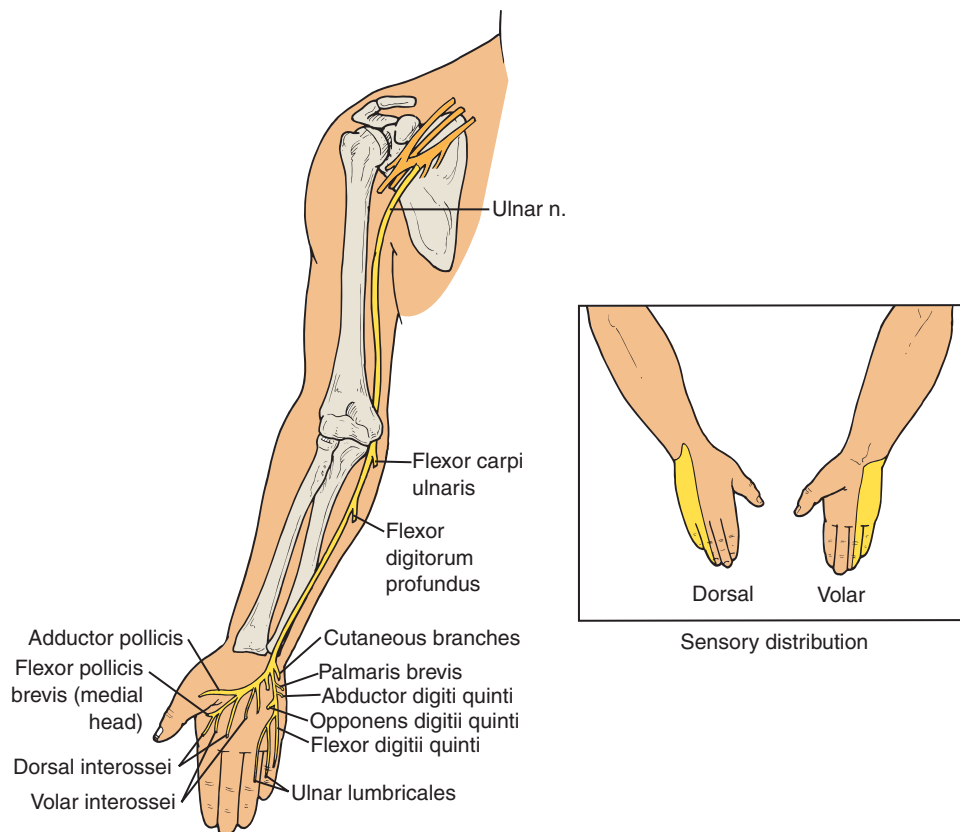

### Radial Nerve: C6–8, T1

The radial nerve (Fig. 13.7) emerges directly from the posterior cord of the brachial plexus at the lower border of the pectoralis

minor. As it descends the arm, it winds around the posterior aspect of the humerus in the spiral groove between the lateral and medial heads of the triceps muscle and continues to the radial aspect of the elbow. In the arm it innervates the triceps, anconeus, and upper portion of the extensor and supinator group of the forearm. Injury to this nerve may occur with shoulder dislocations and midshaft humeral fractures. Also known to all therapists is “crutch palsy,” a condition of nerve compression caused by leaning on axillary crutches. “Saturday night palsy” occurs when sleeping with the person’s head on the arm that is slung over the back of a chair or open car window. The triceps is involved only if the compression or injury to the nerve occurs close to the axilla. At the elbow, the radial nerve pierces the lateral muscular septum anterior to the lateral epicondyle and passes under the origin of the extensor carpi radialis brevis; it then divides into a superficial and a deep branch. The deep branch may become entrapped as it passes under the edge of the extensor carpi radialis brevis and the fibrous slit in the supinator, causing progressive weakness in the wrist and finger extensor and supinator muscles (except the extensor carpi radialis longus, which is innervated proximal to the bifurcation). Impingement may occur here and may be erroneously called tennis elbow (lateral epicondylitis—see

**FIGURE 13.5** Sensory and motor innervations of the median nerve (C6–8, T1).

**FIGURE 13.6** Sensory and motor innervations of the ulnar nerve (C8, T1).

**FIGURE 13.7** Sensory and motor innervations of the radial nerve (C6–8, T1).

Chapter 18). The deep branch passes around the neck of the radius and may be injured with a radial head fracture. The superficial radial nerve may undergo direct trauma that causes sensory changes in the distribution of the nerve.

The radial nerve enters the hand on the dorsal surface as the superficial radial nerve, which is sensory only; therefore, injury to it in the wrist or hand does not cause any motor weakness. The influence of the radial nerve on hand musculature is entirely proximal to the wrist. Injury proximal to the elbow results in wrist drop and inability to actively extend the wrist and fingers. This affects the length-tension relationship of the extrinsic finger flexors, resulting in an ineffective grip unless the wrist is splinted in partial extension. Injury to the radial nerve in the proximal forearm affects only the supinator muscle and extrinsic abductor and extensor pollicis longus muscles.<sup>47</sup>

### Lumbosacral Plexus

The lumbar plexus is formed by the anterior primary divisions of the nerve roots L1, L2, L3, and part of L4 (Fig. 13.8 A); the sacral plexus is formed from L4, L5, S1, and parts of S2 and S3 (Fig. 13.8 B). As with the brachial plexus, the branches and divisions of the lumbosacral plexus organize the content of each of the peripheral nerves coursing into the lower extremity. In addition, the anterior primary rami of the plexus receive

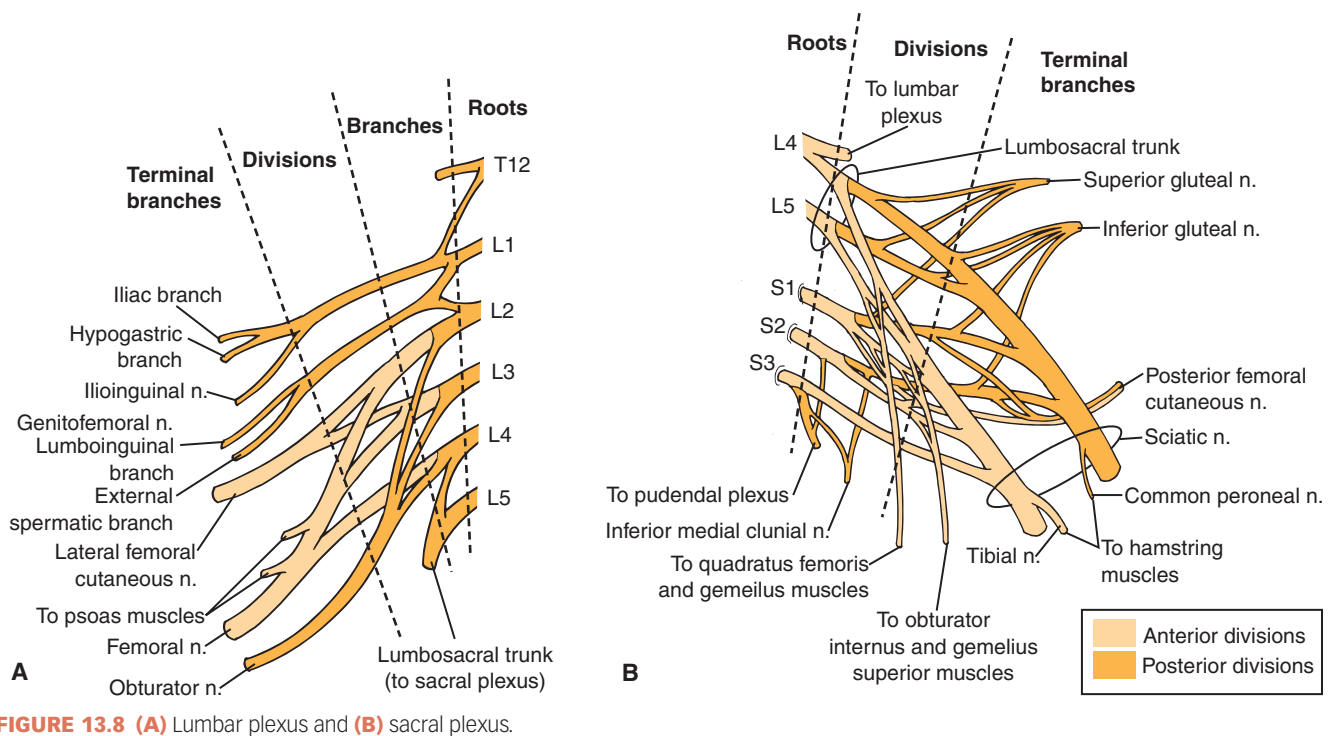

postganglionic sympathetic fibers from the sympathetic chain that innervate blood vessels, sweat glands, and piloerector muscles in the lower extremity. Isolated injuries to the lumbar plexus or sacral plexus are not common; symptoms more commonly arise from disc lesions or spondylitic deformities that affect one or more nerve roots or from tension or compression of specific peripheral nerves.

### Peripheral Nerves in the Lower Quarter

The lumbosacral plexus terminates in three primary peripheral nerves, which are responsible for innervating the tissues of the lower extremity. They are the femoral and obturator nerves from the lumbar plexus and the sciatic nerve from the sacral plexus. Common sites for compression or tension injuries are described in this section. The patterns of muscle weakness with peripheral nerve injuries in the lower quarter and primary impairments are summarized in a table that is available on the FA Davis website associated with this text (see ONLINE Table 13.2).

#### Femoral Nerve: L2–4

The femoral nerve (Fig. 13.9) arises from the three posterior divisions of the lumbar plexus. It emerges from the lateral border of the psoas muscle superior to the inguinal ligament and descends underneath the ligament to the

**FIGURE 13.8 (A)** Lumbar plexus and **(B)** sacral plexus.

femoral triangle, lateral to the femoral artery, to innervate the sartorius and quadriceps muscle group. The iliopsoas is supplied superior to the ligament. Injuries to the nerve may occur with trauma, such as fractures of the upper femur or pelvis, during reduction of congenital dislocation of the hip, or from pressure during a forceps labor and delivery—resulting in weakness of hip flexion and loss of knee extension. Symptoms may occur from neuritis in diabetes mellitus.

#### Obturator Nerve: L2–4

The obturator nerve (Fig. 13.9) arises from the three anterior divisions of the lumbar plexus. It descends through the obturator canal in the medial obturator foramen to the medial side of the thigh to innervate the adductor muscle group and obturator externus. Isolated injury to this nerve is rare, although uterine pressure and damage during labor may cause the injury. If damaged, adduction and external rotation of the thigh are impaired, with the individual having difficulty crossing his or her legs.

#### Sciatic Nerve: L4, 5; S1–3

The sciatic nerve (Fig. 13.10) emerges from the sacral plexus as the largest nerve in the body; its component parts—the tibial and common peroneal nerves—can be differentiated in the common sheath. Muscles in the buttock region (external rotators and gluteal muscles) are innervated by small nerves from the sacral plexus, which emerge proximal to formation of the sciatic nerve. The sciatic nerve exits the pelvis through the greater sciatic foramen and typically courses below, although sometimes through, the piriformis muscle. Piriformis

syndrome may occur from a shortened muscle, causing compression and irritation of the nerve at this site. The nerve is protected under the gluteus maximus as it courses between the ischial tuberosity and greater trochanter, although injury may occur in this region with hip dislocation or reduction. The tibial portion of the sciatic nerve innervates the biarticular hamstring muscles and a portion of the adductor magnus; the common peroneal portion innervates the short head of the biceps femoris. Proximal to the popliteal fossa, the sciatic nerve terminates when the tibial and common peroneal nerves emerge as separate structures.

#### Tibial/Posterior Tibial Nerve: L4, 5; S1–3

The tibial nerve (Fig. 13.10) forms from the anterior primary rami of the sacral plexus, courses with the common peroneal nerve as the sciatic nerve, and then emerges as a separate nerve proximal to the popliteal fossa. After coursing through the popliteal fossa, it sends a branch that joins a branch from the common peroneal nerve to form the sural nerve and continues on as the posterior tibial nerve. In the leg, it innervates the muscles of the posterior compartment, including the plantar flexors, popliteus, tibialis posterior, and extrinsic toe flexors.

In its approach to the foot, the nerve occupies a groove behind the medial malleolus along with the tendons of the tibialis posterior, flexor hallucis longus, and flexor digitorum longus; the groove is covered by a ligament, forming a tunnel. Entrapment, usually from a space-occupying lesion, is known as *tarsal tunnel syndrome*. The nerve then divides into the medial and lateral plantar and calcaneal nerves.

**FIGURE 13.9** Sensory and motor innervations of the femoral (L2–4) and obturator (L2–4) nerves.

**Plantar and calcaneal nerves.** The plantar and calcaneal nerves may become entrapped as they turn under the medial aspect of the foot and pass through openings in the abductor hallucis muscle, especially with overpronation of the foot, which stresses the nerves against the fibrous-edged openings in the muscle. Symptoms elicited are similar to acute foot strain (tenderness at the posteromedial plantar aspect of the foot), painful heel (inflamed calcaneal nerve), and pain in a pes cavus foot. The medial and lateral plantar nerves innervate all the intrinsic muscles of the foot except the extensor digitorum brevis. The innervation pattern of the lateral plantar nerve in the foot corresponds to the ulnar nerve in the hand, and the medial plantar nerve corresponds to the median

nerve. Weakness and postural changes in the foot, such as pes cavus and clawing of the toes, may occur with nerve compression or injury.

#### **Common Peroneal Nerve: L4, 5; S1, 2**

After it bifurcates from the sciatic nerve in the knee region, the common peroneal nerve (Fig. 13.11) passes between the biceps femoris tendon and lateral head of the gastrocnemius muscle, sends a branch to join the tibial nerve and form the sural nerve, and then comes laterally around the fibular neck and passes through an opening in the peroneus longus muscle. Pressure or force against the nerve in this region can cause neuropathy, including sensory changes and weakness in the

**FIGURE 13.10** Sensory and motor innervations of the sciatic nerve (L4, 5, S1–3) and tibial nerve (L4, 5, S1–3).

muscles of the anterior and lateral compartments of the leg. Injury also occurs subsequent to fracture of the head of the fibula, from rupture of the lateral collateral ligament of the knee, or from a tightly applied cast. Also, most people have experienced their foot “falling asleep” from sustained pressure when crossing their legs. The common peroneal nerve bifurcates just below the neck of the fibula into the superficial and deep peroneal nerves.

**Superficial peroneal nerve.** The superficial peroneal nerve descends along the anterior part of the fibula, innervating the peroneus longus and brevis muscles, and continues on with cutaneous innervations. Injury to just this nerve primarily affects eversion. Over time, equinovarus may develop from unopposed inversion.

**Deep peroneal nerve.** The deep peroneal nerve descends the leg along the interosseous membrane and distal tibia, innervating the ankle dorsiflexors, toe extensors, and peroneus

tertius. In the foot, it innervates the extensor digitorum brevis. Injury to the deep peroneal nerve results in foot drop and unopposed eversion during gait. Over time, pes valgus may develop.

## Impaired Nerve Function

### Nerve Injury and Recovery

Peripheral nerve injury may result in motor, sensory, and/or sympathetic impairments. In addition, pain may be a symptom of nerve tension or compression because the connective tissue and vascular structures surrounding and in the peripheral nerves are innervated and the peripheral nerve function is sensitive to hypoxic states. Knowing the mechanism of injury and the clinical signs and symptoms helps the clinician

**FIGURE 13.11** Sensory and motor innervations of the peroneal nerve (L4, 5, S1, 2).

determine the potential outcome for the patient and develop a plan of care.<sup>38,71,74</sup>

## Mechanisms of Nerve Injury

Nerves are mobile and capable of withstanding considerable torsion and lengthening owing to their arrangement. Yet, they are susceptible to various types of injury and malfunction including:<sup>13,71,74</sup>

- Compression (sustained pressure applied externally, such as tourniquet, or internally, such as from bone, tumor, edema, or soft tissue impingement resulting in mechanical or ischemic injury).
- Laceration (knife, gunshot, surgical complication, or injection injury).
- Stretch (excessive tension or tearing from traction forces).
- Radiation.
- Electricity (lightning strike or electrical malfunction).
- Injection (local anesthesia, steroids, or antibiotics).

Injury may be complete or partial and produces symptoms based on the location of the insult.

Biomechanical injuries to the peripheral nervous system are most commonly the result of friction, compression, and stretch.<sup>13,16,71</sup> Secondary injury can be from blood or edema. Compressive forces can affect the microcirculation of the nerve, causing venous congestion and reduction of axoplasmic

transport,<sup>53,71</sup> thus blocking nerve impulses; if sustained, the compression can cause nerve damage. The endoneurium helps maintain fluid pressure and may provide cushioning for nerves, especially when the nerves are close to the surface and subject to greater pressure.

The insult can be acute from trauma or chronic from repetitive trauma or entrapment. Sites where a peripheral nerve is more vulnerable to compression, friction, or tension include tunnels (soft tissue, bony, fibro-osseous), branches of the nervous system (especially if the nerve has an abrupt angle), points at which a nerve is relatively fixed when passing close to rigid structures (across a bony prominence), and at specific tension points.

Response to injury can be pathophysiological or pathomechanical, leading to symptoms derived from adverse tension on the nervous system. Results may be intraneural and/or extraneural.<sup>16</sup>

- **Intraneural.** Pathology that affects the conducting tissues (e.g., hypoxia or demyelination) or connective tissues of the nerve (e.g., scarring of epineurium or irritation of dura mater) may restrict the elasticity of the nervous system itself.
- **Extraneural.** Pathology that affects the nerve bed (e.g., blood), adhesions of epineurium to another tissue (e.g., a ligament), and swelling of tissue adjacent to a nerve (e.g., foraminal stenosis) may restrict the gross movement of the nervous system in relation to surrounding tissues.

## Classification of Nerve Injuries

Nerve injuries are classified using either the Seddon or Sunderland classification systems; both are based on structural and functional changes that occur in the nerve with various degrees of damage.<sup>3,33,38,62,75,78</sup> These systems describe the degree of injury to nerve substructures and the effect on prognosis. Seddon's system describes three levels of pathology: neuropraxia, axonotmesis, and neurotmesis. Sunderland's classification details five levels of injury and potential for recovery. The characteristics of Seddon's classification of nerve injuries are summarized in Box 13.3 and are compared with Sunderland's classification in Figure 13.12.

## Recovery From Nerve Injuries

Nerve tissue that has become irritated from tension, compression, or hypoxia may not have permanent damage and shows signs of recovery when the irritating factors are eliminated.<sup>16</sup> When the nerve has been injured, recovery is dependent on several factors, including the extent of injury to the axon and its surrounding connective tissue sheath, the nature and level of the injury, the timing and technique of the repair (if necessary), and the age and motivation of the person.<sup>13,74</sup>

- **Nature and level of injury.** The more damage to the nerve and tissues, the more tissue reaction and scarring occur. Also, the proximal aspect of a nerve has greater combinations of motor, sensory, and sympathetic fibers, so disruption there

**BOX 13.3 Seddon's Classification and Characteristics of Nerve Injury**<sup>3,33,38,61,75,78</sup>**Neuropraxia**

- Segmental demyelination
- Action potential slowed or blocked at point of demyelination; normal above and below point of compression
- Muscle does not atrophy; temporary sensory symptoms
- The result of mild ischemia from nerve compression or traction
- Recovery is usually complete

**Axonotmesis**

- Loss of axonal continuity but connective tissue coverings remain intact
- Wallerian degeneration distal to lesion
- Muscle fiber atrophy and sensory loss

- The result of prolonged compression or stretch causing infarction and necrosis
- Recovery is incomplete—surgical intervention may be required

**Neurotmesis**

- Complete severance of nerve fiber with disruption of connective tissue coverings
- Wallerian degeneration distal to lesion
- Muscle fiber atrophy and sensory loss
- The result of gunshot or stab wounds, avulsion, rupture
- No recovery without surgery—recovery depends on surgical intervention and correct regrowth of individual nerve fibers in endoneurial tubes

**FIGURE 13.12** Comparison of Sunderland's and Seddon's classifications of nerve injuries. **(1)** First degree injury (neuropraxia): minimal structural disruption—complete recovery; **(2)** second degree (axonotmesis): complete axonal disruption with wallerian degeneration—usually complete recovery; **(3)** third degree (may be either axonotmesis or neurotmesis): disruption of axon and endoneurium—poor prognosis without surgery; **(4)** fourth degree (neurotmesis): disruption of axon, endoneurium, and perineurium—poor prognosis without surgery; **(5)** fifth degree (neurotmesis): complete structural disruption—poor prognosis without microsurgery.<sup>74</sup>

results in a greater chance of mismatching the fibers, thus affecting regeneration. Regeneration is often said to occur at a rate of 1 mm per day, but rates from 0.5 to 9.0 mm per day have been reported based on the nature and severity of the injury, duration of denervation, condition of the tissues, and whether surgery is required.<sup>3,13,62</sup>

- **Timing and technique of repair.** Laceration or crush injuries that disrupt the integrity of the entire nerve require

surgical repair. For optimal nerve regeneration, timing of the repair is critical, as are the skill of the surgeon and the technique used to align the segments accurately and avoid tension at the suture line. Different regenerative potential outcomes following nerve repair have also been reported based on groupings of specific nerves.<sup>3,38,74</sup>

- Excellent regenerative potential: radial, musculocutaneous, and femoral nerves

- Moderate regenerative potential: median, ulnar, and tibial nerves
- Poor regenerative potential: peroneal nerve
- **Age and motivation of the patient.** The nervous system must adapt and relearn use of the pathways once regeneration occurs. Motivation and age play a role in this, especially in the very young and the elderly.<sup>74</sup>

### Outcomes of Nerve Regeneration

Smith<sup>74</sup> described five possible outcomes of nerve regeneration.

1. Exact reinnervation of its native target organ with return of function
2. Exact reinnervation of its native target organ but no return of function due to degeneration of the end organ
3. Wrong receptor reinnervated in the proper territory; therefore, improper input
4. Receptor reinnervation in wrong territory causing false localization of input
5. No connection with an end organ

### Management Guidelines: Recovery from Nerve Injury

In general, recovery from nerve injury can be viewed as occurring in three phases.

- **Acute phase.** This is early after injury or surgery when the emphasis is on healing and prevention of complications.
- **Recovery phase.** This is when reinnervation occurs. Emphasis is on retraining and re-education.
- **Chronic phase.** This occurs when the potential for reinnervation has peaked, and there are significant residual deficits. The emphasis is training compensatory function.

Effective management must consider not only nerve healing, but also connective tissue healing in general (see Chapter 10).

Management guidelines for the three phases of recovery from peripheral nerve injury are summarized in Box 13.4.

### Acute Phase

Following injury or immediately after surgery (e.g., following decompression and release or following repair of a lacerated nerve), there may be a period of immobilization for a minimum of 3 weeks to protect the nerve, minimize inflammation, and minimize compression or traction at the injured/repared site. The specific orthosis or position of the orthosis will depend on the nerve injured or repaired. Encourage active movement of uninvolved joints immediately. As soon as allowed, begin:

- **Pain and edema management.** Elevation, compression, and use of modalities (transcutaneous electrical nerve stimulation [TENS], high voltage galvanic stimulation [HVGS]) to wean off medications.
- **Movement.** Begin range of motion (ROM) of uninvolved joints to minimize joint and connective tissue contractures.
- **Orthosis management.** Use of an orthosis may be necessary to prevent deformities due to strength imbalances (e.g., use of a radial nerve orthosis to prevent wrist drop; a median nerve orthosis to position the thumb in opposition; a plantarflexion orthosis to prevent foot drop), to prevent undue stress on the healing nerve tissue, and to facilitate new movement as reinnervation occurs.
- **Patient education.** Teach the patient safe movements and ways to protect the injured nerve and to avoid injury due to loss of sensation.

### Recovery Phase

The recovery phase begins with signs of reinnervation (volitional muscle contraction and hypersensitivity). With nerve regeneration and recovery, begin:<sup>26</sup>

- **Motor retraining.** When signs of volitional muscle contraction occur, begin place and hold exercises by positioning the

#### BOX 13.4 MANAGEMENT GUIDELINES— Recovery from Peripheral Nerve Injury

##### Acute phase: immediately after injury or surgery

- **Immobilization:** time dictated by surgeon
- **Movement:** amount and intensity dictated by type of injury and surgical repair
- **Orthosis:** may be necessary to prevent deformities
- **Patient education:** protection of the part (see Box 13.5)

##### Recovery phase: signs of reinnervation (muscle contraction, increased sensitivity)

- **Motor retraining:** muscle “hold” in the shortened position
- **Desensitization:** multiple textures for sensory stimulation; vibration
- **Discriminative sensory reeducation:** identification of objects with, then without, visual cues

##### Chronic phase: reinnervation potential peaked with minimal or no signs of neurological recovery

- **Compensatory function:** compensatory function is minimized during the recovery phase but is emphasized when full neurological recovery does not occur
- **Preventive care:** emphasis on lifelong care to involved region (see Box 13.5)

muscle in its shortened position; then ask the patient to hold. Provide assistance as needed to prevent the part from “falling” out of the shortened position.

- Use neuromuscular electrical stimulation to reinforce this active effort.
- When the muscles demonstrate control of some range, begin gravity-eliminated, active-assistive ROM. Continue to protect the weak muscles with an orthosis as needed.
- **Desensitization.** As nerves regenerate, the person experiences increased sensitivity (hypersensitivity) in the area that had previously been without sensation. Use a graded series of multisensory procedures to decrease the irritability, increase cortical representation, and increase reintegration of sensory input.<sup>26</sup> Suggestions are described in Box 13.5.
- **Discriminative sensory re-education.** This is the process of retraining the brain to recognize a stimulus once the

hypersensitivity diminishes. Techniques are summarized in Box 13.5.

- **Patient education.** Instruct the patient to resume use of the extremity gradually while monitoring pain, swelling, or any discoloration; if necessary, modify or temporarily avoid any aggravating activities. While the nerve is recovering or if nerve recovery is incomplete, teach the patient preventive care to avoid injury (Box 13.6).

### Chronic Phase

When the potential for reinnervation has peaked and there are minimal or no signs of reinnervation, emphasize training for compensatory function. The person will probably have to continue to wear the supportive orthosis and preventive care must continue indefinitely.

#### BOX 13.5 Desensitization and Sensory Re-education Techniques

##### Suggestions for graded modalities and procedures for desensitizing:

- Use multiple types of textures or contact for sensory stimulation, such as cotton, rough material, sandpaper of various grades, and Velcro. The textures can be wrapped around dowel rods for finger manipulation or to stroke along the skin for 1-3 minutes.
- Place contact particles, such as cotton balls, beans, macaroni, sand, or other material, with various degrees of roughness in tubs or cans, so the patient can run the involved hand or foot through the material. Have the patient begin by manipulating or placing the extremity in the least irritating texture for 1-3 minutes. As tolerance improves, progress to the next texture of slightly more irritating but tolerable stimulus. Maximum progress occurs when the most irritating texture is tolerated.
- Use vibration. Pattern of recovery after nerve injury is pain (hypersensitivity), perception of slow vibration (30 cps), moving touch, constant touch, rapid vibration (256 cps), and awareness from proximal to distal.<sup>74</sup>

##### Suggestions for retraining the brain to recognize a stimulus:

- Begin by using a moving touch stimulus, such as the eraser end of a pencil, and stroke over the area. The patient first watches, then closes his or her eyes, and tries to identify *where* touch occurred.
- Progress from stroking to using constant touch.
- When the patient is able to localize constant touch, progress to identification of familiar objects of various sizes, shapes, and textures.
- For the hand, use familiar household and personal care objects, such as keys, coins, eating utensils, blocks, toothbrush, and safety pins.
- For the feet, have the patient walk on various surfaces, such as grass, sand, wood, pebbles, and uneven surfaces.

#### BOX 13.6 Patient Instructions for Preventive Care After Nerve Injury

##### While the nerve is regenerating, or if nerve recovery is incomplete:

- Inspect skin regularly; provide prompt treatment of wounds or blisters.
- Compensate for dryness with massage creams or oils.

##### In the upper extremity:

- Avoid handling hot, cold, sharp, or abrasive objects.
- Avoid sustained grasps; change use of tools frequently.
- Redistribute hand pressure by building up the size of the handles.
- Wear protective gloves.

##### In the lower extremity:

- Wear protective shoes that fit properly.
- Inspect feet regularly for pressure points (reddened area) and modify shoes or provide protection if they occur.
- Do not walk barefoot, especially in the dark or on rough surfaces.
- Shift weight frequently when standing for long periods.

## Neural Tension Disorders

Normally, the nervous system has considerable mobility to adapt to the wide range of movements imposed on it by daily activities. Still, there are sites where nerves are vulnerable to increased pressure or tension, especially when excessive or repetitive stresses or strains are imposed on the tissues surrounding the nerves or on the nerves themselves. If a nerve is compressed as it passes near a bony structure or through a confined space, undue deformation may occur as movement occurs proximal or distal to that site. This may be magnified if there is adhesive scar tissue or swelling that restricts elongation and mobility. When examining a patient, the therapist needs to be alert to symptoms described by the patient and

able to understand and interpret positive signs detected with testing maneuvers.

This section summarizes the tests of provocation and describes the techniques that have been reported to mobilize components of the nervous system in order to improve the patient's outcome.<sup>16,62,71</sup>

## Symptoms and Signs of Impaired Nerve Mobility

### History

Vascular and mechanical factors can lead to nerve pathology. Pain is the most common symptom. Sensory responses, reported as stretch pain or paresthesia, occur when tissues are in the neural stretch position.<sup>21</sup> Clinical reasoning is used to understand the possible mechanism of injury, such as pathological insult to the nervous tissue or surrounding tissues or symptoms from movement patterns that place compression or tension on the neural tissues and reproduce symptoms.<sup>71</sup>

### Tests of Provocation

Neurodynamic test maneuvers are performed to detect tension or compression in the neural tissue. The upper limb neurodynamic test (ULNT), straight leg raise (SLR), and slump test are familiar terms that describe various tests and procedures that will be described later in this chapter.<sup>16,71</sup> Points regarding the tests:

- Because the test positions elongate the nerves across multiple joints, every joint in the chain must be examined separately for limitations in ROM, mobility, and symptom provocation prior to neurodynamic testing so that any restriction that occurs during the test is not the result of joint or periarticular tissue limitations.<sup>16,71</sup> Coppieters and associates<sup>21</sup> demonstrated that the stretch position altered the available ROM and sensory responses in 35 normal male subjects during neurodynamic testing and reiterated the importance of looking at other influences prior to neurodynamic testing.
- Additional tests for nerve function include nerve palpation, sensation testing, reflex testing, dexterity testing, and muscle testing.<sup>16,26,71</sup>
- The test positions and maneuvers used to detect nerve mobility are the same as the treatment positions and maneuvers.
- Test the uninvolved or least symptomatic side first. If testing of the uninvolved side produces symptoms, sensitivity of the nerve roots or central sensitization should be considered.<sup>16</sup>
- Perform the tests actively before passively to decrease the patient's anxiety about performing the maneuver. If the active test is found to be sensitive, determine whether a passive test is also needed. A positive active test will also inform the therapist that neurodynamic glides would be an appropriate adjunct to the plan of care.
- For a test to be considered positive it must (1) reproduce the patient's symptoms (pain or paresthesias) within the nerve distribution being tested, plus (2) demonstrate differences from side to side and to known normal responses,

plus (3) support findings from the full examination including symptom pattern and location, physical findings (i.e., strength, ROM, joint mobility), plus (4) the sensitizing maneuvers alter the patient's symptoms.<sup>11,71</sup> Sensitizing maneuvers produce either pain or paresthesias when the neurological system is elongated across multiple joints or is relieved when one of the joints (usually the most proximal or distal) is moved out of the elongated position.

**General testing procedure:** Slowly and carefully elongate the nerve across each joint in succession until there is symptom provocation or tissue restriction is felt (described in detail in the techniques section). When symptoms occur, note the final position. Once symptoms are provoked or limitation in motion occurs, sensitize the maneuver by moving one of the joints out of the elongated position or moving one of the joints proximal or distal into a more elongated position to see if the symptoms are relieved or provoked respectively.

## Causes of Symptoms

Butler<sup>15</sup> originally proposed that symptoms are the result of tension being placed on some component of the nervous system, thus referring to these set of tests as "neural tension tests." He thought that if compression is preventing normal mobility, tension signs occur when the nerve is stressed either proximal or distal to the site of compression. Restriction of movement could be from inflammation and scarring between the nerve and the tissue through which it runs or from actual changes in the nerve itself. More recently, Butler has embraced the concept of "neurodynamics" introduced by Shacklock in 1995. The thought is that "dynamics" is more encompassing, moving away from strictly mechanical causes to include physiological issues as well as changes in plasticity in the nervous system.<sup>16,71</sup>

### FOCUS ON EVIDENCE

Cadaveric and in vivo ultrasound imaging studies have demonstrated that ROM of the moving joint, distance from the moving joint to the site of the lesion, position of adjacent joints, number of moving joints, and whether joint movement elongates or shortens the nerve bed all have an impact on nerve excursion<sup>18-20,25,39,72</sup> and that elongation or shortening of the sciatic, tibial, and plantar nerves occur to various degrees with hip, knee, ankle, and toe movements.<sup>1,11,18,20</sup> In addition, Coppieters<sup>18</sup> demonstrated greater sciatic nerve excursion occurs with simultaneous hip/knee movement than with any of the tensioning techniques.

As with many manual testing techniques, the sensitivity and validity of the tests have yet to be determined. Although the volume of evidence continues to be limited, more recent studies demonstrate the reliability and validity of ULNT to be promising.<sup>60,68,81</sup> In addition, there is emerging evidence that ULNT testing may not only be for brachial plexus and peripheral nerve testing and treatment, but that it may also be effective for

pathology in the cervical region including cervical radiculopathy, entrapment neuropathies, and thoracic outlet syndrome.<sup>48</sup>

The efficacy of interventions based on the neurodynamic maneuvers has been presented in the literature.<sup>17,29,42</sup> A systematic review of research on therapeutic efficacy of neural mobilization evaluated 10 randomized controlled studies.<sup>29</sup> Even though the majority of the studies described positive benefits, the review questioned the quality of the studies and expressed the need for more homogeneity and control in future studies in order to provide evidence for the use of neural mobilization as a therapeutic intervention.

## Principles of Management

The principles of neural mobilization are based on the anatomic and biomechanical properties of peripheral nerves and their response to stress and strain. The goal of neural mobilization is to maximize the excursion of the nerve while minimizing the strain. Strain is defined as the change in nerve length induced by a longitudinal tensile stress.<sup>67</sup> For the nervous system to move normally, it must withstand tensile stress, slide in its container, and be compressible.<sup>71</sup>

The principles of treatment are similar to those of any mobilization technique; however, the greatest error clinicians make with these techniques is being too aggressive and doing too much, too fast.<sup>16,61,71</sup>

- The intensity of the maneuver should be related to irritability of the tissue, patient response, and change in symptoms. The greater the irritability, the gentler the technique.
- The technique, when applied properly, should be symptom free, slow, and rhythmic, utilizing an oscillatory motion.
- **Neural sliding, flossing technique.** Position the patient at the point of tissue resistance or onset of symptoms, then move two joints in the chain simultaneously so that the neural tissue glides proximally or distally. For example, to glide the median nerve proximally once at the position of tissue resistance or onset of symptoms, perform elbow flexion simultaneously with cervical contralateral flexion or wrist flexion simultaneously with elbow flexion.
- **Neural glide technique:** Position the patient at the same point as in the sliding technique. Offload the nerve by placing the neural tissue on slack either by laterally flexing the proximal segment toward the involved side or by releasing the position of the distal segment. Then slowly and in an oscillatory fashion using large movements, gently move one segment in and out of the point of tissue resistance.
- After performing several treatments and determining the tissue response, teach the patient self-mobilization techniques.

## Precautions and Contraindications to Neurodynamic Testing and Treatment

There is incomplete scientific understanding of the pathology and mechanisms that occur when mobilizing the nervous system. The clinician should always perform a thorough subjective

and physical examination which includes a systems review and screening for “red flag” conditions prior to neurodynamic testing and treatment. Caution should be used when loading the neurological system during performance of these techniques. Neurological symptoms of tingling or increased numbness should not last when the position is released.<sup>16,67,71</sup>

### PRECAUTIONS:

- Know what other tissues are affected by the positions and maneuvers.
- Recognize the irritability of the tissues involved and do not aggravate the symptoms with excessive stress or repeated movements.
- Identify whether the condition is worsening and the rate of worsening. A rapidly worsening condition requires greater care than a slowly progressing condition.
- Use care if there is an active disease or other pathology affecting the nervous system.
- Watch for signs of vascular compromise. The vascular system is in close proximity to the nervous system and at no time should show signs of compromise when mobilizing the nervous system.

### CONTRAINDICATIONS:

- Acute or unstable neurological signs
- Cauda equina symptoms related to the spine including changes in bowel or bladder control and perineal sensation
- Spinal cord injury or symptoms
- Neoplasm and infection

## Neural Testing and Mobilization Techniques for the Upper Quadrant

### Median Nerve—ULNT 1 (Passive) (Fig. 13.13)

This maneuver is used when examining and treating symptoms related to median nerve distribution, including carpal tunnel syndrome.<sup>16</sup>

**Patient position and procedure:** Begin with the patient in supine position close to your side (no pillows at the head or knees) with the patient’s upper arm on your thigh. Place your hand closest to the patient in a fist and position it at the superior aspect of the patient’s shoulder, pushing it into the table to control elevation of the shoulder during abduction of the arm (maintaining equal shoulder positions). Abduct the arm to approximately 110° keeping the elbow at 90° flexion. Maintain the shoulder and elbow position, extend the wrist and fingers including the thumb (using your thumb and index finger). Supinate the forearm followed by lateral rotation of the shoulder. Slowly extend the elbow, keeping the wrist and shoulder position constant. Stop the elbow extension when either the patient reports symptoms or you feel tension in the tissue.

**To sensitize the maneuver:** Ask the patient to laterally flex their cervical spine away from the test side and inquire if this movement increases their symptoms. Then ask the patient to laterally flex their cervical spine toward the test side and inquire

**FIGURE 13.13** Position of maximum elongation of the median nerve includes shoulder abduction to 110°; elbow extension; shoulder external rotation and supination of the forearm; wrist, finger, and thumb extension; and finally contralateral cervical side flexion.

if this movement alleviates or lessens their symptoms (if there is concern about “leading” the patient to a particular answer, the clinician can inquire if the movement increases, decreases, or if the symptoms remain unchanged) during the particular sensitizing movement.<sup>16</sup>

### FOCUS ON EVIDENCE

Using ultrasound imaging, Coppiters and associates<sup>20</sup> examined the longitudinal excursion of the median nerve, using several variations of cervical and elbow movements that caused either sliding or tensioning of the median nerve. For the sliding technique, elbow flexion and cervical side flexion were performed simultaneously in the same direction; for one tensioning technique, elbow extension and cervical side flexion were performed simultaneously in opposite directions; and for four techniques, only one joint (elbow or neck) was moved after repositioning the other joint.

Results showed significant differences in the amount of nerve movement with the various techniques ( $P < .0001$ ). Greatest excursion occurred with the sliding technique when the two joints were moved in the same direction (10.2 +/- 2.8 mm); the smallest excursion occurred with the tensioning technique when the two joints were moved in opposite directions (1.8 +/- 4.0 mm). Techniques in which only one joint moved demonstrated larger excursions when the elbow moved (5.6 and 5.5 mm) than when the neck moved (3.3 and 3.4 mm). These tests were performed on healthy volunteers and therefore cannot be generalized to therapeutic effects for patients with different pathologies affecting the median nerve.

### Radial Nerve—ULNT 2 (Fig. 13.14)

This maneuver is important when examining and treating symptoms that are related to shoulder girdle depression, radial nerve distribution, and differentiating between tennis elbow and radial tunnel syndrome, as well as de Quervain’s syndrome and superficial sensory radial nerve involvement.<sup>16</sup>

**Patient position and procedure:** Begin with the patient supine; sequentially apply gentle shoulder girdle depression, then slightly abduct the shoulder to about 10°, extend the elbow, and then medially rotate the whole arm (including forearm pronation). Keep the elbow in extension and add wrist, finger, and thumb flexion and finally ulnar deviation of the wrist. Maintaining this position, slowly abduct the shoulder until reproduction of symptoms or tension is felt in the tissue. The full elongated position includes lateral flexion of the cervical spine away from the test side. Have the patient then laterally flex the cervical spine toward the test side, noting increase or decrease of symptoms.

**FIGURE 13.14** Position of maximum elongation of the radial nerve includes shoulder girdle depression; shoulder abduction; elbow extension; shoulder medial rotation and forearm pronation; wrist, finger, and thumb flexion; wrist ulnar deviation; and finally contralateral cervical side flexion.

### Ulnar Nerve—ULNT 3 (Fig. 13.15)

This maneuver is used when symptoms are related to the lower brachial plexus or ulnar nerve and differentiating between medial epicondylitis and pronator syndrome.<sup>16</sup>

**Patient position and procedure:** Begin with the patient supine. Extend the wrist and fingers, pronate the forearm and flex the elbow. While maintaining this position laterally rotate the shoulder and depress the shoulder girdle. Finally abduct the shoulder to about 110° or until symptoms are felt. The full elongated position includes lateral flexion of the cervical spine away from the test side. Have the patient then laterally flex the cervical spine toward the test side noting increase or decrease of symptoms.

**FIGURE 13.15** Position of maximum elongation on the ulnar nerve includes shoulder girdle depression; shoulder external rotation and abduction; elbow flexion; forearm pronation and wrist extension; and finally contralateral cervical side flexion.

## Neural Testing and Mobilization Techniques for the Lower Quadrant

### Sciatic Nerve: Straight Leg Raising (Fig. 13.16)

**Patient position and procedure:** The patient is supine. Lift the lower extremity in the straight leg raise (SLR) position and add ankle dorsiflexion. Several variations may be done to assist with differentiating the neural load; ankle dorsiflexion, dorsiflexion with eversion, ankle plantar flexion with inversion, hip adduction, hip medial rotation, and passive neck flexion.<sup>16</sup> The maneuver may also be performed long-sitting (slump-sitting position—see below) and side-lying. These various positions of the lower extremity and neck are used to differentiate tight or strained hamstrings from possible sites of restriction or nerve mobility in the lumbosacral plexus and sciatic nerve.<sup>11,34,73</sup> Changing positions of the ankle in conjunction with variations in the hip and knee positions are used to differentiate foot impairments, such as plantar fasciitis and tarsal tunnel syndrome.<sup>1</sup>

Once the position that places tension on the involved neurological tissue is found, maintain the stretch position and then move one of the joints a few degrees in and out of the stretch position, such as ankle plantarflexion and dorsiflexion or knee flexion and extension.

- Ankle dorsiflexion with eversion places more tension on the tibial tract.
- Ankle dorsiflexion with inversion places tension on the sural nerve.
- Ankle plantarflexion with inversion places tension on the common peroneal tract.

**FIGURE 13.16** Position of stretch on the sciatic nerve includes straight-leg raising with adduction and internal rotation of the hip and dorsiflexion of the ankle.

- Adduction of the hip while doing SLR places further tension on the nervous system, because the sciatic nerve is lateral to the ischial tuberosity; medial rotation of the hip while doing SLR also increases tension on the sciatic nerve (see Fig. 13.16).
- Passive neck flexion while doing SLR pulls the spinal cord cranially and places the entire nervous system on a stretch.<sup>16</sup>
- Strain on the medial and lateral plantar nerves increases with toe extension and is larger with ankle dorsiflexion than plantarflexion.<sup>1</sup>

**Neural slide (flossing) technique:** Beginning with the hip and knee in flexion, simultaneously extend the hip and knee to obtain maximum sliding of the sciatic nerve (knee extension loads the tibial and sciatic nerve; hip extension unloads the sciatic nerve).<sup>18</sup>

### FOCUS ON EVIDENCE

A study using ultrasound imaging of the sciatic nerve under different hip and knee movements demonstrated the following biomechanics on the nerve: greatest sliding occurred with simultaneous hip/knee extension (approximately five times larger than with the tensioning techniques of hip flexion with

knee extension and two times larger than during isolated hip and knee movements).<sup>18</sup>

### Slump-Sitting Maneuver (Fig. 13.17)

**NOTE:** The slump test is simply the SLR performed in sitting with the addition of spinal flexion for greater overall neural tension.

**Patient position and procedure:** Begin with the patient sitting upright. Have the patient slump by flexing the spine and neck. Apply gentle overpressure guidance to cervical spine flexion. As a sensitizing maneuver, dorsiflex the ankle and then extend the knee as much as possible to the point of tissue resistance and symptom reproduction. Release the overpressure on the spine and have the patient actively extend the neck to see if symptoms decrease. Increase and release the stretch force by moving one joint in the chain a few degrees, such as knee flexion and extension or ankle dorsiflexion and plantarflexion and note response.

**FIGURE 13.17** Slump-sitting with neck, thorax, and low back flexed, knee extended, and ankle dorsiflexed just to the point of tissue resistance and symptom reproduction.

### FOCUS ON EVIDENCE

A study evaluating the accuracy of the slump test in patients with low back pain found the test was highly sensitive in identifying those with neuropathic pain and that adding the criterion of pain distal to the knee during the maneuver improved specificity.<sup>80</sup>

### Femoral Nerve: Prone Knee Bend (PKB) (Fig. 13.18)

**Patient position and procedure:** Prone with the spine neutral (not extended) and the hips extended to 0°. Flex the knee

**FIGURE 13.18** Position of stretch on the femoral nerve; prone lying with the spine neutral, hip extended to zero degrees, and knee flexed. It is important to maintain the spine in neutral and not allow it to extend.

to the point of resistance and symptom reproduction. Pain in the low back or neurological signs (change in sensation in the anterior thigh) are considered positive for upper lumbar nerve roots and femoral nerve tension. Thigh pain could be rectus femoris tightness. It is important not to hyperextend the spine to avoid confusion with nerve root pressure from decreased foraminal space or facet pain from spinal movement. Flex and extend the knee a few degrees to apply and release tension.

**Alternate position and procedure:** Side-lying with the involved leg uppermost. Stabilize the pelvis and extend the hip with the knee flexed until symptoms are reproduced. Maintain knee flexion, release, and apply tension across the hip by moving it a few degrees at a time.

## Musculoskeletal Diagnoses Involving Impaired Nerve Function

### Thoracic Outlet Syndrome

The thoracic outlet is the region along the pathway of the brachial plexus from just distal to the nerve roots where they exit the intervertebral foramen to the lower border of the axilla (Fig. 13.19). The outlet is bordered medially by the anterior and middle scalene muscles and the first rib; posteriorly by the upper trapezius and scapula; anteriorly by the clavicle, coracoid, pectoralis minor, and deltopectoral fascia; and laterally by the axilla. The plexus enters the outlet between the anterior and middle scalene muscles; the subclavian artery runs posterior to the anterior scalene; and the subclavian vein runs anterior to the anterior scalene muscle. The blood vessels join the brachial plexus and course together under the clavicle, over the first rib, and under the coracoid process posterior

**FIGURE 13.19** Region of the thoracic outlet bordered medially by the scalene muscle and first rib; posteriorly by the upper trapezius and scapula; anteriorly by the clavicle, coracoid, pectoralis minor, and deltopectoral fascia; and laterally by the axilla.

to the pectoralis minor muscle. Vascular and/or upper extremity neurological symptoms that are not consistent with nerve root or peripheral nerve dermatome and myotome patterns should lead the therapist to suspect thoracic outlet problems.<sup>45</sup>

**NOTE:** Sites of impingement of the brachial plexus and vascular structures within the thoracic outlet are described later in this section.

## Related Diagnoses

Thoracic outlet syndrome (TOS) encompasses a variety of clinical problems in the shoulder girdle region. The diagnosis itself is controversial because of the clinical complexity and variability in presentation that involves upper extremity neurological and vascular symptoms, including pain, paresthesia, numbness, weakness, discoloration, swelling, and loss of pulse. Patients may also complain of headaches, which may be related to posture, tension, or vascular compromise. Diagnoses that have been used to describe TOS include cervical rib, scalenus anticus syndrome, costoclavicular syndrome, subcoracoid-pectoralis minor syndrome, droopy shoulder syndrome, and hyperabduction syndrome.<sup>37,43,45,76,83</sup> TOS is categorized into two specific clinical entities: vascular TOS and neurological or neurogenic TOS. Vascular TOS is further subcategorized into arterial and venous, while neurogenic TOS is further subdivided into “true” neurogenic or disputed TOS. It is estimated that over 90% of cases are neurogenic in

origin, whereas 1% are arterial and approximately 3% to 5% are venous.<sup>37,43,76,83,84</sup>

- **True Neurogenic TOS.** This condition is rare. The patient presents with an anatomical abnormality, such as cervical rib or elongated C7 transverse process. The patient describes paresthesias and pain along the medial border of the arm and experiences muscle weakness; there is atrophy in the intrinsic muscles of the hand. There are also positive electromyographic (EMG) findings.<sup>76</sup>
- **Disputed, symptomatic or nonspecific neurogenic TOS.** This is the most common form of TOS. Symptoms are similar to true neurogenic TOS, however there is no definitive radiologic evidence of bony anomaly. There is no evidence of muscle atrophy, and EMG testing is negative. Disputed TOS involves intermittent compression of the neurovascular bundle due to poor posture (especially in those with large amounts of breast tissue), occupation, or sporting incidents. Symptoms are aggravated by repetitive, suspensory, or sustained overhead activity, forward or elevation of the shoulder and/or activities that depress the shoulder girdle. Symptoms are present at rest and at night.<sup>76,83,84</sup>
- **Vascular TOS—arterial.** This condition is rare and is usually the result of structural abnormalities such as cervical rib or other bony abnormality. There is compression of the subclavian or axillary artery with arm motion, especially overhead usage. If the arm fatigues with overhead usage, the person may have to adapt work habits that avoid risk from repetitive trauma to the artery.
- **Vascular syndromes—venous.** Compression of the subclavian or axillary vein does not typically occur in TOS; venous symptoms would be from some other cause, such as thrombosis. Acute thrombosis (sudden, painful swelling with bluish discoloration of the arm) is usually dealt with medically, but the therapist should always be suspicious of unexplained swelling of the arm. Effort thrombosis could occur from sudden maximal arm use, or there could be insidious onset of swelling with prolonged use. If these occur, an immediate referral to an appropriate physician is warranted.

## Etiology of Symptoms

Three causative factors for TOS have been identified that could be interrelated or exist separately: compressive neuropathy, faulty posture, and entrapment.

- **Compressive neuropathy.** Compression of the neurovascular structures can occur if there is a decrease in the size of the area through which the brachial plexus and subclavian vessels pass. Compression can result from muscle hypertrophy in the scalenes or pectoralis minor muscles, anatomical anomalies such as cervical rib or fractured clavicle, adaptive shortening of fascia, or a space-occupying lesion.
- **Faulty posture.** Changes in posture, particularly a forward head with increased thoracic kyphosis, protracted scapulae, and forward shoulders, narrow the spaces through which the neurovascular structures pass. Specifically, adaptive

shortening of the scalene and pectoralis minor muscles can potentially compress the neurovascular tissues or can cause repetitive trauma and adhesions with overuse.<sup>61</sup> If the angle of the clavicle falls below the level of the sternoclavicular joint, the shoulder girdle causes traction on the plexus. In addition, the clavicle can compress the neurovascular structures against the first rib. Hypertrophy of breast tissue may cause postural fatigue or pressure from undergarment support straps. Carrying a heavy briefcase, suitcase, backpack, or shoulder purse may cause pressure across the shoulder girdle, fatigue in the scapular stabilizers, or traction across the shoulder girdle tissues and brachial plexus.

### FOCUS ON EVIDENCE

A study reported by Pascarelli and Hsu<sup>65</sup> of 485 patients with work-related upper quarter pain and symptoms indicated that 70% of patients displayed posture-related neurogenic TOS as a key factor in a series of cascading events, including 78% with protracted shoulders, 71% with forward head posture, 50% with hyperlaxity of fingers and elbows, 20% with sympathetic dysfunction, 64% with cubital tunnel, 60% with medial epicondylitis, 70% with peripheral muscle weakness, and other miscellaneous conditions such as carpal tunnel syndrome. Wood and Biondi<sup>86</sup> pointed out that, among 165 patients with TOS, 44% also had compression of a nerve distally, most commonly in the carpal tunnel (41 cases).

A surgical study reported findings that pathological adhesions of the brachial plexus to the scalene muscles led to nerve fiber distraction as the mechanism behind the symptoms and suggested that the restrictive adhesions were directly related to long-standing postural deviations and myofascial pain syndrome.<sup>22</sup>

- **Entrapment of neural tissue from scar tissue or pressure.** Entrapment affects the ability of nerve tissue of the brachial plexus to tolerate tension as it courses through the various tissues in the thoracic outlet. A possible explanation was offered in a review article by Crotti<sup>23</sup> wherein the pain-immobility-fibrosis loop that occurs after trauma (e.g., following an acceleration-extension motor vehicle injury) leads to the development of adhesions, which cause or perpetuate TOS symptoms. The Halstead test<sup>52</sup> and the upper limb neurodynamic test for the median nerve<sup>16</sup> (see Fig. 13.14) place the brachial plexus and median nerve on stretch and symptoms may indicate restricted nerve gliding. The Halstead test also may obliterate the radial pulse indicating vascular entrapment. Lohman and associates<sup>48</sup> performed a cadaver study that demonstrated strain placed on cervical nerve roots during upper limb neurodynamic testing. They suggested that this could be used in the clinical evaluation of cervical pathology including thoracic outlet syndrome.

Contributing factors in the development of TOS are summarized in Box 13.7.

### BOX 13.7 Summary of Contributing Factors to Thoracic Outlet Syndrome

There is wide latitude of motion in the various joints of the shoulder complex that may result in compression or impingement of the nerves or vessels in TOS.

- **Postural variations**, such as a forward head or round shoulders, lead to associated muscle shortening in the scalene, levator, subscapularis, and pectoralis minor muscles and a depressed clavicle.
- **Postural stress**, such as narrow bra straps, carrying a heavy suitcase, backpack, briefcase, or purse, can place stress across the shoulder girdle, creating pressure in the thoracic outlet or traction on the brachial plexus.
- **Respiratory patterns** that continually use the action of the scalene muscles to elevate the upper ribs lead to hypertrophy of these muscles. Also, the elevated upper ribs decrease the space under the clavicle.
- **Congenital factors**, such as an accessory rib, a long transverse process of the C-7 vertebra, or other anomalies in the region, can reduce the space for the vessels. A traumatic or arteriosclerotic insult can also lead to TOS symptoms.
- **Traumatic injuries**, such as clavicular fracture or subacromial dislocations of the humeral head, can injure the plexus and vessels, leading to TOS symptoms.
- **Hypertrophy or scarring** in the pectoralis minor muscles can lead to TOS symptoms.
- **Injuries** that result in inflammation, scar tissue formation, and adhesions can restrict nerve tissue mobility when the nerve is elongated. This may occur anywhere from the intervertebral foramina at the spine to the distal-most portion of the peripheral nerve.

## Sites of Compression or Entrapment

There are three primary sites for compression or entrapment of the neurovascular structures.<sup>43,45</sup>

- **Interscalene triangle:** bordered by the anterior and middle scalene muscles and the first rib. If these muscles are hypertrophied, tight, or have anatomical variations, or if the first rib is elevated, they may compress the subclavian artery or the upper, middle or lower trunks of the brachial plexus and impair normal mobility of the neural tissues with head and arm movements.

Symptoms from dysfunction in this area are reproduced with the Adson maneuver, which decreases the space for the neurovascular bundle. If the artery is compressed, there is also a decreased pulse.<sup>45,52</sup> Palpation of the scalene muscles may also provoke symptoms.

- **Costoclavicular space:** between the clavicle, the subclavius muscle, and the costocoracoid ligament anteriorly and the first rib posteriorly. Compression of the neurovascular bundle can occur between the clavicle and first rib, especially if the clavicle is depressed for periods of time, as occurs when carrying a heavy suitcase, a backpack or shoulder bag, or

with a slouched posture. A fractured clavicle or anomalies in the region can also lead to symptoms. An elevated first rib, which can occur with first rib subluxation or upper thoracic breathing (as with asthma or chronic emphysema), also narrows the costoclavicular space.

Symptoms caused by a depressed clavicle are reproduced when the shoulders are retracted and depressed as with the Military Brace Test.<sup>52</sup> If a patient is asked to take in a breath while in this posture and symptoms are reproduced, the rib elevation is causing the symptoms. The mobility of the clavicle and first rib should also be examined.

- **Rectropectoralis minor space:** *between the second through fourth ribs anteriorly, posterior to the pectoralis minor muscle, and inferior to the coracoid process.* Compression or restricted movement of the neurovascular structures may occur in this region if the pectoralis minor muscle is tight owing to faulty posture with the scapula tipped forward or from repetitive overuse.

Holding the arms in an elevated position compresses the cords of the brachial plexus and axillary artery and vein. Compression of the neurovascular bundle in this space may be tested utilizing Roos test.<sup>52</sup> Palpation pressure against the pectoralis minor may also reproduce the neurological symptoms if the muscle is tight.

## Common Impairments of Structure and Function in TOS

- Intermittent brachial plexus and vascular symptoms of pain, paresthesia, numbness, weakness, discoloration, and swelling
- Muscle length–strength imbalance in the shoulder girdle with tightness in anterior and medial structures and weakness in posterior and lateral structures
- Faulty postural awareness in the upper quarter
- Poor endurance in the postural muscles
- Poor scapular control
- Shallow respiratory pattern characterized by upper thoracic breathing
- Poor clavicular and first rib mobility
- Neurological symptoms when the brachial plexus is placed on stretch

## Common Activity Limitations and Participation Restrictions

- Sleep disturbances that could be from excessive pillow thickness or arm position
- Inability to carry briefcase, backpack, suitcase, purse with shoulder strap, or other weighted objects on the involved side
- Inability to maintain prolonged overhead reaching position
- Inability to do sustained computer or desk work, cradle a telephone receiver between head and involved shoulder, or drive a car for prolonged periods
- Inability to do sustained overhead work such as electrical work or painting a ceiling

## Nonoperative Management of TOS

Conservative management is often recommended for all types of TOS in the absence of any acute or progressive neurological or vascular lesion. The primary emphasis of management may involve medication, injection therapy, rest, and activity modification in addition to physical therapy. Physical therapy management often involves postural education, strengthening and endurance exercises, scapular stabilization, and manual therapy.<sup>81,84</sup>

A program is developed utilizing interventions that specifically address the presenting impairments, activity limitations, and participation restrictions (Box 13.8). Also, secondary or associated complaints, such as myofascial trigger points, glenohumeral joint pathology, cervical pathology, or distal peripheral neuropathies, should be identified, and appropriate interventions incorporated into the program.<sup>45,84</sup> Consider the following precautions and interventions.

**PRECAUTIONS:** Shoulder girdle exercises may cause worsening of symptoms in some patients with venous or arterial TOS, or they may be progressing favorably and then symptoms worsen. Worsening of neurological or vascular symptoms may indicate axonal disruption or vascular compromise. Refer the patient to his or her physician; surgical decompression may be indicated.

### BOX 13.8 Summary of Guidelines for Management of Thoracic Outlet Syndrome

#### Educate the patient.

- Teach posture correction.
- Teach how to modify provoking stresses.
- Teach safe exercises for home exercise program.

#### Correct impaired posture.

- See Chapter 14

#### Mobilize restricted neurological tissue.

- Nerve mobilization techniques if testing is positive for restricted mobility

#### Mobilize restricted joints, connective tissue, and muscle.

- Tissue-specific manual techniques to restricted structures if testing is positive for restricted mobility
- Self-stretching exercises for restricted muscle flexibility

#### Improve muscle performance.

- Develop control and endurance in postural muscles.
- Progress strengthening exercises.

#### Correct faulty breathing patterns.

- Relax upper thorax.
- Teach abdominal diaphragmatic or bi-basilar breathing patterns.

#### Progress functional independence.

- Involve patient in all aspects of program.

- **Patient education.** Teach the patient how to modify or eliminate provoking postures and activities and provide a home exercise program that includes flexibility, muscle performance, and postural exercises (see Chapter 14). Emphasize the importance of compliance to reduce the stresses on the nerve and vascular structures.
- **Nerve tissue mobility.** Use nerve mobilization maneuvers if neurodynamic tests are positive.<sup>16,71,85</sup> These are described earlier in this chapter.
- **Joint, muscle, and connective tissue mobility.** Use manual and self-stretching techniques to address any mobility impairments. Restricted joint mobility might be present in the upper thoracic, scapulothoracic, glenohumeral, sternoclavicular, or first costotransverse articulations. Common muscle restrictions with an impaired postural component include but are not limited to the scalene, levator scapulae, pectoralis minor, pectoralis major, anterior portion of the intercostals, and suboccipital muscles. Stretching exercises to increase mobility in these muscles are described in Chapter 14 (section on posture exercises) and Chapter 17.
- **Muscle performance.** Develop a program to improve control and endurance in the postural muscles. Common weaknesses include but are not limited to scapular adductors and upward rotators, shoulder lateral rotators, deep cervical flexor muscles, and thoracic extensors. Identification of postural exercises to improve muscle performance are listed in Chapter 14 (section on posture exercises).
- **Respiratory patterns and elevated upper ribs.** If the patient tends to use apical breathing patterns and has increased tension in the scalene muscles, teach abdominodiaphragmatic

or bi-basilar breathing patterns and relaxation of the upper thorax.

- **Functional independence.** Increase patient awareness and ability to manage symptoms through education. Have patients actively involved in all aspects of their program and interventions.

## Carpal Tunnel Syndrome

The carpal tunnel is a confined space between the carpal bones dorsally and the transverse carpal ligament (flexor retinaculum) volarly (Fig. 13.20). In this region, the median nerve is susceptible to pressure as it courses through the tunnel along with the extrinsic finger flexor tendons on their way into the hand. Carpal tunnel syndrome (CTS) is characterized by the sensory loss and motor weakness that occur when the median nerve is compromised in the carpal tunnel. Anything that decreases the space in the carpal tunnel or causes the contents of the tunnel to enlarge could compress or restrict the mobility of the median nerve, causing a compression or traction injury, ischemia, and neurological symptoms distal to the wrist.<sup>2,7,53,54</sup>

### Etiology of Symptoms

Etiology is multifactorial, including both local and systematic factors.<sup>54</sup> Local factors include synovial thickness and scarring in the tendon sheaths (tendinosis) or irritation, inflammation,

**FIGURE 13.20** Boundaries of the carpal tunnel.

and swelling of the tendons (tendinitis) as a result of repetitive or sustained wrist flexion, extension, or gripping activities. Because of this, CTS is frequently classified as a cumulative trauma or overuse syndrome. Swelling in the wrist area due to local trauma (e.g., a fall or blow to the wrist, with or without a carpal or distal radius fracture), carpal dislocation, or osteoarthritis or systematic factors, such as pregnancy (hormonal changes and water retention), rheumatoid arthritis, or diabetes, could decrease the carpal tunnel space. Awkward wrist postures (flexion or extension), compressive forces from sustained equipment usage, and vibration against the carpal tunnel could also lead to median nerve compression and trauma.<sup>2,7,54</sup>

## Examination

In a review on the sensitivity and specificity of the various tests used when screening for CTS, MacDermid and Doherty<sup>50</sup> summarized the key signs and symptoms that increase the probability of diagnosing CTS.

**History.** The patient describes sensory changes in the median nerve distribution of the hand (excluding the palm, which is innervated by the palmar cutaneous branch of the median nerve arising proximal to the carpal tunnel) and nocturnal numbness and pain that is relieved by flicking the wrists.

Positive clinical findings. Depending on severity, there may be atrophy of the thenar eminence. Results of tests include thenar muscle weakness, positive Phalen's test (sustained wrist flexion), loss of two-point discrimination, positive carpal compression test, and positive Tinel's sign (tapping the median nerve).<sup>7,54</sup> Electrophysiological studies (nerve conduction and electromyography) are used to assist with a differential diagnosis.<sup>2,7,54</sup>

**Associated areas to clear.** Because there can be other causes of median nerve symptoms, such as tension, compression, or restricted mobility of the nerve roots in the cervical intervertebral foramen, of the brachial plexus in the thoracic outlet, or of the median nerve as it courses through tissues in the forearm region (pronator syndrome and anterior interosseous nerve syndrome); each of these sites must be ruled out to determine if they are contributing to the median nerve symptoms (see Fig. 13.5).<sup>39,46,54</sup>

**Double crush injury.** With nerve irritability, it is possible to develop what is known as a double crush injury<sup>16,40,51,55,61</sup> in which the nerve develops symptoms at other areas along its course as well as at the primary site. Seror<sup>69,70</sup> reported a lack of evidence supporting a relationship between unambiguous CTS in true neurogenic TOS (< 1/100), although disputed neurogenic TOS was frequently found (mild to moderate clinical symptoms and signs) even when there were no significant findings on electrodiagnostic tests. Fernández-de-Las-Peñas and colleagues<sup>31</sup> demonstrated increased mechanical nerve pain sensitivity of the entire median nerve in subjects with CTS, as measured by pressure pain thresholds. They suggested that there is both central and peripheral sensitization of the entire nerve trunk in this condition.

## Common Impairments of Structure in CTS

- Increasing pain and paresthesias in the hand with repetitive use
- Progressive weakness or atrophy in the thenar muscles and first two lumbricals
- Irritability or sensory loss in the median nerve distribution (see Fig. 13.5)
- Possible decreased joint mobility in the wrist and metacarpophalangeal joints of the thumb and digits 2 and 3
- Sympathetic nervous system changes may develop
- Faulty forward head posture and decreased cervical ROM<sup>24</sup>

## Common Impairments of Function, Activity Limitations, and Participation Restrictions

- Decreased prehension in tip-to-tip, tip-to-pad, and pad-to-pad activities requiring fine neuromuscular control of thumb opposition, such as buttoning clothes and manipulating small objects
- Avoidance of using the area of the hand where there is decreased sensation
- Inability to perform provoking sustained or repetitive wrist or finger motion, such as cashier checkout scanning, assembly line work, fine tool manipulation, cutting/styling hair, or typing
- Sleep disturbances

## Nonoperative Management of CTS

Guidelines are summarized in Box 13.9. In patients with mild to moderate symptoms, conservative intervention is directed toward minimizing or eliminating the causative factor.<sup>4,7,50,53,54,64</sup> Considerations include:

- **Nerve protection.** The use of a static wrist orthosis at night positioned in neutral is highly recommended to reduce compression in the carpal tunnel.<sup>4,7,50,53,54,64</sup>
- **Activity modification and patient education.** Identify faulty wrist, cervical, and upper extremity postures and activities.
  - *Activity modification.* Modify activities to keep the wrist in neutral and to reduce forceful prehension.
  - *Education.* Teach the patient about the mechanisms of compression and their effect on the circulation and nerve pressure, as well as how to modify or eliminate provoking postures and activities. Also, instruct the patient to observe areas with decreased sensitivity to avoid tissue injury (see Box 13.6).
  - *Home exercise program.* Teach the patient safe exercises for a home exercise program. Emphasize the importance of compliance to reduce stresses on the nerve and tendinous structures. Incorporate postural exercises for the spinal and shoulder girdle regions.

### BOX 13.9 Summary of Guidelines for Nonoperative Management of Carpal Tunnel Syndrome

#### Protect the nerve

- Place in static wrist orthosis, in neutral position at night
- Protect areas that have decreased sensitivity

#### Modify activity and educate the patient

- Teach patient about provoking activities and how to modify them
- Teach safe exercises for home exercise program
- Teach patient how to protect areas of decreased sensitivity in the hand (see Box 13.5)

#### Mobilize restricted joints, connective tissue, and muscle/tendon

- Mobilize carpals if restricted
- Tendon gliding exercises
- Median nerve mobilization exercises

#### Improve muscle performance

- Gentle multi-angle muscle setting
- Progress to resistance and endurance
- Fine-finger dexterity

#### Progress functional independence

- Involve patient in all aspects of program
- Self-monitoring of symptoms

#### ■ Mobility techniques

- Joint mobilization.** If there is restricted joint mobility, mobilize the carpals for increased carpal tunnel space (see Fig. 5.39 and its description in Chapter 5).
- Tendon-gliding exercises.** Teach the patient tendon-gliding exercises for mobility in the extrinsic tendons; they should be performed gently to prevent increased swelling (see Figure 19.17 and the description in the exercise section of Chapter 19<sup>4</sup>).
- Median nerve mobilization.**<sup>4,16,30,54,64</sup> The six positions for median nerve mobilization in the wrist and hand are illustrated in Figure 13.21. Begin with position A and slowly progress to each succeeding position until the median nerve symptoms just begin to be provoked (tingling). That is the maximum position to use. Alternate between that position and the preceding position. When the patient can be moved into that position without symptoms, progress to the next position and repeat the mobilizing routine. The mobilization exercise should be done three or four times per day unless symptoms are exacerbated then the intensity and frequency should be reduced but not eliminated.

Additional median nerve mobilization techniques, including the entire upper extremity and neck, is recommended and if symptoms warrant (see Fig. 13.14 and the description of principles earlier in this chapter under upper limb neurodynamics).

**FIGURE 13.21** Positions for median nerve glides and mobilization in the hand: (A) wrist neutral with fingers and thumb flexed; (B) wrist neutral with fingers and thumb extended; (C) wrist and fingers extended, thumb neutral; (D) wrist, fingers, and thumb extended; (E) wrist, fingers, and thumb extended and forearm supinated; (F) wrist, fingers, and thumb extended, forearm supinated, and thumb stretched into extension.

### FOCUS ON EVIDENCE

Bialosky and associates<sup>6</sup> compared a group treated with median nerve mobilization techniques and a group with a sham technique that did not place the entire median nerve on a stretch; wrist and finger flexion/extension was consistent in both groups. A series of tests was conducted at the beginning and after 3 weeks of treatment (two times per week for up to six treatments); both groups received orthoses to wear at night. There was no control group. The only significant difference between groups was a reduction of temporal summation of symptoms in the group receiving the mobilization to the median nerve. The authors speculated that improved outcomes in most of the measures seen in both groups were related to receiving manual therapy and were independent of the specific mechanical force on the median nerve. Oskouei and associates<sup>64</sup> compared two groups of patients with CTS. Twenty patients and a total of 32 hands were assigned to either routine physical therapy (control group) or routine physical therapy plus neuromobilization (treatment group). Symptom severity scale, VAS, functional status scale, Phalen's test, median nerve neurodynamic test, and EMG (distal sensory and motor latency) were assessed. Routine physical therapy included the use of an orthosis positioned in neutral, TENS, and ultrasound. Improvements in both groups were noted with the symptom severity scale, VAS, median nerve neurodynamic test, and Phalen's test; however, the functional status scale and EMG studies were significantly improved

in only the treatment group. The authors concluded that the combination of routine physical therapy and neuromobilization is an effective noninvasive treatment for patients with CTS.

### ■ **Muscle performance**

- **Gentle multiple-angle muscle-setting exercises.** Initially, gentle muscle-setting exercises are the only resistance exercises done. It is important that they do not provoke symptoms.
- **Strengthening and endurance exercises.** Add proximal stabilization, postural strengthening, and endurance exercises.<sup>53</sup> Utilize exercises that prepare the patient for a return to functional activities.
- **Speed, coordination, endurance, and fine finger dexterity.** Emphasize these activities when the symptoms are no longer provoked. Utilize activities that develop tip-to-tip and tip-to-pad prehension in order to improve use of the thenar muscles.
- **Functional independence.** Teach the patient how to monitor his or her hand for recurrence of symptoms and the provoking factors and how to modify activities to decrease nerve injury. Usually, sustained wrist flexion, ulnar deviation, and repetitive wrist flexion and extension combined with gripping and pinching are the most aggravating motions.

### **FOCUS ON EVIDENCE**

In a Cochrane review of 21 trials involving 884 people, a hand brace significantly alleviated symptoms of CTS after 4 weeks; in one trial involving 21 people, symptoms were significantly diminished after 3 weeks with carpal bone mobilization (compared to no intervention). Other evidence supported the use of oral steroids, ultrasound, and yoga.<sup>63</sup>

## **Surgical and Postoperative Management for CTS**

If conservative measures do not relieve the nerve symptoms or the neurological symptoms are severe (persistent numbness, weakness, pain, and decreased functional use of the hand),<sup>2,7,50,54</sup> surgical decompression involving transection of the transverse carpal ligament and excision of scar tissue is performed to increase the volume of the carpal tunnel and relieve the compressive forces on the median nerve. Surgery may be an open carpal tunnel release or endoscopically assisted carpal tunnel release.<sup>2,7,54</sup> Postoperative therapy is open to debate, especially following an uncomplicated carpal tunnel release; however, it may be initiated after surgery if there are postoperative complications. The most important contribution following surgery is wound management and patient education regarding proper exercises, activity restrictions, and return to activity.<sup>30</sup>

Pillar pain is a relatively uncommon complication of unknown etiology following carpal tunnel surgery. The pain is

localized in the thenar and hypothenar eminences and should be distinguished from incisional pain or scar tenderness. Usually the pain decreases over time and may be treated with neuromodulation using a local anesthetic.<sup>30,56</sup>

### **Maximum Protection Phase**

Usually a bulky dressing or orthosis is used following surgery. The protective orthosis is removed during therapy.

**PRECAUTION:** Avoid active wrist flexion and extension for the first 2 weeks after surgery.

- **Patient education.** Educate the patient on expectations for recovery. Initial decreases in grip and pinch strength should gradually resolve with normal use of the hand.<sup>53</sup> Neurological symptoms should resolve with time, with light touch returning first.
- **Wound management, control of edema and pain.**
- **Active tendon-gliding.** Tendon-gliding (see Fig. 19.17 in Chapter 19) exercises are important to prevent adhesion formation from restricting motion in the carpal tunnel.<sup>4</sup>
- **Exercises for related areas.** Active forearm, elbow, and shoulder exercises are important to initiate in the initial phase following surgery.

### **Moderate and Minimum Protection Phases**

Sutures are removed between the 10th to 12th postoperative day, and more active treatment is allowed.<sup>30</sup> The patient should be able to return to full activity by 6 to 12 weeks. Residual impairments may include weakness, and sensory deficits, persistent edema, limited motion, hypersensitivity, and pain.

Suggested interventions include:

- **Scar tissue mobilization.** Use soft tissue mobilization techniques to the palmar fascia and scar.
- **Progressive neuromobilization.** Begin gentle neuromobilization techniques for the median nerve once symptoms have resolved and the scar is completely healed. (2-3 weeks post operatively)
- **Muscle performance.** Begin isometric strengthening exercises approximately 4 weeks after surgery. Progress to grip and pinch exercises by 6 weeks. Emphasize strength, coordination, and endurance toward functional goals. Wrist and hand exercises are described and illustrated in detail in Chapter 19.
- **Dexterity exercises.** Begin as soon as signs of motor recovery occur. Suggestions include picking up small objects using pad-to-pad, tip-to-tip, and tip-to pad prehension patterns; turning over cards; stacking checkers; writing; and holding the perimeter of a jar lid and having the thumb move around the edge in a circumduction motion.
- **Desensitization and discriminative sensory reeducation.** Desensitization of hypersensitive scar tissue and skin is a priority. As the nerve recovers, help desensitize and reprogram awareness.<sup>30</sup> These techniques were described earlier in this chapter. Educate the patient about the progression of nerve recovery such that an area that had absence of

sensation may have increased sensitivity and pain as it recovers. Symptoms typically subside within 1 to 6 months.

## Ulnar Nerve Compression in the Tunnel of Guyon

Entrapment of the ulnar nerve in the Tunnel of Guyon, also referred to as Guyon's canal or ulnar tunnel, is second only to entrapment at the elbow. There are three sites (zones) where entrapment can occur.<sup>27,28</sup>

- Zone 1 is proximal to the bifurcation of the nerve; compression causes combined motor and sensory loss.
- Zone 2 is just distal to the bifurcation of the nerve; compression causes loss of motor function in ulnar-innervated muscles in the hand.
- Zone 3 encompasses the sensory branch; compression causes sensory loss to the hypothenar eminence, small finger, and part of the ring finger.

### Etiology of Symptoms

Injury or irritation of the ulnar nerve in the tunnel between the hook of the hamate and pisiform is the result of sustained pressure, such as prolonged handwriting or leaning forward onto extended wrists while biking; from repetitive gripping with the fourth and fifth fingers, as with knitting, tying knots, or using pliers and staplers; from trauma, such as falling on the ulnar border of the wrist (with or without a fracture to the hook of the hamate); or from a space-occupying lesion, such as a ganglion or aneurysm of the ulnar artery.<sup>27</sup>

### Examination

**History.** The patient describes sensory symptoms in the little finger and ulnar side of the ring finger and may complain of fatigue or weakness in the hand with repetitive motions and difficulty with activities, such as opening jars or turning doorknobs.

**Positive clinical findings.** Depending on severity, there may be atrophy of the hypothenar eminence and intrinsic muscles and a partial claw hand posture. Results of tests include intrinsic muscle weakness and positive Tinel's sign over the tunnel of Guyon (tapping the ulnar nerve).<sup>27,28</sup>

**Associated areas to clear.** There can be other causes of ulnar nerve symptoms, such as tension, compression, or restricted mobility of the nerve roots in the cervical intervertebral foramen, the brachial plexus in the thoracic outlet, or the ulnar nerve as it courses through the bicipital groove, or there could be impingement between the heads of the flexor carpi ulnaris muscle. Each of these sites must be examined and ruled out as the cause of the symptoms<sup>28,61</sup> (see Fig. 13.6). In addition, with nerve irritability it is possible to develop what is known as a double crush injury,<sup>40</sup> where

the nerve develops symptoms at other areas along its course as well as at the primary site.

### Common Impairments of Structure

- Pain and paresthesia along the ulnar side of the palm and in the 4<sup>th</sup> and 5<sup>th</sup> digits in the distribution of the ulnar nerve (see Fig. 13.6)
- Progressive weakness or atrophy in the intrinsic muscles innervated by the ulnar nerve
- Restricted mobility in the flexor carpi ulnaris and extensor carpi ulnaris
- Possible adhesions and restricted mobility of the pisiform

### Common Impairments of Function, Activity Limitations, and Participation Restrictions

- Decreased grip strength
- Fatigue in the hand with repetitive or sustained activities
- Inability to use fourth and fifth digits for spherical or cylindrical power grips
- Decreased ability to perform provoking activity

### Nonoperative Management

- Follow the same guidelines as for CTS. Modify the provoking activity, avoid pressure to the base of the palm of the hand, and provide rest with a hand-based ulnar gutter orthosis.
- Ulnar nerve mobilization: Move the wrist into extension and radial deviation, then apply overpressure stretch into extension against the ring and little finger. Include forearm pronation and elbow flexion to move the nerve in a proximal direction. To test and mobilize the entire ulnar nerve, see Figure 13.15.

### Surgical Release and Postoperative Management

If the patient's symptoms do not improve with 6 to 12 weeks of conservative treatment, or if there is progressive paralysis, long-standing muscle wasting, and clawing of the digits, surgical release of the ulnar tunnel is performed.<sup>27</sup> After release, the wrist is immobilized 3 to 5 days; then treatment begins with gentle ROM. Follow the same guidelines as with carpal tunnel surgery but with ulnar nerve mobilization techniques.

## Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS) is a painful, disabling, and often chronic condition with a prevalence of an estimated 50,000 new cases diagnosed in the United States

every year.<sup>77</sup> The most frequent causes of CRPS involve surgery and trauma, and it occurs acutely in about 7% of patients who have limb fractures, limb surgery, or other injuries, with hand surgery being a particularly relevant factor.<sup>12,77</sup> CRPS is diagnosed purely on the basis of clinical signs and symptoms. There are two key elements in the diagnosis of CRPS, the first being that there is continuing pain disproportionate to the inciting event and the second being that there is no other diagnosis that explains the signs and symptoms.<sup>8</sup> It is widely accepted that there are three forms of CRPS as summarized in Box 13.10. CRPS Type I is caused by an initiating noxious event, such as a crush or soft tissue injury, immobilization, a tight cast or surgery, and involves the absence of an identified nerve lesion. CRPS Type II involves the presence of an identifiable nerve lesion, and CRPS-NOS (not otherwise specified) is where symptoms are consistent with CRPS but a specific injury or lesion has not been determined as the cause. Regardless, multidisciplinary clinical care, which centers on a functionally based approach, is recommended.<sup>9,12,14,32,36,44,59</sup>

## Signs and Symptoms of CRPS

CRPS is distinguished from other chronic pain conditions by the presence of signs indicating prominent autonomic and inflammatory changes in the region of pain. Pain is a key feature; however, other signs and symptoms may include sensory

abnormalities (burning pain and allodynia), trophic changes, impairment of motor function, and emotional/psychological responses<sup>12,36,49,77</sup> (see Box 13.10).

## Etiology of Symptoms

The underlying mechanism that stimulates the onset of these syndromes is unclear; however, there has been significant progress over the past few years in understanding the various pathophysiological aspects of CRPS.<sup>8</sup> After trauma or surgery, the presence of inflammation is physiological; however, in CRPS the inflammation lasts indefinitely. There is an abundance of inflammatory mediators with a lack of anti-inflammatory mediators. This proinflammatory response sensitizes the peripheral and spinal nociceptive systems facilitating the release of neuropeptides inducing the signs of inflammation and stimulates bone cell and fibroblast proliferation and endothelial dysfunction leading to vascular changes. During this inflammatory stage, sensory-motor integration becomes disturbed, leading to loss of motor function and distortion of body representation, leading to autonomic disturbances.<sup>8,77</sup>

## Clinical Course

Clinical signs and symptoms seem to be dynamic in nature, where the impacted limb evolves from an acute warm phase (limb is sensitive, swollen, and displays an elevated temperature) to a chronic cold phase (resolution of inflammatory appearance, decreased temperature, pain and disability persist). In general, the evolution of CRPS is characterized by the transition from an acute state with prominent peripheral characteristics (Fig. 13.22) to a chronic state characterized by central changes (such as central sensitization), including persistent pain along with significant cognitive and mood alterations.<sup>12,49,77</sup>

### BOX 13.10 Classification and Clinical Features of Complex Regional Pain Syndromes

#### CRPS type I

- Develops after an initiating noxious event
- Spontaneous pain or allodynia/hyperalgesia
- Edema, vascular abnormalities
- Abnormal sudomotor activity
- Non-nerve origin

#### CRPS type II

- Develops after nerve injury
- Not limited to territory of injured nerve
- Edema; skin blood flow abnormality
- Abnormal sudomotor activity

#### CRPS-NOS (not otherwise specified)

- Specific injury or lesion has not been determined as the cause of symptoms

#### Clinical features of CRPS (in addition to the differences listed above)

- Symptoms more marked distally in an extremity
- Symptoms progress in intensity and spread proximally
- Symptoms vary with time
- Disproportion of symptoms in relation to the causing event
- A specific diagnosis, such as diabetes or fibromyalgia, has been excluded

### CLINICAL TIP

It is important to recognize the early symptoms of CRPS when the limb is in the acute warm stage because early intervention may prevent progression to the cold chronic stage.<sup>12</sup>

## Common Impairments of Structure in CRPS

- Pain or hyperesthesia in the extremity disproportionate to any inciting event
- Limitation of motion and/or motor dysfunction (weakness tremor, dystonia)
- Sudomotor/edema: Edema and/or sweating changes and/or sweating asymmetry (hyper or hypohydrosis)
- Vasomotor instability: temperature asymmetry and/or skin color changes and/or asymmetry
- Trophic changes: increased or decreased hair and nail growth and/or skin changes (thin or shiny)

**FIGURE 13.22 (A)** In the early stages of complex regional pain syndrome, generalized edema is present. This edema is often localized over the dorsum of the hand in the metacarpal and proximal interphalangeal joint areas. **(B)** The edema is usually of a pitting nature, as indicated by the indentation that remains once the pressure is removed.

### Common Impairments of Function, Activity Limitations, and Participation Restrictions

- Pain avoidance behaviors, resulting in decreased use of the involved limb in ADLs, which may cause muscle atrophy or osteoporosis/ osteopenia in chronic stages
- Slower at initiating movement and/or slower and more inaccurate in executing targeted movement with the involved limb
- Gait abnormalities (when the lower extremity is involved)
- Limitations in ability to participate in gainful employment and/or housework
- Limitations in ability to participate in leisure activities

### Management

Effective treatment for CRPS requires recognition and prompt intervention. Of patients with CRPS treated within the first year of injury, 80% will show significant improvement and

only 50% of those treated after 1 year will show signs of improvement.<sup>44</sup> It requires that the therapist is aware of pain responses that exceed the normally expected reaction following seemingly minor injuries as well as to be in tune with common diagnoses that have a higher incidence for the development of CRPS. It also requires the therapist to be alert to the development of adverse symptomatology, which can be addressed early despite the possibility of an incorrect or incomplete diagnosis.<sup>44,82</sup>

There is no gold standard for the treatment of CRPS, although there is significant evidence to support the integration of physical therapy focusing on functional restoration in combination with pharmacotherapy and psychotherapy.<sup>10,32,36,59</sup> Functional restoration is based on a gradual and steady progression from activation of presensorimotor cortices (motor imagery) to very gentle active movements such as progressing from active ROM to weight-bearing activities as described below.<sup>36</sup> The emphasis is on early diagnosis, early treatment, and avoidance of implementing drug therapy independently in order to prevent disuse of the affected limb and the psychological consequences of living in pain.<sup>59</sup>

**Medical management.** Medical management and pharmacology are most effective in combination with functional restoration. If a patient is unable to participate in therapy due to pain or other associated symptoms, medication can help facilitate their progress. In the acute inflammatory phase, oral corticosteroids are often beneficial. To address mild to moderate pain a simple analgesic or opioids may be used to provide relief while interventional blocks may be necessary to manage excruciating or intractable pain. For neuropathic pain, anticonvulsants or tricyclic antidepressants may be prescribed. Because there is often an emotional or psychological component, medical intervention may include medications to manage this area (sedatives, antidepressants, anti-anxiety) in addition to psychotherapy.<sup>12,32,59</sup> As with all medical interventions, but especially with CRPS, it is critical for the physical therapist to have a thorough understanding of medication in order to anticipate their impact on their patient's plan of care.

**Physical therapy management.** The goals for treating patients with CRPS include minimizing edema, desensitizing the painful limb, normalizing sensation, promoting normal positioning, decreasing muscle guarding, and increasing functional use of the extremity.<sup>33,66</sup> There is very little evidence to support the effectiveness of physical therapy despite the fact that most literature on CRPS cites the use and critical importance for therapy intervention.<sup>9,12,66,73,82</sup> Therefore, a practical, common sense approach can be taken based on the patient's presenting signs and symptoms including tissue irritability, vasomotor status, and identified impairments. The guidelines for management of CRPS are summarized in Box 13.11.

- **Pain and edema control.** Use modalities such as HVGS, TENS, or heat or ice (depending on vasomotor status). Fluidotherapy is particularly beneficial (despite the lack of

### BOX 13.11 Summary of Guidelines for Management of Complex Regional Pain Syndrome Type I

#### Early intervention

##### Relieve pain and control edema

- Modalities
- Retrograde massage
- Elevate, compression sleeve or glove

##### Correct sensorimotor incongruence

- Mirror therapy
- Graded motor imagery

##### Increase mobility (specific to involved tissues)

- Gentle active motion specific to involved extremity

##### Improve muscle performance

- Active loading (closed chain activities)
- Distraction

##### Improve total body circulation

- Low impact aerobic exercise
- Aquatic exercise

##### Desensitize the area

- Desensitization techniques for brief periods 5×/day

##### Educate the patient

- Teach interventions that deal with variable vasomotor responses; when to use heat, cold, gentle exercises

#### Chronic stage

##### Manage pain

- Modalities prior to or in conjunction with exercise as needed
- Desensitize the area
- Progress desensitization techniques to increase tolerance of various textures
- Progress mirror therapy

##### Increase mobility (specific to involved tissues)

- Joint mobilization/ manipulation of the upper thoracic or lumbar spine (location of sympathetic ganglia) and soft tissue mobilization/ manipulation as indicated
- Neuromobilization
- Passive and self-stretching techniques

##### Improve functional performance

- Carefully monitor and progress strength, endurance, and functional exercises

empirical evidence) as active exercise may be combined with this modality and has been shown to decrease pain.<sup>82</sup> Utilize retrograde massage (as tolerated), elevation, compression sleeves or gloves, and pneumatic compression treatment for edema management.<sup>82</sup>

- **Mobility.** In the early stages, use gentle, active exercises to manage stiffness.<sup>82</sup> It is important to avoid increasing painful reactions that would decrease mobility. Have the patient actively move each joint for a short period of time.

They should follow this program of brief motion frequently throughout the day.

- In the hand, include tendon glide exercises (see Chapter 19, Fig. 19.17)
- In the feet, include towel curls, sitting balance board progressing to gradual weight bearing, weight shifting, and balancing on the involved limb during gait training.<sup>32,36</sup>
- Aquatic therapy has also been shown to facilitate early weight bearing.<sup>32</sup>
- **Muscle performance.** Facilitate active muscle contractions. Include joints proximal to the symptoms (shoulder/hip); they often develop restrictions due to pain or lack of use. Use active load bearing, utilizing closed chain techniques for the upper and lower extremity. Distraction activities such as carrying a light bag for the upper extremity should be included for neuromuscular control as well as afferent fiber stimulation. The objective is to provide tissue stress with minimal joint motion.
- **Mirror therapy.** Patients with CRPS have an altered body perception of their affected limb. They are slower to “connect” with their affected limb before movement, and disruptions in their motor planning and processing have been well described in the literature. Patient’s with CRPS often closely guard their affected limb and disengage from normal activities due to pain. The purpose of mirror therapy is to correct the sensorimotor incongruence by visualizing the unaffected limb in the felt position of the affected limb. Mirror therapy is an inexpensive and easily accessible tool that brings significant pain relief to some patient’s with CRPS, especially in the early stages.<sup>57,58</sup>
  - Position the involved limb inside the box with the uninvolved limb parallel to mirror. Be sure and remove all jewelry, watches, or other objects that might confuse the brain.
  - Have the patient look into the mirror to see the reflection of the limb, which will give the illusion that they are looking at the limb that is hidden.
  - Begin by keeping both limbs still, progress to moving the limb outside the box while keeping the hidden one still. To progress further, move the hidden limb within its limit while taking the uninvolved limb through large movements. The final progression would be to move the limbs equally.
- **Graded motor imagery.** This approach targets the activation of different brain regions in a graded manner. Treatment consists of three components that include left/right discrimination of the affected area, motor imagery rehearsal, and mirror therapy. (Refer to the work by Moseley for detailed instruction.<sup>57,58</sup>)
  - Left/right discrimination links the unconscious brain representation of a person’s body part and/or movement of it. It is to be done as quickly as possible in order to access deep movement planning areas in the brain.
  - Explicit motor imagery is an imagined movement. Start by having the patient imagine a movement away from the affected area so that they can experience the task and

obtain feedback on how it should feel. Progress by working toward the affected area.

- Mirror therapy is as described on page 412.
- **Total body circulation and cardiac output.** Initiate a program of low-impact aerobic exercises. Consider aquatic exercises to facilitate activity while minimizing the load in early stages.
- **Desensitization.** Utilize desensitization techniques (as described earlier in this chapter) for brief periods five times per day, such as having the patient work with various textures, percussion, pressure, and vibration. The therapist should initiate desensitization techniques outside of the area of hypersensitivity gradually narrowing the area toward the area of greatest sensitivity.<sup>36,82</sup>
- **Patient education.** Emphasize the importance of using the affected limb in daily activity, even if it involves mild increases in pain or associated symptoms. Care must be taken, and working within the patient's tolerance is essential so as not to reinforce anxiety and passive coping, which can lead to further functional impairment.<sup>9</sup>
  - Teach the patient interventions that deal with the variable vasomotor responses with the use of gentle heat, gentle exercises for short periods throughout the day, and use of associated parts of the extremity.
  - Patient education involves explaining fear avoidance using the patient's individual symptoms, beliefs, and behaviors. Patients are taught to view their various autonomic and vasomotor disturbances as a condition that can be

self-managed, rather than a disease where the affected limb needs to be protected. During therapy, the patient identifies painful or threatening situations and the therapist gradually increases their exposure to these activities until anxiety levels have decreased.<sup>32</sup>

### CLINICAL TIP

Pain continues to be a variable throughout a patient's recovery, and therefore the initiation of any therapeutic exercise or manual therapy technique should be carefully monitored and adapted to the patient at each visit to minimize exacerbation of symptoms.<sup>82</sup>

### FOCUS ON EVIDENCE

Evidence supports effective use of physical therapy for CRPS with early intervention (acute stage), but there is contradictory evidence for its effectiveness during the later stages.<sup>35,41</sup> In one study, the primary predictors for success and satisfaction with patients during the chronic phase after 6 months of therapy (evaluated at 12 months) was with the patient group that began therapy at a higher baseline of function, higher baseline ROM and strength, and less baseline pain.<sup>41</sup>

## Independent Learning Activities

### Critical Thinking and Discussion

1. Your patient describes intermittent sensory changes in the index and middle finger. What are the possible causes? What tests would you use to examine this patient? What results would lead you to determine nerve mobility restrictions?
2. You have a new client who describes intermittent tingling and sensations of heaviness in his hands whenever working with his hands in an overhead position. He is an auto mechanic and frequently has to work this way. Identify possible causes of these symptoms. What is usually the source of "tingling" sensations? What may be the source of the "heaviness" feelings? Why would the overhead position cause both vascular and neurological symptoms? Identify possible sites that could cause these symptoms. What tests would you use to confirm or rule out your hypotheses?
3. A 19-year-old patient presents with the medical diagnosis of complex regional pain syndrome type I and the following history.
  - Three-month history of midfoot pain that increases with standing more than 5 minutes or running. Symptoms have increased over the past 3 weeks.
  - Stress fracture to the navicular was detected on radiography, so patient was placed in a BK nonweight-bearing cast.
  - Foot discomfort increased and became more diffuse, radiating into the lateral forefoot and digits even after pain medications were prescribed.
  - Symptoms increased with burning or stinging pain, edema, and discoloration of the digits.
  - Examination 3 weeks after cast applied: digits cool, edematous, hyperesthetic, and hyperhidrotic. Passive and active motions of ankle and toes were moderately painful. Radiographs showed diffuse osteoporosis.

What would be your goals for this patient? Develop a program of interventions.
4. Identify and describe everyday activities and/or positions that mimic the neurodynamic test positions. These activities/positions may be patient complaints that indicate further neurodynamic testing. For example, getting into a car by straightening the leg and ducking the head mimics the "slump" position.

## Laboratory Practice

1. With your laboratory partner, practice each of the neurodynamic positions. Demonstrate how you would mobilize restrictions for each of the nerves.
2. Practice each of the thoracic outlet tests and describe the mechanics of each test. Identify and practice techniques you could use to increase mobility or reduce compression on the brachial plexus at each of the sites where compression or tension might occur. Design an exercise program and progression for managing impairments that could cause TOS symptoms.
3. Practice desensitization and sensory reeducation techniques by doing each of the following.
  - Gather 10 pieces of material of various textures. Place them in order of least irritating to most irritating. Practice

sensory stimulation techniques by gently rubbing each material across your fingers.

- Use five plastic tubs or buckets. Place each of the following in a container: dry peas or beans, spiral macaroni, sand, fine gravel, and seeds. Practice sensory stimulation by moving your hand (or foot) through each of the textures.
- Have your laboratory partner place several familiar household items in a bag (e.g., key, dime, penny, can opener). Without looking, attempt to identify each one.

### Independent Learning Activities 439

*Posture* is alignment of the body parts whether upright, sitting, or recumbent. It is described by the positions of the joints and body segments and also in terms of the balance between the muscles crossing the joints.<sup>46</sup> Impairments in the joints, muscles, or connective tissues may lead to faulty postures, or, conversely, faulty postures may lead to impairments in the joints, muscles, and connective tissues as well as symptoms of discomfort and pain. Many musculoskeletal complaints can be attributed to stresses that occur from repetitive or sustained activities when in a habitually faulty postural alignment. This chapter reviews the structural relationships of the spine and extremities to normal and abnormal posture and describes the mechanisms that control posture. Common postural impairments and general guidelines for their management are described. Specific exercises for the various body regions are highlighted in this chapter and are described in detail in the succeeding chapters in Part IV of the text. Chapter 15 describes the common

pathologies associated with the spine and details management guidelines, and Chapter 16 describes spinal exercises and manual interventions in detail.

## Structure and Function of the Spine

### Structure

The structure of the spinal column consists of 33 vertebrae (7 cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 3 or 4 coccygeal) and their respective intervertebral discs. Articulating with the spine are the 12 pair of ribs in the thoracic region, the cranium at the top of the spine at the occipital-atlas joint, and the pelvis at sacroiliac joints (Fig. 14.1).

**FIGURE 14.1** (A) Lateral and (B) posterior views showing the five regions of the spinal column. (From Levangie, P, and Norkin, C [eds]: *Joint Structure and Function: A Comprehensive Analysis*, ed. 5. Philadelphia: F.A. Davis, 2011, p 141 with permission.)

### Functional Components of the Spine

Functionally, the spinal column is divided into anterior and posterior pillars (Fig. 14.2).<sup>16</sup>

- The *anterior pillar* is made up of the vertebral bodies and intervertebral discs and is the hydraulic, weight-bearing, shock-absorbing portion of the spinal column. The size of

the disc influences the amount of motion available between two vertebrae.

- The *posterior pillar*, or vertebral arch, is made up of the articular processes and facet joints, which provide the gliding mechanism for movement. The orientation of the facets influences the direction of motion. Also part of the posterior unit are the bony levers, the two transverse processes, and the spinous process to which the muscles attach and function to cause and control motions and provide spinal stability.

**FIGURE 14.2** Spinal segment showing (A) the anterior weight-bearing, shock-absorbing portion and (B) the posterior gliding mechanism and lever system for muscle attachments.

### Motions of the Spinal Column

Motion of the spinal column is described both globally and at the functional unit or motion segment. The functional unit is comprised of two vertebrae and the joints in between (typically, two zygapophyseal facet joints and one intervertebral disc). Generally, the axis of motion for each unit is in the nucleus pulposus of the intervertebral disc. Because the spine can move from top down or bottom up, motion at a functional unit is defined by what is occurring with the anterior portion of the body of the superior vertebra (Fig. 14.3).

**FIGURE 14.3** Motions of the spinal column. (A) Flexion/extension (forward/backward bending). (B) Lateral flexion (side bending). (C) Rotation. (D) Anterior/posterior shear. (E) Lateral shear. (F) Distraction/compression.

## The Six Degrees of Motion

**Flexion/extension.** Motion in the sagittal plane results in flexion (forward bending) or extension (backward bending). With flexion, the anterior portion of the bodies approximate and the spinous processes separate; with extension, the anterior portion of the bodies separate and the spinous processes approximate.

**Side bending.** Motion in the frontal plane results in side bending (lateral flexion) to the left or right. With side bending, the lateral edges of the vertebral bodies approximate on the side toward which the spine is bending and separate the opposite side.

**Rotation.** Motion in the transverse plane results in rotation. Rotation to the right results in relative movement of the body of the superior vertebrae to the right and its spinous process to the left; the opposite occurs with rotation to the left. If movement occurs from the pelvis upward, the motion is still defined by the relative motion of the top vertebra.

**Anterior/posterior shear.** Forward or backward shear (translation) occurs when the body of the superior vertebra translates forward or backward on the vertebra below.

**Lateral shear.** Lateral shear (translation) occurs when the body of the superior vertebra translates sideways on the vertebra below.

**Compression/distraction.** Separation or approximation occurs with a longitudinal force, either away from or toward the vertebral bodies.

## Arthrokinematics of the Zygapophyseal (Facet) Joints

Each region of the spine has its own special considerations as pertains to arthrokinematic movement and function. The arthrokinematics of the craniovertebral (suboccipital) area

are described below. The remainder of the cervical spine and all the thoracic facets have relatively flat articular surfaces and glide on the adjacent facet joint.<sup>16</sup> The superior facets of the lumbar spine are concave and articulate with the adjacent inferior convex facets.<sup>65</sup> The arthrokinematics that are described in this section are summarized in ONLINE Table 14.1 available on the FA Davis website associated with this text.

Coupled motions typically occur at a segmental level when a person side bends or rotates their spine. *Coupled motion* is defined as “consistent association of one motion about an axis with another motion around a different axis”<sup>16</sup> and varies depending on the region, the spinal posture, the orientation of the facets, and factors such as extensibility of the soft tissues. When motions of side bending and rotation are coupled, foraminal opening is dictated by the side bending component.

**Cervical spine.** The cervical spine can be divided into the craniovertebral region and the “typical” cervical region.

- The *craniovertebral region* is composed of the occiput, atlas, and superior facets of the axis.
- The occipito-atlanto (OA) joint is considered a ball and socket joint; the convex facets of the occiput articulate with the concave facets of the atlas. Its primary motions are forward and backward nodding (flexion and extension) (Fig. 14.4). There is a small amount of side bending available at the OA joint; rotation and side bending are coupled in opposite directions in this region.
- The atlanto-axial (AA) joint consists of convex articulating surfaces of the atlas articulating on the convex articulating surfaces of the axis; its primary motion is rotation as the atlas pivots around the dens of the axis. It is important to note that, during rotation, one side of the AA joint complex is behaving as though it is flexing (moving forward) and the other side as though it is extending (moving backward) (Fig. 14.5).
- The *typical cervical region* includes the inferior facets of the axis and rest of the cervical spine; it features facet joints that are angled at 45° from the horizontal plane. Side bending and rotation typically couple toward the same side.
- Another unique characteristic of the cervical spine is the *joints of Luschka*. These bony projections provide lateral stability to the spine and reinforce the vertebral disc posterolaterally.

**Thoracic spine.** The thoracic facets begin in a frontal plane orientation and transition to a sagittal plane orientation as they near the lumbar spine. The ribs articulate with the thoracic spine at the transverse processes as well as the vertebral bodies and IV discs. In the upright posture, side bending and rotation typically couple in the same direction in the upper thoracic spine and in the opposite directions in the lower thoracic region,<sup>16</sup> although variability has been described.<sup>78</sup>

**Lumbar spine.** As the lumbar facets transition from a sagittal plane to a frontal plane orientation, some of the facets have a biplanar orientation.<sup>16</sup> Coupling varies in that with lateral flexion, rotation occurs to the same side, but with rotation,

## ATLANTO-OCCIPITAL JOINT MOTION

**FIGURE 14.4** Nodding motions of the atlanto-occipital joints. **(A)** Flexion. **(B)** Extension. (From Levangie, P, and Norkin, C [eds]: *Joint Structure and Function: A Comprehensive Analysis*, ed. 5. Philadelphia: F.A. Davis, 2011, p 141 with permission.)

lateral flexion occurs opposite<sup>16</sup>; there is variability with flexion and extension.

### Structure and Function of Intervertebral Discs and Cartilaginous End-Plates

The intervertebral disc, consisting of the annulus fibrosus and nucleus pulposus, is one component of a three-joint complex between two adjacent vertebrae and cartilaginous end-plates

of the vertebral bodies. The structure of the disc dictates its function (Fig. 14.6).<sup>16,50</sup>

**Annulus fibrosus.** The outer portion of the disc is made up of dense layers of type I collagen fibers. The collagen fibers in any one layer are parallel and angled around 60° to 65° to the axis of the spine, with the tilt alternating in successive layers.<sup>31,47</sup> Because of the orientation of the fibers, tensile strength is provided to the disc by the annulus when the spine is distracted, rotated, or bent. This structure helps restrain the various spinal motions as a complex ligament. The annulus is firmly attached to adjacent vertebrae, and the layers are firmly bound to one another. Fibers of the innermost layers blend with the matrix of the nucleus pulposus. The annulus fibrosus is supported by the anterior and posterior longitudinal ligaments.

**Nucleus pulposus.** The central portion of the disc is a gelatinous mass that normally is contained within, but whose loosely aligned type II collagen fibers merge with the inner layer of the annulus fibrosus. It is located centrally in the disc except in the lumbar spine, where it is situated closer to the posterior border than the anterior border of the annulus. Aggregating proteoglycans, normally in high concentration

**FIGURE 14.6** Intervertebral disc. **(A)** The annular rings enclose the nucleus pulposus, providing a mechanism for dissipating compressive forces. **(B)** Orientation of the layers of the annulus provides tensile strength to the disc with motions in various directions.

in a healthy nucleus, have great affinity for water. The resulting fluid mechanics of the confined nucleus functions to distribute pressure evenly throughout the disc and from one vertebral body to the next under loaded conditions. Because of the affinity for water, the nucleus imbibes water when pressure is reduced on the disc and squeezes water out under compressive loads. These fluid dynamics provide transport for nutrients and help maintain tissue health in the disc.

With flexion (forward bending) of a vertebral segment, the anterior portion of the disc is compressed, and the posterior is distracted. The nucleus pulposus generally does not move in a healthy disc but may have slight distortion with flexion, potentially to redistribute the load through the disc.<sup>48</sup> Asymmetrical loading in flexion results in distortions of the nucleus toward the contralateral posterolateral corner, where the fibers of the annulus are more stretched.

**Cartilaginous end-plates.** End-plates cover the nucleus pulposus superiorly and inferiorly and lie between the nucleus and vertebral bodies. Each is encircled by the apophyseal ring of the respective vertebral body.<sup>16</sup> The collagen fibers of the inner annulus fibrosus insert into the end-plate and angle centrally, thus encapsulating the nucleus pulposus. Nutrition diffuses from the marrow of the vertebral bodies to the disc via the end-plates.<sup>16</sup> The end-plates are also responsible for containing the nucleus from migrating superior/inferior.

## Intervertebral Foramina

The intervertebral foramina are between each vertebral segment in the posterior pillar. Their anterior boundary is the intervertebral disc, the posterior boundary is the facet joint, and the superior and inferior boundaries are the pedicles of the superior and inferior vertebrae of the spinal segment. The

mixed spinal nerve exits the spinal canal via the foramen along with blood vessels and recurrent meningeal or sinuvertebral nerves. The size of the intervertebral foramina is affected by spinal motion, being larger with forward bending and contralateral side bending and smaller with extension and ipsilateral side bending.

## Biomechanical Influences on Postural Alignment

### Curves of the Spine

The adult spine is divided into four curves: two *primary*, or posterior, curves, so named because they are present in the infant and the convexity is posterior, and two *compensatory*, or anterior, curves, so named because they develop as the infant learns to lift the head and eventually stand, and the convexity is anterior.

- Posterior curves are in the thoracic and sacral regions. *Kyphosis* is a term used to denote a posterior curve. Kyphotic posture refers to an excessive posterior curvature of the thoracic spine.<sup>46</sup>
- Anterior curves are in the cervical and lumbar regions. *Lordosis* is a term also used to denote an anterior curve, although some sources reserve the term lordosis to denote abnormal conditions such as those that occur with a sway back.<sup>46</sup>
- The curves and flexibility in the spinal column are important for withstanding the effects of gravity and other external forces.<sup>16,56</sup>
- The structure of the bones, joints, muscles, and inert tissues of the lower extremities are designed for weight bearing; they support and balance the trunk in the upright posture. Lower extremity alignment and function are described in greater detail in each of the extremity chapters (see Chapters 20 to 22).

### Gravity

When looking at posture and function, it is critical to understand the influence of gravity on the structures of the trunk and lower extremities. Gravity places stress on the structures responsible for maintaining the body upright and therefore provides a continual challenge to stability and efficient movement. For a weight-bearing joint to be stable, or in equilibrium, the gravity line of the mass must fall exactly through the axis of rotation, or there must be a force to counteract the moment caused by gravity.<sup>49</sup> In the body, the counterforce is provided by either muscle or inert structures. In addition, the standing posture usually involves a slight anterior/posterior swaying of the body of about 4 cm, so muscles are necessary to control the sway and maintain equilibrium.

In the upright posture, the line of gravity transects the spinal curves, which are balanced anteriorly and posteriorly,

and it is close to the axis of rotation in the lower extremity joints. The following describes the standard of a balanced upright posture (Fig. 14.7).

**FIGURE 14.7** Lateral view of standard postural alignment. A plumb line is typically used for reference and represents the relationship of the body parts with the line of gravity. Surface landmarks are slightly anterior to the lateral malleolus, slightly anterior to the axis of the knee joint, through the greater trochanter (slightly posterior to the axis of the hip joint), through the bodies of the lumbar and cervical vertebrae, through the shoulder joint, and through the lobe of the ear.

**Ankle.** For the ankle, the gravity line is anterior to the joint, so it tends to rotate the tibia forward about the ankle. Stability is provided by the plantarflexor muscles, primarily the soleus muscle.

**Knee.** The normal gravity line is anterior to the knee joint, which tends to keep the knee in extension. Stability is provided by the anterior cruciate ligament, posterior capsule (locking mechanism of the knee), and tension in the muscles posterior to the knee (the gastrocnemius and hamstring muscles). The soleus provides active stability by pulling posteriorly on the tibia. With the knees fully extended, no muscle support is required at that joint to maintain an upright posture; however, if the knees flex slightly, the gravity line shifts posterior to the joint, and the quadriceps femoris muscle must contract to prevent the knee from buckling.

**Hip.** The gravity line at the hip varies with the swaying of the body. When the line passes through the hip joint, there is equilibrium, and no external support is necessary. When the

gravitational line shifts posterior to the joint, some posterior rotation of the pelvis occurs but is controlled by tension in the hip flexor muscles (primarily the iliopsoas). During relaxed standing, the iliofemoral ligament provides passive stability to the joint, and no muscle tension is necessary. When the gravitational line shifts anteriorly, stability is provided by active support of the hip extensor muscles.

**Trunk.** Normally, the gravity line in the trunk goes through the bodies of the lumbar and cervical vertebrae, and the curves are balanced. Some activity in the muscles of the trunk and pelvis helps maintain the balance. (This is described in greater detail in the following sections.) As the trunk shifts, contralateral muscles contract and function as guy wires. Extreme or sustained deviations are supported by inert structures.

**Head.** The center of gravity of the head falls anterior to the atlanto-occipital joints. The posterior cervical muscles contract to keep the head balanced.

## Stability

When standing, the center of gravity typically falls slightly anterior to S2 in the pelvis. So long as the line of gravity from the center of mass falls within the base of support, a structure is stable. Stability is improved by lowering the center of gravity or increasing the base of support. In the upright position, the body is relatively unstable because it is a tall structure with a small base of support. When the center of gravity falls outside the base of support, either the structure falls or some force must act to keep the structure upright. Both inert and dynamic structures support the body against gravitational and other external forces. The inert osseous and ligamentous structures provide passive tension when a joint reaches the end of its range of motion (ROM). Muscles act as dynamic guy wires, responding to perturbations by providing counterforces to the torque of gravity as well as stability within the ROM so stresses are not placed on the inert tissues.

## Postural Stability in the Spine

Spinal stability is described in terms of three subsystems: passive (inert structures/bones and ligaments), active (muscles), and neural control.<sup>24,64</sup> The three subsystems are interrelated and can be thought of as a three-legged stool; if any one of the legs is not providing support, it affects the stability of the whole structure.<sup>64</sup> Instability of a spinal segment is often a combination of inert tissue damage, insufficient muscular strength or endurance, and poor neuromuscular control.<sup>3,24</sup>

## Inert Structures: Influence on Stability

Penjabi<sup>63,64</sup> described the ROM of any one segment as being divided into an elastic zone and a neutral zone. When spinal segments are in the neutral zone (midrange/neutral range), the inert joint capsules and ligaments provide minimal passive

resistance to motion and therefore minimal stability. As a segment moves into the elastic zone, the inert structures provide restraint as passive resistance to the motion occurs. When a structure limits movement in a specific direction, it provides stability in that direction. In addition to the inert tissues providing passive stability when limiting motion, the sensory receptors in the joint capsules and ligaments sense position and changes in position. Stimulation of these receptors provides feedback to the central nervous system, thus influencing the neural control system.<sup>64,66</sup> The stabilizing features of the inert tissues in the spine are summarized in ONLINE Table 14.2 available on the FA Davis website associated with this text.

## Muscles: Influence on Stability

The muscles of the trunk not only act as prime movers or as antagonists to movement caused by gravity during dynamic activity; they are important stabilizers of the spine.<sup>3,9,11,27,39,54,66</sup> Without the dynamic stabilizing activity from the trunk muscles, the spine would collapse in the upright position.<sup>14</sup>

### Role of Global and Segmental Muscle Activity

Both superficial (global) and deep (segmental) muscles play critical roles in providing stability and maintaining the upright posture. Table 14.1 summarizes the stabilizing characteristics of these two muscle groups.

**Global muscle function.** In the lumbar spine, the global muscles, being the more superficial of the two groups, are the large guy wires that respond to external loads imposed on the trunk that shift the center of mass (Fig. 14.8 A). Their reaction is

direction specific to control spinal orientation.<sup>3,39</sup> The global muscles are unable to stabilize individual spinal segments except through compressive loading because they have little or no direct attachment to the vertebrae. If an individual segment is unstable, compressive loading from the global guy wires may lead to or perpetuate a painful situation as stress is placed on the inert tissues at the end of the range of that segment (Fig. 14.8 B).

**Deep/segmental muscle function.** The deeper, segmental muscles, which have direct attachments across the vertebral segments, provide dynamic support to individual segments in the spine and help maintain each segment in a stable position, so the inert tissues are not stressed at the limits of motion (Fig. 14.9).<sup>39,43,44,55</sup>

**FIGURE 14.8** (A) Guy wire function of global trunk muscles provides overall stability against perturbations. (B) Instability in the multisegmental spine cannot be controlled by the global trunk muscle guy wires. Compressive loading from the long guy wires leads to stress on the inert tissues at the end-ranges of the unstable segment.

### Muscle Control in the Lumbar Spine

General muscle function and stabilizing actions of the muscles of the spine described in this section are summarized in ONLINE Table 14.3 available on the FA Davis website associated with this text.

**Abdominal muscles (Fig. 14.10).** The rectus abdominis (RA), external oblique (EO), and internal oblique (IO) muscles are large, multisegmental global trunk flexor muscles and are important guy wires for stabilizing the spine against postural perturbations. The transversus abdominis (TrA) is the deepest of the abdominal muscles and responds uniquely to postural perturbations. It attaches posteriorly to the lumbar vertebrae via the posterior and middle layers of the thoracolumbar fascia (Figs. 14.11 and 14.12) and through its action develops tension that acts like a girdle of support around the abdomen and lumbar vertebrae. Only the TrA is active with both isometric trunk flexion and extension, whereas the other abdominal muscles have decreased activity with resisted extension. This is attributed to the stabilization function of the TrA.<sup>13,41</sup>

**FIGURE 14.10** Abdominal muscles.

**FIGURE 14.11** Transverse section in the lumbar region shows the relationships of the three layers of the thoracolumbar fascia to the muscles in the region and their attachments to the spine. (ES, erector spinae; MF, multifidus; TA, transversus abdominis; IO, internal obliques; EO, external obliques; LD, latissimus dorsi; PM, psoas major; QL, quadratus lumborum muscles)

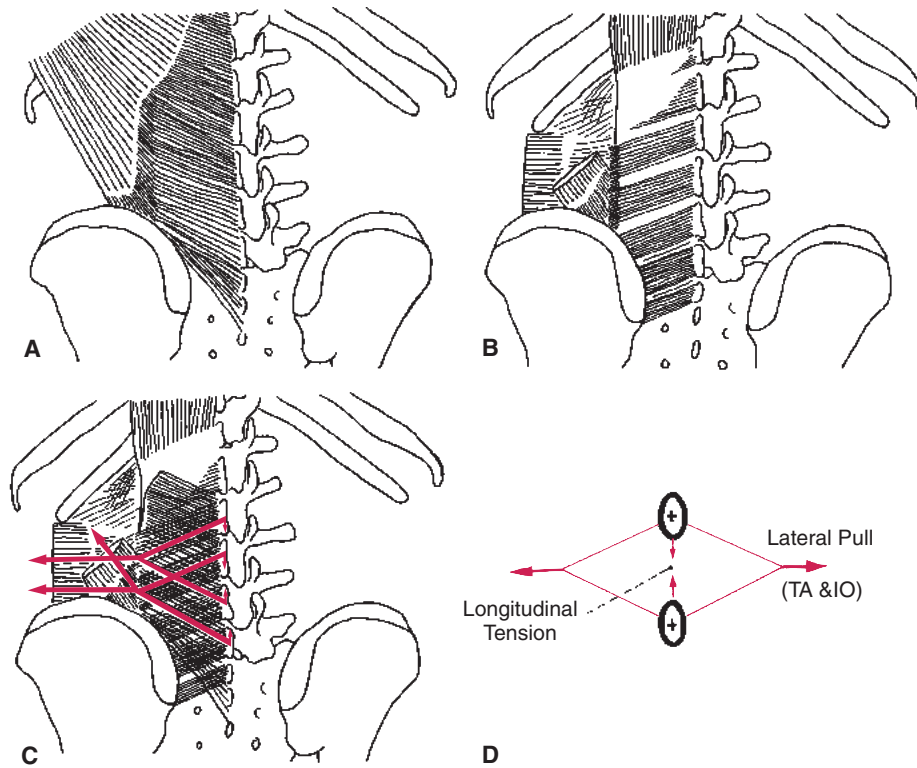

**Transversus abdominis stabilization activity.** Early electromyographic research studies of the activity of the deeper abdominal muscles in their stabilization function were done with surface electrodes and did not discriminate activity between the TrA and IO. By using ultrasound imaging techniques, insertion of fine-needle electrodes into the various muscles has produced evidence of differing functions between these two muscles with perturbations to balance in healthy individuals as well as those who have low back pathology.<sup>37</sup>

The TrA responds with anticipatory activity and with rapid arm and leg movements (before the other abdominals) and coordinates with respiration during these activities.<sup>39,43,44</sup> The TrA also has a coordinated link with the perineum and pelvic floor muscle function (see Chapter 25),<sup>7,15,57,69,70</sup> as well as with the deep fibers of the multifidi.<sup>39,42-44,55</sup> The “drawing-in” maneuver is used to activate the TrA voluntarily and, with training, produces the most independent activity of this muscle.<sup>67,76</sup> Training the TrA for postural control and stability has been shown to improve the long-term outcome in patients experiencing their first episode of low back pain.<sup>32</sup> (See Chapter 16 for a description of this maneuver.)

### FOCUS ON EVIDENCE

In a study involving 42 healthy controls and 56 people with back pain, the thickness of the TrA and LM muscle groups measured with ultrasound imaging was calculated at rest and then during a stabilizing contraction with no resistance. The results were expressed as a percentage of change in thickness during these times of measurement. It was found that the healthy group average increase was 60% for the TrA and 30% for the LM. This was compared with 40% and 20%, respectively, for the group with LBP.<sup>19</sup> However, a systematic review reported conflicting evidence for a relationship in percentage of change in LM thickness and functional outcomes following various conservative interventions.<sup>80</sup>

**Erector spinae muscles (Fig. 14.13).** The erector spinae muscles are the long, multisegmental extensors that begin as a large musculotendinous mass over the sacral and lower

**FIGURE 14.12** Orientation and attachments of the posterior layer of the thoracolumbar fascia. From the lateral raphe, (A) the fibers of the superficial lamina are angled inferiorly and medially and (B) the fibers of the deep lamina are angled superiorly and medially. (C) Tension in the angled fibers of the posterior layer of the fascia is transmitted to the spinous processes in opposing directions, resisting separation of the spinous processes. (D) Diagrammatic representation of a lateral pull at the lateral raphe, resulting in tension between the lumbar spinous processes that oppose separation, thus providing stability to the spine. (A–C: adapted from Bogduk, N, and MacIntosh, JE: *The applied anatomy of the thoracolumbar fascia*. *Spine* 9:164–170, 1984, pp 166–167, 169, with permission; D: adapted from Gracovetsky, S, Farfan, H, and Helleur, C: *The abdominal mechanism*. *Spine* 10:317–324, 1985, p 319, with permission.)

lumbar vertebrae. They are important global guy wires for controlling the trunk against postural perturbations.

**Multifidus stabilization activity.** The multifasciculated multifidi muscle group has a high distribution of type I fibers and large capillary network, emphasizing its role as a tonic stabilizer. Its segmental attachments are able to control movement of the spinal segments as well as increase spinal stiffness. The multifidus, along with the erector spinae, are encased by the posterior and middle layers of the lumbodorsal fascia (see Fig. 14.11), so bulk and muscle contraction increase tension on the fascia, adding to the stabilizing function of the fascia (see below for a description of this mechanism).

In patients with low back impairment, the fibers of the multifidi quickly atrophy at the spinal segment,<sup>6,33</sup> and a moth-eaten appearance has been reported in patients undergoing surgery for lumbar disc disease.<sup>66</sup> Additionally, it has been reported that individuals with LBP have been shown to have significantly more fatty infiltration in the LM when compared with healthy controls.<sup>10,18</sup> This reflects that muscle quality might be a precursor in reoccurring LBP. Evidence supports the idea that training with specific exercises increases the function of the multifidi as well as the erector spinae in general.<sup>17,32,34</sup> Other deep muscles that theoretically play a role in segmental stability but to this point in time have been difficult to assess because of their depth include the intersegmental

muscles (rotators and intertransversarii muscles) and deep fibers of the quadratus lumborum.

### FOCUS ON EVIDENCE

Inactivity has been shown to increase the risk of high fat content in the multifidus as well as higher pain intensity and disability.<sup>73</sup> Additionally, it has been reported in a systematic review that the paraspinal muscles are significantly smaller in patients with chronic LBP.<sup>22</sup> However, no significant correlation has been associated with decreased physical activity and a decreased cross-sectional area of the multifidi or erector spinae.<sup>73</sup> Conversely, in another systematic review, strong evidence was identified that changes in TrA thickness during contraction were unrelated to low back pain intensity and changes in the multifidi muscles and clinical outcomes were uncertain.<sup>79</sup>

**Thoracolumbar (lumbodorsal) fascia.** The thoracolumbar fascia is an extensive fascial system in the back that consists of several layers.<sup>8,9,27-29</sup> It surrounds the erector spinae, multifidi, and quadratus lumborum, thus providing support to these muscles when they contract<sup>28</sup> (see Fig. 14.11). Increased bulk in these muscles increases tension in the fascia, perhaps contributing the stabilizing function of these muscles.

**FIGURE 14.13** Muscles of the back.

The aponeurosis of the latissimus dorsi and fibers from the serratus posterior inferior, internal oblique, and transverse abdominis muscles blend together at the lateral raphe of the thoracolumbar fascia, so contraction in these muscles increases tension through the angled fascia, providing stabilizing forces for the lumbar spine<sup>28</sup> (see Fig. 14.12). In addition, the “X” design of the latissimus dorsi and contralateral gluteus maximus has the potential to provide stability to the lumbosacral junction.

### Muscle Control in the Cervical Spine

The fulcrum of the head on the spine is through the occipital/atlas joints. The center of gravity of the head is anterior to the joint axis and therefore has a flexion moment. The weight of the head is counterbalanced by the cervical extensor muscles (upper trapezius and cervical erector spinae). Tension and fatigue in these muscles, as well as in the levator scapulae (which supports the posture of the scapulae), is experienced by most people who experience postural stress to the head and neck (Fig. 14.14). The position of the mandible and the tension in the muscles of mastication are influenced by the postural relationship between the cervical spine and head.

**Mandibular elevator group.** The mandible is a movable structure that is maintained in its resting position with the

**FIGURE 14.14** Head balance on the cervical spine. The posterior cervical muscles (trapezius and semispinalis capitis) counter the weight of the head. The mandibular elevating muscles (masseter, temporalis, medial pterygoid) maintain jaw elevation opposing the mandibular depression force of gravity and tension in the anterior throat muscles (suprahyoid and infrahyoid groups). The scalene and levator muscles stabilize against the posterior and anterior translatory forces on the cervical vertebrae. (TR, trapezius; SC, semispinalis capitis; M, masseter; T, temporalis; MT, medial pterygoid; SH, suprahyoid; IH, infrahyoid; S, scalene; LS, levator scapulae; G, center of gravity; ▲, axis of motion.)

jaw partially closed through action of the mandibular elevators (masseter, temporalis, and medial pterygoid muscles).

**Suprahyoid and infrahyoid group.** The anterior throat muscles assist with swallowing and balancing the jaw against the muscles of mastication. These muscles also function to flex the neck when rising from the supine position. With a forward head posture, they, along with the longus colli, tend to be stretched and weak so the person lifts the head with the sternocleidomastoid (SCM) muscles. In addition, with a forward head posture, the suprahyoid muscles have a tendency to pull the mandible into depression due to their orientation and attachments at the hyoid and mandible. This is counteracted by the mandibular elevator muscle group, which creates a sustained contraction in order to keep the mouth closed.

**Rectus capitis anterior and lateralis, longus colli, and longus capitis (Fig. 14.15).** The deep craniocervical flexor muscles have segmental attachments and provide dynamic support to the cervical spine and head.<sup>30</sup> The longus colli is important in the action of axial extension (retraction) and works with the SCM for cervical flexion. Without the segmental influence of the longus colli, the SCM would cause increased cervical lordosis when attempting flexion.<sup>5</sup>

**Multifidus.** With its segmental attachments, the multifidus is thought to have a local stabilizing function in the cervical spine similar to its function in the lumbar region (see Fig. 14.13).<sup>30</sup>

**FIGURE 14.15** Deep segmental musculature in the cervical spine: rectus capitis anterior and lateralis, longus colli, longus capitis, and scalene muscles.

### Role of Muscle Endurance

Strength is critical for controlling large loads or responding to large and unpredictable loads (such as during laborious activities, sports, or falls), but only about 10% of maximum contraction is needed to provide stability in usual situations.<sup>3</sup> Slightly more might be needed in a segment damaged by disc disease or ligamentous laxity when muscles are called on to compensate for the deficit in the passive support.<sup>3</sup> In a study that looked at 17 mechanical factors and the occurrence of low back pain in 600 subjects (ages 20 through 65), poor muscular endurance in the back extensors muscles had the greatest association with low back pain.<sup>59</sup>

Greater percentages of type I fibers than type II fibers are found in all back muscles, which is reflective of their postural and stabilization functions.<sup>58</sup>

### Neurological Control: Influence on Stability

The muscles of the neck and trunk are activated and controlled by the nervous system, which is influenced by peripheral and central mechanisms in response to fluctuating forces and activities. Basically, the nervous system coordinates the response of muscles to expected and unexpected forces at the right time and by the right amount by modulating stiffness and movement to match the various imposed forces.<sup>3,20,39</sup>

**Feedforward control and spinal stability.** The central nervous system activates the trunk muscles in anticipation of the load imposed by limb movement to maintain stability in the spine.<sup>44</sup> Research has demonstrated that there are feedforward mechanisms that activate postural responses of all trunk muscles preceding activity in muscles that move the extremities<sup>39,42,44</sup> and that anticipatory activation of the transversus abdominis and deep fibers of the multifidus is independent of

the direction or speed of the postural disturbance.<sup>37,38,43,55</sup> The more superficial trunk muscles vary in response depending on the direction of arm and leg movement, reflective of their postural guy wire function, which controls displacement of the center of mass when the body changes configuration.<sup>39,44</sup> There are reported differences in patterns of muscle recruitment in patients with low back pain with delayed recruitment of the transversus abdominis in all movement directions and delayed recruitment of the rectus abdominis, erector spinae, and oblique abdominal muscles specific to the direction of movement compared to healthy subjects.<sup>40</sup>

### FOCUS ON EVIDENCE

A study by Allison and associates<sup>1</sup> collected data from muscle activity of the TrA, internal obliques, erector spinae, and multifidus muscle groups bilaterally in seven subjects and provided evidence that challenges the concept of bilateral feed forward symmetry in the activation of the TrA and that also contradicts previously published studies that contraction of the TrA is independent of the direction of arm movement causing trunk perturbations. The data support the motor control strategy of feed-forward activity but challenge the influence of support to the spine through symmetrical force generation due to the asymmetry in activation patterns dependent on side and direction of arm movement and thus direction of trunk perturbations. The authors acknowledge the value of TrA training but suggest further research is needed to provide explanation for the mechanism of its stabilizing action.

### Effects of Limb Function on Spinal Stability

Without adequate stabilization of the spine, contraction of the limb-girdle musculature transmits forces proximally and causes motions of the spine that place excessive stresses on spinal structures and the supporting soft tissue.

### CLINICAL TIP

- Stabilization of the pelvis and lumbar spine by the abdominal muscles against the pull of the iliopsoas muscle is necessary during active hip flexion to avoid increased lumbar lordosis and anterior shearing of the vertebrae.
- Stabilization of the ribs by the intercostal and abdominal muscles is necessary for an effective pushing force from the pectoralis major and serratus anterior muscles.
- Stabilization of the cervical spine by the longus colli muscle is necessary to prevent excessive lordosis from contraction of the upper trapezius as it functions with the shoulder girdle muscles in lifting and pulling activities.

**Localized muscle fatigue.** Localized fatigue in the stabilizing spinal musculature may occur with repetitive activity or heavy

exertion or when the musculature is not utilized effectively due to faulty postures. There is a greater chance of injury in the supporting structures of the spine when the stabilizing muscles fatigue. Marras and Granata<sup>52</sup> reported significant changes in motion patterns between the spine and lower extremity joints as well as significant changes in muscle recruitment patterns with repetitive lifting during an extended period of time, resulting in increased anterior/posterior shear in the lumbar spine.

**Muscle imbalances.** Imbalances in the flexibility and strength of the hip, shoulder, and neck musculature cause asymmetrical forces on the spine and affect posture. Common problems are described in the section later in this chapter on “Common Faulty Postures.”

## Effects of Breathing on Posture and Stability

Inspiration and thoracic spine extension elevate the rib cage and assist with posture. The intercostal muscles function as postural muscles to stabilize and move the ribs. They act as a dynamic membrane between the ribs to prevent sucking in and blowing out of the soft tissue with the pressure changes during respiration.<sup>4</sup> The stabilizing function of the TrA also works in conjunction with the diaphragm in a feed-forward response to rapid arm motions. Contraction of the diaphragm and increased intra-abdominal pressure (IAP) occur prior to rapid arm movement, irrespective of the phase of respiration or the direction of the arm motion.<sup>39,41</sup> The tonic activities of the TrA and diaphragm are modulated to meet respiratory demands during both inspiration and expiration and provide stability to the spine when there are repetitive limb movements.<sup>35,36</sup>

## Effects of Intra-abdominal Pressure and the Valsalva Maneuver on Stability

During the Valsalva maneuver, contraction of the TrA, IO, and EO muscles increase IAP.<sup>13</sup> Contraction of the TrA alone pushes the abdominal contents up against the diaphragm; therefore, to complete the enclosed chamber, the diaphragm and pelvic floor muscles contract in synchrony with the TrA.<sup>57</sup> There are several ideas that explain how IAP improves spinal stability. The increased pressure in the enclosed chamber may act to unload the compressive forces on the spine as well as increase the stabilizing effect by pushing out against the abdominal muscles, increasing their length-tension relationship and tension on the thoracolumbar fascia (Figs. 14.16 and 14.17).<sup>69</sup> It is also suggested that the IAP may act to prevent buckling of the spine and thus prevent tissue strain or failure.<sup>12</sup>

The Valsalva maneuver is a technique frequently used by individuals lifting heavy loads and potentially has cardiovascular risks (see Chapter 6), so it is recommended that individuals be taught to exhale while maintaining the abdominal contractions to decrease the risks. In addition, Hodges and associates<sup>41</sup> found that if a static expulsive effort is maintained

**FIGURE 14.16** Coordinated contraction of the transversus abdominis, diaphragm, and pelvic floor musculature increases intra-abdominal pressure, which unloads the spine and provides stability.

**FIGURE 14.17 (A)** Increased intra-abdominal pressure (IAP) pushes outward against the transversus abdominis and internal obliques, creating increased tension on the thoracolumbar fascia, resulting in improved spinal stability. **(B)** Reduced pressure decreases the stabilizing effect. (Adapted from Gracovetsky, S: *The Spinal Engine*. New York: Springer-Verlag Wein, 1988, p 114, with permission.)

(holding the breath while contracting the abdominal muscles), activation of the transverse abdominis is delayed. Because activation of the transversus abdominis is necessary for segmental spinal stability, expiration during exertion reinforces this stabilizing function.

## Impaired Posture

In order to make sound clinical decisions when managing patients with activity or participation restrictions due to spinal impairments, it is necessary to understand the underlying effects of faulty posture on flexibility, strength, and the pain experienced by the individual. Impaired posture may be the underlying cause of the patient's pain or may be the result of some traumatic or pathological event. In this section, the etiology of pain and common faulty postures are described in detail followed by guidelines for developing therapeutic exercise interventions.

## Etiology of Pain

The ligaments, facet capsules, periosteum of the vertebrae, muscles, anterior dura mater, dural sleeves, epidural areolar adipose tissue, and walls of blood vessels are innervated and responsive to nociceptive stimuli.<sup>16</sup>

## Effect of Mechanical Stress

Mechanical stress to pain-sensitive structures, such as sustained stretch to ligaments or joint capsules or compression of blood vessels, causes distention or compression of the nerve endings, which leads to the experience of pain. This type of stimulus occurs in the absence of an inflammatory reaction. It is not a pathological problem but a mechanical one because signs of acute inflammation with constant pain are not present.

Relieving the stress to the pain-sensitive structure relieves the pain stimulus, and the person no longer experiences pain. If the mechanical stresses exceed the supporting capabilities of the tissues, breakdown ensues. If it occurs without adequate healing, musculoskeletal disorders or overuse syndromes with inflammation and pain affect function without an apparent injury (see Chapter 10). Relieving the mechanical stress (i.e., correcting the posture) along with decreasing the inflammation is important.

### CLINICAL TIP

To illustrate the mechanical effects of prolonged stress on tissues, have your patient/client take one of their fingers to the end of the range in extension and hold the position with their other hand. After a brief period of time when they begin to feel some discomfort, have them move out of the end

range position and note relief. Point out that this is what is happening to their joints and ligaments when they are in a sustained faulty posture.

## Effect of Impaired Postural Support From Trunk Muscles

Little muscle activity is required to maintain upright posture, but with total relaxation of muscles, the spinal curves become exaggerated and passive structural support is called on to maintain the posture. When there is continued end-range loading, strain occurs with creep and fluid redistribution in the supporting tissues, making them vulnerable to injury.<sup>74</sup>

Continual exaggeration of the curves leads to postural impairment and muscle strength and flexibility imbalances as well as other soft tissue restrictions or hypermobility. Muscles that are habitually kept in a stretched position tend to test weaker because of a shift in the length-tension curve; this is known as *stretch weakness*.<sup>46</sup> Muscles kept in a habitually shortened position tend to lose their elasticity. These muscles test strong only in the shortened position but become weak as they are lengthened. This condition is known as *tight weakness*.<sup>26</sup>

## Effect of Impaired Muscle Endurance

Endurance in muscles is necessary to maintain postural control. Sustained postures require continual, small adaptations in the stabilizing muscles to support the trunk against fluctuating forces. Large, repetitive motions also require muscles to respond so as to control the activity. In either case, as the muscles fatigue, the mechanics of performance change and the load is shifted to the inert tissues supporting the spine at the end-ranges.<sup>71</sup> With poor muscular support and a sustained load on the inert supporting tissues, creep and distention occur, causing mechanical stress. In addition, injuries occur more frequently after a lot of repetitive activity or long periods of work and play when there is muscle fatigue.

## Pain Syndromes Related to Impaired Posture

**Postural fault.** A postural fault is a posture that deviates from normal alignment but has no structural impairments.

**Postural pain syndrome.** Postural pain syndrome refers to the pain that results from mechanical stress when a person maintains a faulty posture for a prolonged period; the pain is usually relieved with activity. There are no impairments in functional strength or flexibility, but if the faulty posture continues, strength and flexibility imbalances eventually develop.

**Postural dysfunction.** Postural dysfunction differs from postural pain syndrome in that adaptive shortening of soft

tissues and muscle weakness are involved. The cause may be prolonged poor postural habits, or the dysfunction may be a result of contractures and adhesions formed during the healing of tissues after trauma or surgery. Stress to the shortened structures causes pain. In addition, strength and flexibility imbalances may predispose the area to injury or overuse syndromes that a normal musculoskeletal system could sustain.

**Postural habits.** Good postural habits in the adult are necessary to avoid postural pain syndromes and postural dysfunction. Also, careful follow-up in terms of flexibility and posture training exercises is important after trauma or surgery to prevent impairments from contractures and adhesions. In the child, good postural habits are important to avoid abnormal stresses on growing bones and adaptive changes in muscle and soft tissue.

## Common Faulty Postures: Characteristics and Impairments

The head, neck, thorax, lumbar spine, and pelvis are all inter-related, and deviations in one region affect the other areas. For clarity of presentation, the lumbopelvic (or lower quarter) and cervicothoracic (or upper quarter) regions and typical muscle length-strength impairments for each region are described separately in this section and illustrated in Figure 14.18.

**FIGURE 14.18** (A) Lordotic posture characterized by an increase in the lumbosacral angle, increased lumbar lordosis, increased anterior tilting of the pelvis, and hip flexion. (B) Relaxed or slouched posture characterized by excessive shifting of the pelvic segment anteriorly, resulting in hip extension, and shifting of the thoracic segment posteriorly, resulting in flexion of the thorax on the upper lumbar spine. A compensatory increased thoracic kyphosis and forward head placement are also seen. (C) Flat low-back posture characterized by a decreased lumbosacral angle, decreased lumbar lordosis, and posterior tilting of the pelvis. (D) Flat upper back and cervical spine characterized by a decrease in the thoracic curve, depressed scapulae, depressed clavicle, and an exaggeration of axial extension (flexion of the occiput on the atlas and flattening of the cervical lordosis).

## Pelvic and Lumbar Region

### Lordotic Posture

Lordotic posture (see Fig. 14.18 A) is characterized by an increase in the lumbosacral angle (the angle that the superior border of the first sacral vertebral body makes with the horizontal, which optimally is 30°), an increase in lumbar lordosis, and an increase in the anterior pelvic tilt and hip flexion. It is often seen with increased thoracic kyphosis and forward head and is called kypholordotic posture.<sup>46</sup>

### Potential Muscle Impairments

- Mobility impairment in the hip flexor muscles (iliopsoas, tensor fasciae latae, rectus femoris) and lumbar extensor muscles (erector spinae)
- Impaired muscle performance due to stretched and weak abdominal muscles (rectus abdominis, internal and external obliques, and transversus abdominis) and hip extensors (gluteus maximus and hamstrings)

### Potential Sources of Symptoms

- Stress to the anterior longitudinal ligament.
- Narrowing of the posterior disc space and narrowing of the intervertebral foramen. This may compress the dura and blood vessels of the related nerve root or the nerve root itself, especially if there are degenerative changes in the vertebra or intervertebral disc.
- Approximation of the articular facets. Weight bearing through the facets may increase, which may cause synovial irritation and joint inflammation and may eventually accelerate degenerative changes if not corrected.

### Common Causes

Sustained faulty posture, pregnancy, obesity, and weak abdominal muscles are common causes.

### Relaxed or Slouched Posture

The relaxed or slouched posture (see Fig. 14.18 B) is also called swayback.<sup>46</sup> The amount of pelvic tilting is variable, but usually there is a shifting of the entire pelvic segment anteriorly, resulting in hip extension, and shifting of the thoracic segment posteriorly, resulting in flexion of the thorax on the upper lumbar spine. This results in increased lordosis in the lower lumbar region, increased kyphosis in the thoracic region, and usually a forward head. The position of the mid and upper lumbar spine depends on the amount of displacement of the thorax. When standing for prolonged periods, the person usually assumes an asymmetrical stance in which most of the weight is borne on one lower extremity with pelvic drop (lateral tilt) and hip abduction on the unweighted side. This affects frontal plane symmetry.

A sitting slouched posture occurs when there is an overall kyphotic curve throughout the entire thoracic and lumbar spine.

### Potential Muscle Impairments

- Mobility impairment in the upper abdominal muscles (upper segments of the rectus abdominis and obliques), internal intercostal, hip extensor, and lower lumbar extensor muscles and related fascia
- Impaired muscle performance due to stretched and weak lower abdominal muscles (lower segments of the rectus abdominis and obliques), extensor muscles of the lower thoracic region, and hip flexor muscles

### Potential Sources of Symptoms

- Stress to the iliofemoral ligaments, the anterior longitudinal ligament of the lower lumbar spine, and the posterior longitudinal ligament of the upper lumbar and thoracic spine. With asymmetrical postures, there is also stress to the iliotibial band on the side of the elevated hip. Other frontal plane asymmetries may also be present and are described in the following section.
- Narrowing of the intervertebral foramen in the lower lumbar spine that may compress the blood vessels, dura, and nerve roots, especially with arthritic conditions.
- Approximation of articular facets in the lower lumbar spine.

### Common Causes

As the name implies, this is a relaxed posture in which the muscles are not used to provide support. The person yields fully to the effects of gravity, and only the passive structures at the end of each joint range (e.g., ligaments, joint capsules, bony approximation) provide stability. Causes may be attitudinal (the person feels comfortable when slouching), fatigue (seen when required to stand for extended periods), or muscle weakness (the weakness may be the cause or the effect of the posture). A poorly designed exercise program—one that emphasizes thoracic flexion without balancing strength with other appropriate exercises and postural training—may perpetuate these impairments.

### Flat Low-Back Posture

Flat low-back posture (see Fig. 14.18 C) is characterized by a decreased lumbosacral angle, decreased lumbar lordosis, hip extension, and posterior tilting of the pelvis.

### Potential Muscle Impairments

- Mobility impairment in the trunk flexor (rectus abdominis, intercostals) and hip extensor muscles
- Impaired muscle performance due to stretched and weak lumbar extensor and possibly hip flexor muscles

### Potential Sources of Symptoms

- Lack of the normal physiological lumbar curve, which reduces the shock-absorbing effect of the lumbar region and predisposes the person to injury
- Stress to the posterior longitudinal ligament
- Increase of the posterior disc space, which allows the nucleus pulposus to imbibe extra fluid and, under certain circumstances, may protrude posteriorly when the person attempts extension. This increased weight bearing on the disc may lead to degenerative changes.

### Common Causes

Common causes include habitual slouching in flexion when sitting or standing and overemphasis on flexion exercises in general exercise programs.

## Cervical and Thoracic Region

### Round Back (Increased Kyphosis) With Forward Head

The round back with forward head posture (see Fig. 14.18 B) is characterized by an increased thoracic curve, protracted scapulae (round shoulders), and forward (protracted) head. A forward head involves increased flexion of the lower cervical and the upper thoracic regions, increased extension of the upper cervical vertebra, and extension of the occiput on C1. There also may be temporomandibular joint dysfunction with protrusion and depression of the mandible.

### Potential Muscle Impairments

- Mobility impairment in the muscles of the anterior thorax (intercostal muscles), muscles of the upper extremity originating on the thorax (pectoralis major and minor, latissimus dorsi, serratus anterior), muscles of the cervical spine and head that attached to the scapula and upper thorax (levator scapulae, sternocleidomastoid, scalene, upper trapezius), and muscles of the suboccipital region (rectus capitis posterior major and minor, obliquus capitis inferior and superior)
- Impaired muscle performance due to stretched and weak lower cervical and upper thoracic erector spinae and scapular retractor muscles (rhomboids, middle and lower trapezius), anterior throat muscles (suprahyoid and infrahyoid muscles), and capital flexors (rectus capitis anterior and lateralis, superior oblique longus colli, longus capitis)
- With temporomandibular joint symptoms, the muscles of mastication (pterygoid, masseter, temporalis muscles) may experience increased tension

### Potential Sources of Symptoms

- Stress to the anterior longitudinal ligament in the upper cervical spine and to the posterior longitudinal ligament and ligamentum flavum in the lower cervical and thoracic spine
- Fatigue of the thoracic erector spinae and scapular retractor muscles
- Irritation of facet joints in the upper cervical spine
- Narrowing of the intervertebral foramina in the upper cervical region, which may impinge on the blood vessels and nerve roots, especially if there are degenerative changes
- Impingement on the neurovascular bundle from anterior scalene or pectoralis minor muscle tightness (see “Thoracic Outlet Syndrome” in Chapter 13)
- Strain on the neurovascular structures of the thoracic outlet from scapular protraction<sup>45</sup>
- Impingement of the cervical plexus from levator scapulae muscle tightness
- Impingement on the greater occipital nerves from a tight or tense upper trapezius muscle, leading to tension headaches
- Temporomandibular joint pain from joint compression due to mandibular malalignment and tension headaches resulting from associated muscle tension in the mandibular elevator muscle group (see section on “Temporomandibular Joint Dysfunction” in Chapter 15).
- Lower cervical disc lesions from the faulty flexed posture

### Common Causes

- The effects of gravity, slouching, and poor ergonomic alignment in the work or home environment. Occupational or functional postures requiring leaning forward or tipping the head backward for extended periods; faulty sitting postures, such as working at an improperly placed computer keyboard or screen, relaxed postures, or the end result of a faulty pelvic and lumbar spine posture are common causes of forward head posture. Causes are similar to the relaxed lumbar posture or the flat low-back posture in which there is continued slouching and overemphasis on flexion exercises in general exercise programs.

### Flat Upper Back and Neck Posture

The flat upper back and neck posture (see Fig. 14.18 D) is characterized by a decrease in the thoracic curve, depressed scapulae, depressed clavicles, and decreased cervical lordosis with increased flexion of the occiput on atlas. It is associated with an exaggerated military posture but is not a common postural deviation. There may be temporomandibular joint dysfunction with protraction of the mandible.

### Potential Muscle Impairments

- Mobility impairment in the anterior neck muscles, thoracic erector spinae, and scapular retractors, and potentially restricted scapular movement, which decreases the freedom of shoulder elevation
- Impaired muscle performance in the scapular protractor and intercostal muscles of the anterior thorax

### Potential Sources of Symptoms

- Fatigue of muscles required to maintain the posture
- Compression of the neurovascular bundle in the thoracic outlet between the clavicle and ribs
- Temporomandibular joint pain and occlusive changes
- Decrease in the shock-absorbing function of the kypholordotic curvature, which may predispose the neck to injury

### Common Causes

As noted, this is not a common postural deviation and occurs primarily with exaggeration of the military posture.

## Frontal Plane Deviations: Scoliosis and Lower Extremity Asymmetries

### Scoliosis

Scoliosis is defined as a lateral curvature in the spine. It usually involves the thoracic and lumbar regions. Typically, in right-handed individuals, there is a mild right thoracic, left lumbar S-curve, or a mild left thoracolumbar C-curve. There may be asymmetry in the hips, pelvis, and lower extremities.

**Structural scoliosis.** *Structural scoliosis* involves an irreversible lateral curvature with fixed rotation of the vertebrae (Fig. 14.19 A). Rotation of the vertebral bodies is toward the convexity of the curve. In the thoracic spine, the ribs rotate with the vertebrae, so there is prominence of the ribs posteriorly on the side of the spinal convexity and prominence anteriorly on the side of the concavity. A posterior rib hump is detected on forward bending in structural scoliosis (Fig. 14.19 B).<sup>49</sup>

**FIGURE 14.19 (A)** Mild right thoracic left lumbar structural scoliosis with prominence of the right scapula. **(B)** Forward bending produces a slight posterior rib hump, indicating fixed rotation of the vertebrae and rib cage.

**Nonstructural scoliosis.** *Nonstructural scoliosis* is reversible and can be changed with forward or side bending and with positional changes, such as lying supine, realignment of the pelvis by correction of a leg-length discrepancy, or with muscle contractions. It is also called *functional* or *postural scoliosis*.

### Potential Impairments

- Mobility impairment in joints, muscles, and fascia on the concave side of the curves.
- Impaired muscle performance due to stretch and weakness in the musculature on the convex side of the curves.
- If one hip is adducted, the adductor muscles on that side have decreased flexibility, and the abductor muscles are stretched and weak. The opposite occurs on the contralateral extremity.<sup>46</sup>
- With advanced structural scoliosis, there is decreased rib expansion; cardiopulmonary impairments may result in difficulty breathing.

### Potential Sources of Symptoms

- Muscle fatigue and ligamentous strain on the side of the convexity
- Nerve root irritation on the side on the concavity
- Joint irritation from approximation of the facets on the side of the concavity

### Common Causes: Structural Scoliosis

Neuromuscular diseases or disorders (e.g., cerebral palsy, spinal cord injury, progressive neurological or muscular diseases), osteopathic disorders (e.g., hemivertebra, osteomalacia, rickets, fracture), and idiopathic disorders in which the cause is unknown are common causes of structural scoliosis.

### Common Causes: Nonstructural Scoliosis

Leg-length discrepancy (structural or functional), muscle guarding or spasm from a painful stimuli in the back or neck, and habitual or asymmetrical postures are common causes of nonstructural scoliosis.

## Frontal Plane Deviations From Lower Extremity Asymmetries
