Any lower extremity inequality has an effect on the pelvis that, in turn, affects the spinal column and structures supporting it.<sup>23</sup> When dealing with spinal posture, it is imperative to assess lower extremity alignment, symmetry, foot posture, ROM, muscle flexibility, and strength. (See Chapters 20 through 22 for principles, procedures, and techniques for treating the hip, knee, ankle, and foot.) Frontal plane deviations may also be seen with faulty postural habits such as perpetually standing with a pelvic drop on one side as frequently seen with relaxed postures. This may result in muscle imbalances in the hip and spine and an apparent leg-length discrepancy.

### Characteristic Deviations

When standing with weight equally distributed to both lower extremities, an elevated ilium on the long leg (LL) side and lowered on the short leg (SL) side typically results in the following deviations (Fig. 14.20).

- The LL side is in hip adduction with greater shear stress, and the SL side is in hip abduction with greater compression stress.
- The sacroiliac (SI) joint on the LL side is more vertical with greater shear stress; on the SL side, it is more horizontal with greater compression stress.

**FIGURE 14.20** Frontal plane asymmetries. Pictured is an individual with a long leg and elevated ilium on the right side. Typically, hip adduction, vertical sacroiliac (SI) joint, side bending toward and rotation opposite that of the lumbar spine, and compensations in thoracic and cervical spine are seen on the long-leg side.

- There is side bending of the lumbar spine toward the LL side coupled with rotation in the opposite direction.
- The vertebral side bending and rotation compresses the intervertebral disc on the LL side and distracts the disc on the SL side; it also causes torsional stress.
- There is extension and compression of the lumbar facets on the LL side (concave portion of the curve) and flexion and distraction of the lumbar facets on the SL side (convex portion of the curve).
- There is narrowing of the intervertebral foramina on the LL side.
- The thoracic and cervical spine has compensatory scoliosis in the opposite direction.

### Potential Muscle Impairments

- Mobility impairment from decreased flexibility in the hip adductors on the LL side and abductors on the SL side. There may also be asymmetrical differences in the iliopsoas, quadratus lumborum, piriformis, erector spinae, and multifidus muscles, with those on the concave side of the curve or the LL side having decreased flexibility.
- Impaired muscle performance from stretched and weakened muscles that typically includes hip adductors on the SL side, abductors on the LL side, and in general muscles on the convex side of the curve.

### Potential Sources of Symptoms

- Greater shear forces occur in the hip and SI joints on the LL side, which increases stress in the supporting ligaments and decreases the load-bearing surface in the joint. Degenerative changes occur more frequently in hips on the LL side.<sup>21</sup>

- Stenosis in the lumbar intervertebral foramina on the LL side may cause vascular congestion or nerve root irritation.
- Lumbar facet compression and irritation on the LL side leading to early degenerative changes.
- Intervertebral disc breakdown from torsional and asymmetrical forces.
- Muscle tension, fatigue, or spasm in response to asymmetrical loading and response.
- Lower extremity overuse syndromes.

**Common Causes**

Asymmetry in the lower extremities may result from structural or functional deviations at the hip, knee, ankle, or foot. Common functional problems include unilateral flat foot and imbalances in the flexibility of muscles. The resulting asymmetrical ground reaction forces transmitted to the pelvis and back may lead to tissue breakdown and overuse, particularly as a person ages, becomes overweight, or is generally deconditioned from inactivity.

## Management of Impaired Posture

Faulty posture underlies many spinal and extremity disorders and functional restrictions. Often by simply correcting the underlying postural stresses, the primary symptoms can be

minimized or even alleviated. Because of this the following guidelines may become part of most rehabilitation programs. Exercises for use with postural impairments are identified in this section and are described in detail in the respective chapters that follow.

## General Management Guidelines

Before developing a plan of care and selecting interventions for management, evaluate the findings from the examination of the patient, including the history, review of systems, and specific tests and measures, and document the findings.

- Postural alignment (sitting and standing), balance, and gait
- ROM, joint mobility, and flexibility
- Muscular strength and endurance for repetitions and holding
- Ergonomic assessment, if indicated
- Body mechanics
- Cardiopulmonary endurance/aerobic capacity, breathing pattern

Common impairments and a summary of the information that follows on management of patients with impaired posture are summarized in Box 14.1.

### BOX 14.1 MANAGEMENT GUIDELINES— Impaired Posture

**Structural and Functional Impairments**

- Pain from mechanical stress to sensitive structures and from muscle tension
- Impaired mobility from muscle, joint, or fascial restrictions
- Impaired muscle performance associated with an imbalance in muscle length and strength between antagonistic muscle groups
- Impaired muscle performance associated with poor muscular endurance
- Insufficient postural control of scapular and trunk stabilizing muscles
- Decreased cardiopulmonary endurance
- Altered kinesthetic sense of posture associated with poor neuromuscular control and prolonged faulty postural habits
- Lack of knowledge of healthy spinal control and mechanics

**Plan of Care**

**Intervention**

1. Develop awareness and control of spinal posture	1. Kinesthetic training; cervical and scapular motions, pelvic tilts, control of neutral spine. Utilize procedures to develop and reinforce control of posture when sitting, standing, walking, and performing targeted functional activities
2. Educate the patient about the relationship between faulty posture and symptoms	2. Practice positions and movements to experience control of symptoms with various postures
3. Increase mobility in restricting muscles, joints, fascia	3. Manual stretching and joint mobilization/manipulation; teach self-stretching

**BOX 14.1** MANAGEMENT GUIDELINES—  
**Impaired Posture—cont'd**

Plan of Care	Intervention
4. Develop neuromuscular control, strength, and endurance in postural and extremity muscles	4. Stabilization exercises; progress repetitions and challenge with extremity motions; progress to dynamic trunk strengthening exercises
5. Teach safe body mechanics	5. Functional exercises to prepare for safe mechanics (squatting, lunges, reaching, pushing/pulling, lifting and turning loads with stable spine)
6. Ergonomic assessment of home, work, recreational environments	6. Adapt work, home, recreational environment
7. Stress management/relaxation	7. Relaxation exercises and postural stress relief
8. Identify safe aerobic activities	8. Implement and progress an aerobic exercise program
9. Promote healthy exercise habits for self-maintenance	9. Integration of a fitness program, regular exercise, and safe body mechanics into daily life

## Awareness and Control of Spinal Posture

Initially, good spinal posture may be prevented because of restricted mobility of muscle, connective tissue, or vertebral segment, but developing patient awareness of balanced posture and its effects should begin as soon as possible in the treatment program in conjunction with stretching and muscle-training maneuvers.

### Posture Training Techniques

Isolate each body segment and train the patient to properly move that segment. If one region is out of alignment, it is likely that there are compensatory deviations in the alignment throughout the spine. Therefore, total posture correction, including upper and lower extremity alignment, should be emphasized. Direct the patient's attention to the feel of proper movement and muscle contraction and relaxation. Another technique is to have the patient assume an extreme corrected posture, then ease away from the extreme toward mid-position, and finally hold the corrected posture. Use verbal, tactile, and visual reinforcement cues such as:

- **Verbal reinforcement.** As you interact with the patient, frequently interpret the sensations of muscle contraction and spinal positions that he or she should be feeling.
- **Tactile reinforcement.** Help the patient position the head and trunk in correct alignment and touch the muscles that need to contract to move and hold the parts in place.
- **Visual reinforcement.** Use mirrors so the patient can see how he or she looks, what it takes to assume correct alignment, and then how it feels when properly aligned.

### Axial Extension (Cervical Retraction) to Decrease a Forward Head Posture

**Patient position and procedure:** Sitting or standing, with arms relaxed at the side. Lightly touch above the lip under the nose and ask the patient to lift the head up and away as if a string was pulling their head upward (Fig. 14.21 A). Verbally reinforce the correct posture and draw attention to the way it feels. Have the patient move to the extreme of the correct posture and then return to midline.

### Scapular Retraction

**Patient position and procedure:** Sitting or standing. For tactile and proprioceptive cues, gently resist movement of the inferior angle of the scapulae and ask the patient to pinch them together (retraction). Suggest that the patient imagine “holding a quarter between the shoulder blades” or imagine

**FIGURE 14.21** Training the patient to correct (A) forward-head posture and (B) protracted scapulae.

“putting their elbows in their back pockets” The patient should not extend the shoulders or elevate the scapulae (Fig. 14.21 B).

### Pelvic Tilt and Neutral Spine

**Patient position and procedure:** Sitting, then standing with the back against a wall. Teach the patient to roll the pelvis forward and backward to isolate an anterior and posterior pelvic tilt. After the patient has learned to isolate the movement, instruct him or her to practice control of the pelvis and lumbar spine by moving from extreme lordosis to extreme flat back and then assume mild lordosis. Identify the midposition as the “neutral spine” so the patient becomes familiar with the term. Show that the hand should be able to easily slip between the back and the wall and that he or she can then feel the back with one side of the hand and the wall with the other side. If the patient has difficulty tilting the pelvis, suggest that he or she imagine that the pelvis is a bushel basket with a rounded bottom and the waist is the rim of the basket. Have the patient then imagine and practice tipping the “basket” forward and backward and then finding the neutral spine position.

### Thoracic Spine

**Patient position and procedure:** Standing. The position of the thorax affects the posture of the lumbar spine and pelvis; consequently, the feel of thoracic movement is incorporated in posture training for the lumbar spine. As the patient assumes a mildly lordotic posture, have him or her breathe in and lift the rib cage (extension). Guide him or her to a balanced posture, not an extremely extended posture. Standing with the back against a wall (as in the pelvic tilt training above) encourages thoracic extension.

### Total Spinal Movement and Control

**Patient position and procedure:** Sitting or standing. Instruct the patient to curl the entire spine by first flexing the neck, then the thorax, and then the lumbar spine. Give cues for unrolling by first touching the lumbar spine as the patient extends it, then the thoracic spine as he or she extends it and takes in a breath to elevate the rib cage. Then direct attention to adducting the scapulae while you gently resist the motion and then lifting the head in axial extension while you give slight pressure against the upper lip (see Fig. 14.21). If the patient overcorrects his or her posture, have them relax slightly to a neutral spinal position. Verbally and visually reinforce the correct posture when it is obtained.

**Reinforcement techniques.** It is not possible for a person always to maintain good posture. Therefore, to reinforce proper performance, teach the patient to use cues throughout the day to check posture. For example, instruct the patient to check the posture every time he or she walks past a mirror, waits at a red traffic light while driving a car, sits down for a meal, enters a room, or begins talking with someone. Find out what daily routines the patient has that could be used for reinforcement or reminders; instruct the patient to practice and report the results. Provide positive feedback as the patient becomes actively involved in the relearning process.

**Postural support.** If necessary, provide external support with a postural splint or tape to prevent the extreme posture of round shoulders and protracted scapulae. These supports help train correct muscle functioning by acting as a reminder for the patient to assume correct posture when he or she slouches. Also, by preventing the position of stretch from occurring, stretch weakness can be corrected. These devices should be used only on a temporary basis for training so the patient does not become dependent on them.

## Posture, Movement, and Functional Relationships

Once the patient has learned how to assume correct postures, it is important to have him or her experience the effect sustained or repetitive faulty postures have on pain and function, followed by their ability to alter these affects by correcting their posture.

**Relationship of impaired posture and pain.** Have the patient assume the faulty posture and wait. When he or she begins to feel discomfort, point out the posture and then instruct how to correct it and notice the feeling of relief. Many patients do not accept such a simple relationship between stress and pain, so draw their attention to noticing what posture they are in (including when at work, home, driving/riding in a car, or in bed), when their symptoms develop, and how they can control the discomfort with the following techniques.

**Relationship of impaired posture and extremity function.** Have the patient assume their faulty posture and attempt a functional activity such as reaching upward with their upper extremity, moving their lower extremity, or opening and closing their jaw. They then assume a corrected posture, repeat the same activity, and note the difference. Once the improved range and quality of movement are experienced, reinforce them so the patient can understand the value of developing and maintaining good alignment when performing functional activities.

## Joint, Muscle, and Connective Tissue Mobility Impairments

Common muscle imbalances in length and strength were described in the previous section on impaired postures. It is critical that specific mobility restrictions are identified so that stretching techniques can be selective. For example, the transition areas between the cervicothoracic, thoracolumbar, and lumbosacral regions typically have greater mobility. When faulty postural habits dominate, the segmental mobility in these areas tends to become exaggerated in the direction of the faulty posture. Stretching should proceed cautiously so as not to accentuate the problem while attempting to correct the tissues with decreased mobility. Stretching techniques for the cervical, thoracic, and lumbar regions are described in Chapter 16. Specific spinal mobilization/manipulation techniques directed at specific hypomobile segments are described in Chapters 15 and 16. Although any structure could be involved, particularly

following an injury or pathological condition, the muscle flexibility impairments most typically seen are identified in Box 14.2. Included are references for self-stretching/flexibility exercises for each muscle group. Specific instructions and precautions are described in the text accompanying the pictures in the respective chapters.

## Impaired Muscle Performance

Typically impaired postural muscles that support the body in sustained postures succumb to the effects of gravity, become less active,<sup>61</sup> and develop stretch weakness.<sup>46</sup> Strengthening alone does not correct this problem, so any exercises must be

done in conjunction with posture training for control, as described earlier in this section. In addition, exercises for muscular endurance are necessary to prepare the muscles to function over an extended period of time. Finally, environmental adaptations must be made to minimize the stresses of sustained and repetitive postures. Muscles that typically demonstrate stretch weakness or poor postural endurance are identified in Box 14.3. In-depth descriptions of the exercises are in the chapters identified.

## Body Mechanics

Muscle strengthening for safe body mechanics includes not only strengthening specific muscles, but also functional activities that prepare the body for specific stresses that it is required to do for a particular function, as identified in Box 14.4. Instruction in body mechanics is described in detail in Chapter 16 in the section “Functional Training.”

## Ergonomics: Relief and Prevention

It is critical to help the patient adapt postures and activities that are performed on a sustained or repetitive basis at work, at home, recreationally, or socially if they are contributing to

### BOX 14.2 Self-Stretching Techniques for Common Mobility Impairments

- *Suboccipital region*: self-stretch with capital nodding; apply a gentle self-stretch against the occiput with the lateral border of the hand
- *Levator scapulae*: self-stretch with scapular depression and cervical flexion and rotation to the opposite side (see Fig. 17.35 in Chapter 17)
- *Scalenes*: self-stretch with axial extension, side bend neck opposite and then rotate neck toward side of restriction (see position Fig. 16.3 in Chapter 16)
- *Pectoralis major and anterior thorax*: self-stretch with corner stretches (see Fig. 17.31 in Chapter 17) or while lying supine on a foam roll placed longitudinally under the spine (see Fig. 16.1 B in Chapter 16)
- *Latissimus dorsi*: self-stretch lying supine on a foam roll, reach arms overhead (see Fig. 16.1 A in Chapter 16)
- *Lumbar and hip extensors*: self-stretch lying supine, bring knees to chest; or quadruped position, move buttocks back over the feet (see Figs. 16.13 and 16.14 in Chapter 16)
- *Lumbar flexors*: self-stretch with prone press-ups or standing back bends (see Fig. 16.15 in Chapter 16)
- *Hip flexors*: self-stretch lying supine in Thomas position or standing in modified fencer’s squat (see Figs. 20.10 and 20.11 in Chapter 20)
- *Tensor fascia lata*: self-stretch either supine, side-lying, or standing; extend, laterally rotate, then adduct the hip (see Figs. 20.19, 20.20, and 20.21 in Chapter 20)
- *Iliotibial band foam roll stretch*: side-lying on a foam roll placed perpendicular to the thigh, gently roll the thigh back and forth with body weight applying the stretch force (see Fig. 21.22 in Chapter 21)
- *Piriformis*: self-stretch lying supine or sitting and bringing the flexed knee toward the opposite shoulder. Flex, adduct, and internally rotate the hip (see Fig. 20.15 in Chapter 20)
- *Hamstrings*: self-stretch with a straight-leg maneuver either lying supine or long-sitting (see Figs. 20.17 and 20.18 in Chapter 20)
- *Gastrocsoleus (heel cords)*: self-stretch in a forward stride position with the heel of the back leg maintained on the floor, or stand on an incline board or edge of a step (see Fig. 22.9 in Chapter 22)

### BOX 14.3 Training and Strengthening Techniques for Common Muscle Impairments

- Activate and learn control of the longus colli and deep capital flexors (see Figs. 16.39 B and 16.59 in Chapter 16)
- Lower cervical extension (see Fig. 16.40 in Chapter 16)
- Scapular retraction and shoulder lateral rotation (see Fig. 16.45 in Chapter 16 and Figs. 17.46 and 17.47 in Chapter 17)
- Lumbar spinal stabilization (see Figs. 16.47 through 16.56 plus accompanying text in Chapter 16)
- Hip abduction; posterior gluteus medius; begin side-lying, progress to standing. Place emphasis on maintaining the hip in extension with slight lateral rotation while abducting (see Fig. 20.26 B in Chapter 20)

### BOX 14.4 Functional Exercises in Preparation for Safe Body Mechanics

- Upper extremity pulling and pushing (see Fig. 17.58 in Chapter 17)
- Wall slides—progress to squatting and squatting with lifting (see Fig. 20.29 in Chapter 20)
- Lunges—progress to lunges with lifting and with pushing and pulling (see Fig. 20.32 in Chapter 20 and Figs. 23.31 and Fig. 23.36 in Chapter 23)

the postural stresses and musculoskeletal disorders.<sup>60</sup> It may be necessary to use a lumbar pillow for support or to modify the work environment (workstation) to relieve sustained stressful postures. There are many resources, such as the Occupational Safety and Health Administration website (<http://www.osha.gov/SLTC/ergonomics/>) and others (<http://ergo.human.cornell.edu/>) that provide information on ergonomic assessment and adaptation to work environments to relieve postural stress and musculoskeletal disorders. Principles of ergonomic interventions are listed in Box 14.5.

### FOCUS ON EVIDENCE

There is strong evidence, documented in a 3-year prospective study of 632 newly hired computer users, that a computer workstation may be the source of symptoms if the chair, desk, keyboard, mouse, and monitor are improperly positioned for the individual.<sup>25,51</sup> There is also mixed evidence, summarized in a systematic study of the literature on the relationship of posture and repetitive stresses in the work environment, regarding the development of low back pain.<sup>77</sup> In a 3-year follow-up study that involved 12,550 workers, it was determined that prolonged standing, awkward lifting, and squatting/kneeling were the top mechanical factors related to job related low back pain.<sup>72</sup>

## Stress Management/Relaxation

A component of the educational process is to teach the individual how to relax tense muscles and relieve postural stress. Muscle relaxation techniques can be incorporated throughout the day to relieve postural stress, and conscious relaxation training increases patient awareness and control over tension in the muscles.

**PRECAUTION:** These techniques are not appropriate for managing acute pain due to inflammation, joint swelling, or

### BOX 14.5 Basic Principles of Ergonomic Interventions

- Set up work station to keep everything within easy reach and at the proper height so that joints function in neutral positions and neutral postures can be maintained
- Minimize excessive repetitive motions
- Reduce excessive forces
- Minimize need to maintain a static hold on objects or maintain a static posture leading to fatigue
- Minimize pressure points
- Maintain adequate clearance around work station for safe movement
- Move head, spine, and extremities through their ROM frequently
- Use adequate lighting

disc derangements. If the patient is recovering from a pathologic condition in the spine, caution him or her that these techniques should not increase symptoms (other than a stretching sensation in chronic conditions), especially radicular symptoms. Caution should also be used with flexion in patients with a medical diagnosis of herniated disc so that symptoms should not peripheralize.

## Muscle Relaxation Techniques

Whenever discomfort develops from maintaining a constant posture or from sustaining muscle contractions for a period of time, active ROM in the opposite direction aids in taking stress off supporting structures, promoting circulation, and maintaining flexibility. All motions are performed slowly, through the full range, with the patient paying particular attention to the feel of the muscles. Repeat each motion several times. Suggest to the patient that these are mini rest breaks or micro breaks to be done at work, home, or whenever tension, stress, or postural pain is experienced.

### Cervical and Upper Thoracic Region

**Patient position and procedure:** Sitting with the arms resting comfortably on the lap, or standing. Instruct the patient to:

- Bend the neck forward and backward. (Backward bending is contraindicated with symptoms of nerve root compression—if numbness or pain radiates down the arm, examine to identify cause; see Chapter 15 for interventions to treat nerve root compression.)
- Side bend the head in each direction; then rotate the head in each direction.
- Roll the shoulders; protract, elevate, retract, and then relax the scapulae (in a position of good posture).
- Circle the arms (shoulder circumduction). This is accomplished with the elbows flexed or extended, using either small or large circular motions with the arms pointing either forward or out to the side. Both clockwise and counterclockwise motions should be performed, but conclude the circumduction by going forward, up, around, and then back so the scapulae end up in a retracted position. This has the benefit of helping retrain proper posture.

### Lower Thoracic and Lumbar Region

**Patient position and procedure:** Sitting or standing. If standing, the feet should be shoulder-width apart with the knees slightly bent. Have the patient place the hands at the waist with the fingers pointing backward. Instruct the patient to:

- Extend the lumbar spine by leaning the trunk backward (see Fig. 16.15 B). This is particularly beneficial when the person must sit or stand in a forward-bent position for prolonged periods.
- Flex the lumbar spine by contracting the abdominal muscles, causing a posterior pelvic tilt; or bend the trunk forward while sitting, dangling the arms toward the floor. This motion is beneficial when the person stands in a lordotic or swayback posture for prolonged periods.
- Side bend in each direction.

- Rotate the trunk by turning in each direction while keeping the pelvis facing forward.
- Stand up and walk around at frequent intervals when sitting for extended periods.

### Conscious Relaxation Training for the Cervical Region

Specific techniques in guided imagery for the cervical region develop the patient's kinesthetic awareness of a tensed or relaxed muscle and how consciously to reduce tension in the muscle. In addition, if done with posture training techniques in mind, as described earlier in the chapter, the patient can be helped to recognize decreased muscular tension when the head is properly balanced and the cervical spine is aligned in midposition.

**Patient position and procedure:** Sitting comfortably with arms relaxed, such as resting on a pillow placed on the lap; the eyes are closed. Position yourself next to the patient to use tactile cues on the muscles and help position the head as necessary. Have the patient perform the following activities in sequence.

- Use diaphragmatic breathing and breathe in slowly and deeply through the nose, allowing the abdomen to relax and expand; then relax and allow the air to be expired through the relaxed open mouth. This breathing is reinforced after each of the following activities.
- Next, relax the jaw. The tongue rests gently on the hard palate behind the front teeth with the jaw slightly open. If the patient has trouble relaxing the jaw, have him or her click the tongue and allow the jaw to drop. Practice until the patient feels the jaw relax and the tongue rests behind the front teeth. Follow with relaxed breathing.
- Slowly flex the neck. As the patient does so, direct the attention to the posterior cervical muscles and the sensation of how the muscles feel. Use verbal cues such as, "Notice the feeling of increased tension in your muscles as your head drops forward."
- Then slowly raise the head to neutral, inhale slowly, and relax. Help the patient position the head properly and suggest that he or she note how the muscles contract to lift the head, and then relax once the head is balanced.
- Repeat the motion; again, direct the patient's attention to the feeling of contraction and relaxation in the muscles as

he or she moves. Imagery can be used with the breathing such as "fill your head with air and feel it lift off your shoulders as you breathe in and relax."

- Then go through only part of the range, noting how the muscles feel.
- Next, just think of letting the head drop forward and then tightening the muscles (setting); then think of bringing the head back and relaxing. Reinforce to the patient the ability to influence the feeling of contraction and relaxation in the muscles.
- Finally, just think of tensing the muscles and relaxing, letting the tension go out of the muscles even more. Point out that he or she feels even greater relaxation. Once the patient learns to perceive tension in muscles, he or she can then consciously think of relaxing the muscles. Emphasize the fact that the position of the head also influences muscle tension. Have the patient assume various head postures and then correct them until the feeling is reinforced.

### Modalities and Massage

Once acute symptoms are under control, the use of modalities and massage are minimized or decreased so the patient learns self-management through exercises, relaxation, and posture retraining and does not become dependent on external applications of interventions for comfort.

### Healthy Exercise Habits

It is important to integrate a progression of postural control into all exercises, aerobic conditioning, and functional activities (see Chapter 16). The patient is carefully observed as greater challenges to activities are performed, and, if necessary, reminders are provided to find the neutral spinal position and to initiate contraction of the stabilizing muscles prior to the activity. For example, when reaching overhead, the patient learns to contract the abdominal muscles to maintain a neutral spine position and not allow the spine to extend into a painful or unstable range. This is incorporated into body mechanics, such as when going from picking up and lifting to placing an object on a high shelf, or into sport activities when reaching up to block or throw a ball. Once developed under your guidance, encourage the patient to continue with a healthy lifestyle, fitness level, and body mechanics.

## Independent Learning Activities

### Critical Thinking and Discussion

1. What are the functional differences between the way the cervical spine and lumbar spine are used in daily activities?
2. Explain how faulty posture can cause painful symptoms.
3. Explain why a "one-size-fits-all" exercise program for posture correction cannot benefit everyone, or how it may be detrimental to some individuals. Discuss this in relation to each of the faulty postures described in this chapter.

## Laboratory Practice

1. Practice identifying the effects various postures have on the various regions of the spine—that is, what happens to the cervical and lumbar spine when in supine, prone, side-lying, sitting, and standing postures; does the spine tend to move into flexion or extension? Determine what is needed to change the position; that is, if flexion is emphasized in a particular posture, what is needed to move the spine into a more neutral (midrange) position?
2. Identify and feel what happens to the various portions of the spine when moving from one position to another (i.e., rolling supine to prone and return, moving from supine to sit, sit to stand and reverse). What happens to the lumbar spine and pelvis when walking; how is this affected if the person has a hip-flexion contracture or a contracture in the external rotators of the hip?
3. Examine the standing posture of a classmate; then examine the joint ROM, muscle flexibility, and muscle strength. Identify any muscle imbalances in length and strength; then design an intervention program to influence change in the impairments. Use the guidelines presented in this chapter and summarized in Box 14.1 as well as Chapters 16 through 22 for suggested exercises and their safe application.
4. Identify and compare the similarities and differences in flexibility and muscle weakness between a person with excessive lumbar lordosis and an anterior pelvic tilt and a person with a slouched posture who stands with the pelvis shifted forward and the thorax flexed. What effect does each pelvic posture have on the hip position, and what muscles would develop restricted mobility? Usually in the slouched posture the thorax and upper lumbar spine are flexed; would the curl-up exercise be beneficial, or would it contribute to this problem? Develop an exercise program that addresses the common flexibility and strength impairments without reinforcing the faulty posture.

## Case Studies

### Case 1

Your patient is a 35-year-old computer programmer who is referred to you because of pain symptoms in the right cervical, posterior shoulder, and arm regions. The symptoms get progressively worse when at work; usually the pain begins within 1 hour, and it is 6/10 by lunchtime. The same cycle occurs in the

afternoon. There is occasional “tingling” in the thumb and index finger. The symptoms have progressively worsened over the last 3 months, ever since being placed in a priority job. Recreational activities include tennis and reading; the tennis does not cause symptoms, but reading makes the neck pain worse.

Examination reveals forward head and round shoulder posture. Capital flexion 50% range, cervical rotation and side bending are each 80% range, shoulder external rotation is 75°. There is restricted flexibility in the pectoralis major, pectoralis minor, levator scapulae, and scalene muscles. Cervical quadrant test reproduces the tingling in the right hand; all other neurological tests are negative. Strength of the suprahyoid and infrahyoid muscles, scapular retractors, and shoulder lateral rotators is 4/5.

- What is provoking the patient’s symptoms and signs? What are the functional limitations? What is the prognosis?
- Identify impairment and functional outcome goals.
- Establish a program of intervention. How can you progress this person to functional independence?

### Case 2

A 51-year-old auto mechanic is referred to physical therapy because of pain symptoms in the left buttock and posterior thigh. The symptoms are worse when standing and reaching overhead for more than 15 minutes, which is what he does when working on a car that is up on the racks. Carrying heavy objects (> 50 lb), standing, and walking for more than a half-hour increase the symptoms. There is no precipitating incident, but the symptoms have been recurrent over the past year. Symptoms also increase with the recreational activity of backpacking. Symptoms ease when in the rocker recliner, lying on a couch with knees bent, or when hugging knees to chest.

Examination reveals swayback posture when standing; decreased flexibility in the low back, gluteus maximus, hamstrings (straight leg raising to 60°), and upper abdominals; and increased pain with backward bending. Strength of the lower abdominals is 3/5. He is able to do repetitive lunges and partial squats for a maximum of 20 seconds.

- What is provoking the patient’s symptoms and signs? What are the functional limitations? What is the prognosis?
- Identify impairment and functional outcome goals.
- Establish a program of intervention. Use the taxonomy of motor tasks discussed in Chapter 1 (see Figs. 1.6 and 1.7 and accompanying text) to develop a progression of exercises and tasks to progress this person to functional independence.

### Independent Learning Activities 483

In theory, treating impairments and activity limitations related to the tissues of the spinal column and trunk is the same as treating tissue injuries of the extremities. The major complicating factor in the spine is the close proximity of key structures to the spinal cord and nerve roots. The challenge for the therapist is to recognize the complex functional relationships of the facet joints, the intervertebral joints, the muscles, the fascia, and the nervous system and know how to examine and evaluate the individual who presents with pain and activity limitations. Activity, rather than prolonged bed rest, has long been accepted as important in the management of patients with spinal and postural pain<sup>2,242</sup> but defining what are beneficial and safe activities during the process of healing and rehabilitation is the task of the therapist.

The medical model of diagnosis does not lend itself to direct therapeutic exercise intervention strategies, particularly because patients' complaints of back or neck pain often do not relate to specific pathologies. Efforts are being made to determine the most effective way to categorize patients with symptoms affecting spine and trunk function in order to be more accurate with outcome research.<sup>37,49,73,158,159,204,214</sup> In addition, results from research studies have provided some criteria for predicting outcomes in subgroups of patients with back and neck pain so therapists can better identify the interventions that are more likely to result in positive outcomes.<sup>9,14,38,42,103,145,198,200,233,249</sup> The approach described in this text supports the importance of treatment based on the presenting structural and functional impairments that result in activity limitations while respecting the pathomechanics, pathophysiology, and precautions of specific medical diagnoses.

The content of this chapter has three major emphases. The first section reviews the pathology and pathomechanics of spinal structures. The focus of the second section is on principles and guidelines for managing patients with impaired function in the spine. This section includes principles of interventions for the broad categories of acute, subacute, and chronic spinal conditions and also expands on specific interventions for impairment-based diagnostic categories and their relationship to the Clinical Practice Guidelines.<sup>37,48</sup> Techniques geared toward treating specific impairments are described in these sections.

The third major section contains medical diagnoses unique to the thoraco-lumbopelvic and upper thoraco-cranio-cervical regions. Because the function of the temporomandibular joint (TMJ) is closely related to the cervical spine, physical therapy management guidelines for impairments related to the TMJ conclude the chapter.

General therapeutic exercise techniques of intervention for all spinal and postural impairments are described in Chapter 16. Chapters 14, 15, and 16 are written with the assumption that the reader has completed or is concurrently taking a course in examination and evaluation of the spine and posture.

## Spinal Pathologies and Impaired Spinal Function

### Pathology of the Intervertebral Disc

Normal structure and function of the intervertebral (IV) disc are described in Chapter 14. Trauma, as well as normal aging, can lead to degeneration of the disc and affect the mechanics of the entire spine.<sup>91,195</sup>

### Injury and Degeneration of the Disc

Various authors have defined the terms herniation, protrusion, and extrusion differently.<sup>23,65,148,158,213</sup> The following definitions are used in this text (Fig. 15.1):

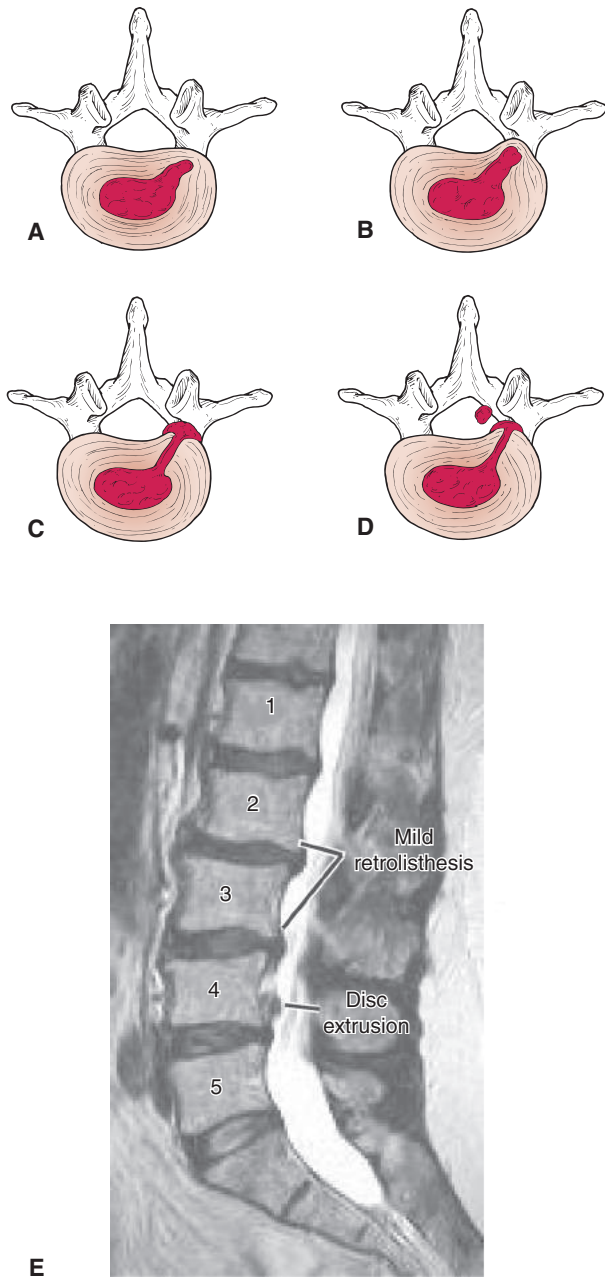

- **Herniation:** displacement of disc material beyond the normal limits of the IV disc space. It may include the nucleus pulposus, cartilage, fragmented apophyseal bone, or annulus fibrosus. Herniated discs are further described as *protrusions* or *extrusions*, based on the shape of material outside the disc space.<sup>88</sup>
- **Protrusion:** the displaced disc material is continuous with the material within the disc. This is also described as the nuclear material being contained by the outer layers of the annulus and supporting ligamentous structures.
- **Extrusion:** extension of nuclear material beyond the confines of the posterior longitudinal ligament or above and below the disc space, as detected on magnetic resonance imaging (MRI),<sup>213</sup> but may still be in contact with the disc,<sup>158</sup> or may be completely sequestered.<sup>65</sup>
- **Sequestration:** the extruded disc material is no longer contained by the outer annulus and has separated and moved away from the IV disc.<sup>65,158</sup>

### Fatigue Breakdown and Traumatic Rupture

A decrease in the continuity and integrity of structure of the annulus fibrosus may be a consequence of the normal aging process resulting in annular fissures or may be caused by fatigue breakdown or traumatic rupture

**Fatigue breakdown.** Over time, the annulus breaks down as a result of repeated overloading of the spine in flexion with asymmetrical forward bending and torsional stresses.<sup>3,4,66</sup>

- With torsional stresses, the annulus becomes distorted, most obviously at the posterolateral corner opposite the direction of rotation. The layers of the outer annulus fibrosus lose their cohesion and begin to separate from each other. Each layer then acts as a separate barrier to the nuclear material. Eventually, radial tears occur, and there is communication of the nuclear material between the layers.<sup>66</sup>
- With repeated forward bending and lifting or prolonged postural stresses, the layers of the annulus are strained.

**FIGURE 15.1** Disc breakdown, showing (A) breakdown and compression of fibrous layers of the annulus and displacement of disc material; (B) radial fissures with nuclear material bulging against the outer annulus; (C) extrusion of nuclear material through the outer annulus but still in contact with the disc; (D) sequestration of nuclear material beyond the annulus; and (E) MRI scan of a 61-year-old patient with low back pain and symptoms radiating into the leg. The scan demonstrates moderate multilevel degenerative disc disease of T12–L1 through L4–5 with mild retrolisthesis of L2 on L3 and L3 on L4. At the L4–5 level, note a small diffuse disc herniation with large paracentral disc extrusion dissecting cranially.

They become tightly packed together in the posterolateral corners, radial fissures develop, and the nuclear material migrates down the fissures.<sup>3,4</sup> Outer layers of annular fibers can contain the nuclear material so long as they remain a continuous layer.<sup>3</sup> After injury, there is a tendency for the

nucleus to swell and distort the annulus. Distortion is more severe in the region in which the annular fibers are stretched.<sup>4</sup> If the outer layers rupture, nuclear material may herniate through the fissures.

- Healing is attempted, but there is poor circulation in the disc.<sup>17</sup> There may be self-sealing of a defect with nuclear gel or proliferation of cells of the annulus. Any fibrous repair is weaker than normal and takes a long time because of the relative avascular status of the disc.

**Traumatic rupture.** Rupture of the annulus can occur as a one-time event, or it can be superimposed on a disc where there has been gradual breakdown of the annular rings. This is seen most commonly in traumatic hyperflexion injuries.<sup>4</sup>

### Axial Overload

Axial overload (compression) of the spine usually results in end-plate damage or vertebral body fracture before there is any damage to the annulus fibrosus.<sup>25</sup> Scheuermann's disease occurs when the nucleus migrates either superior or inferior through a cracked end-plate. When there is a compression fracture, flexion and axial loading usually causes increased pain. Pain may occur without nerve root involvement, although there may be referred pain in the extremities. Scheuermann's disease and compression fracture are discussed in the third section of this chapter.

### Age

Individuals are most susceptible to symptomatic disc injuries between the ages of 30 and 45 years. During this time the nucleus is still capable of imbibing water, but the annulus weakens owing to fatigue loading over time and therefore is less able to withstand increased pressures when there are disproportionately high or repetitive stresses. The nuclear material may protrude into the tears or fissures, which most commonly are posterolateral and, with increased pressures, may bulge against the outer annular fibers, causing annular distortion. The nuclear material may also extrude from the disc through complete fissures in the annulus.<sup>3,17,66,148</sup>

### Degenerative Changes

Any loss of integrity of the disc from infection, disease, herniation, or an end-plate defect becomes a stimulus for degenerative changes in the disc.<sup>17</sup> A strong genetic component has been linked to disc degeneration, whereas smoking and a history of heavy lifting appear to have little effect on this disease process.<sup>16</sup> Battie<sup>16</sup> identified people who were diagnosed with a disc injury prior to turning age 21 and found they were four to five times more likely to have a significant family history of IV disc pathologies.

- Degeneration is characterized by progressive fibrous changes in the nucleus, loss of the organization of the rings of the annulus fibrosus, and loss of cartilaginous end-plates.<sup>14</sup>
- As the nucleus becomes more fibrotic, it loses its capacity to imbibe fluid. Water content decreases, and there is an

associated decrease in the size of the nucleus. Acute disc protrusions caused by a bulging nucleus pulposus against the annulus or extrusions of the nucleus through a torn annulus are rare in older people.

- It is possible to have protrusions of the annulus fibrosus without bulging from nuclear pressure. Myxomatous degeneration with annular protrusion has been demonstrated in disc lesions in older people.<sup>248</sup>

### Effect on Spinal Mechanics

Injury or degeneration of the disc affects spinal mechanics in general.<sup>187</sup> During the early stages, there is increased mobility of the segment with greater than normal flexion/extension and forward and backward translation of the vertebral body, leading to segmental instability. Force distribution through the entire segment is altered, causing abnormal forces in the facets and supporting structures.<sup>31,66</sup>

## Disc Pathologies and Related Conditions

Disc herniation, tissue fluid stasis, discogenic pain, and swelling from inflammation are conditions that may result from prolonged flexion postures, repetitive flexion micro-trauma, or traumatic flexion injuries. Initially, symptoms may be exacerbated when attempting extension but then may be decreased when using carefully controlled extension motions. Several studies have documented that patients with a herniated nucleus pulposus (HNP) who have symptom reduction with an extension approach to treatment respond favorably to conservative nonsurgical treatment.<sup>9,26,48,133,201,220</sup>

### Tissue Fluid Stasis

During sustained end-range flexed postures in the spine, the discs, facet joints, and ligaments are placed under sustained loading.<sup>23</sup> The intradiscal pressure increases, and there is compression loading on the cartilage of the facets and a distractive tension on the posterior longitudinal ligament and posterior fibers of the annulus fibrosus. Ligamentous creep and fluid transfer occur. Sudden movement into extension does not allow for redistribution of the fluids and so increases the vulnerability of the distended tissue to injury and inflammation.<sup>234</sup> Symptoms may be similar to those described for disc lesions because they lessen with repeated extension motions and respond to treatment described in the management section (under Extension Bias) later in the chapter.

## Signs and Symptoms of Disc Lesions and Fluid Stasis

### Etiology of Symptoms

The disc is innervated by the mixed spinal nerve and the gray ramus communicans. Since only the outer one-third of the

annulus has nerve innervation,<sup>189</sup> not all disc protrusions are symptomatic.

**Pain.** Symptoms of pain arise from pressure of a swollen disc or swollen tissues against pain-sensitive structures (ligaments, dura mater, blood vessels around nerve roots) or from the chemical irritants of inflammation if there is herniated disc material.<sup>17,197</sup>

**Neurological signs and symptoms.** Neurological signs arise from pressure against the spinal cord or nerve roots. The only true neurological signs and symptoms are specific myotome weaknesses and specific dermatome sensory changes. Radiating pain in a dermatomal pattern, increased myoelectric activity in the hamstrings, decreased straight-leg raising, and depressed deep tendon reflexes can also be associated with referred pain stimuli from spinal muscles, interspinous ligaments, the disc, and facet joints and therefore are not true signs of nerve root pressure.<sup>126,164</sup>

**Variability of symptoms.** Symptoms are variable depending on the degree and direction of the protrusion as well as the spinal level of the lesion.

- Posterior or posterolateral protrusions are most common. With a small posterior or posterolateral lesion, there may be pressure against the posterior longitudinal ligament or against the dura mater or its extensions around the nerve roots. The patient may describe a severe midline backache or pain spreading across the back into the buttock and thigh.
- A large posterior protrusion may cause spinal cord signs such as loss of bladder control and saddle anesthesia. If a large protrusion is untreated or undiagnosed in the cervical region, it may lead to cervical myelopathy.
- A large posterolateral protrusion may cause partial cord or nerve root signs.
- An anterior protrusion may cause pressure against the anterior longitudinal ligament, resulting in back pain. There are no neurological signs.
- The most common levels of protrusion are the segments between the fourth and fifth lumbar vertebrae and between the fifth lumbar vertebra and sacrum,<sup>149,190,191,217</sup> although a protrusion may occur at any level, including the cervical spine. Disc herniations in the thoracic spine are extremely rare (only 1 in 1,000<sup>190,191</sup>) due in part to the small disc to vertebrae ratio and the stable osseous anatomy of the thoracic region. They are most common at T11 and T12 because of the increased mobility in this area. A herniation in the thoracic region is much more severe than a herniation in the lumbar spine because if the disc herniates directly posterior, this will place the person at risk for spinal cord compression.

**Shifting symptoms.** Symptoms from a disc lesion may shift if there is integrity of the annular wall because the hydrostatic mechanism is still intact.<sup>158,159</sup>

**Inflammation.** Contents of the nucleus pulposus in the neural canal may cause an inflammatory reaction and irritate the dural sac, its nerve root sleeves, or the nerve roots. The symptoms may persist for extended periods and are not responsive to purely mechanical changes. The back pain may be worse than leg pain on the straight-leg raising test. Poor resolution of this inflammatory stimulus may lead to fibrotic reactions, nerve mobility impairments, and chronic pain.<sup>155,209,212</sup> Early medical intervention with anti-inflammatory agents is usually necessary.<sup>209</sup> However, patients with large sequestration fragments have better success with surgery.<sup>127,226</sup>

### Onset and Behavior of Symptoms From Disc Lesions

**Onset.** Onset is usually between 20 and 55 years of age but most frequently from the mid-30s to 40s. Except in cases of trauma, symptomatic onset in the lumbar spine is usually associated simply with bending, bending and lifting, or attempting to stand up after having been in a prolonged recumbent, sitting, or forward-bent posture. The person may or may not have the sensation of something tearing.<sup>159</sup> Although cervical disc lesions are not as prevalent, a prolonged flexed spinal position as in a forward head posture may lead to or exacerbate symptoms from a protrusion. Many patients have a predisposing history of a faulty flexion posture.

**Pain behavior.** Pain may increase gradually when the person is inactive, such as when sitting or after a night's rest. The patient often describes increased pain when attempting to get out of bed in the morning or when first standing up. Symptoms are usually aggravated with activities that increase the intradiscal pressure, such as sitting, forward bending, coughing, straining, or when attempting to stand after being in a flexed position. Usually, symptoms are lessened when walking except when the bulge is large or the nuclear material has prolapsed and moved beyond the confines of the annulus.<sup>159</sup>

**Acute pain.** When there is inflammation during the acute phase, pain is almost always present but varies in intensity, depending on the person's position or activity.

When there is a lumbar disc lesion, initially discomfort is noticed in the lumbosacral or buttock region. Some patients experience aching that extends into the thigh or leg. In the cervical spine, initially pain is noticed in the midscapular and shoulder area. Numbness or muscle weakness (neurological signs) is not noted unless the protrusion has progressed to a degree to which there is nerve root, spinal cord, or cauda equina compression.

### Objective Clinical Findings in the Lumbar Spine

**NOTE:** The following information relates to a contained posterior or posterolateral nuclear protrusion in the lumbar spine.<sup>159</sup> The impairments are summarized in Box 15.1.

- The patient usually prefers standing and walking to sitting.

#### BOX 15.1 Summary of Common Impairments Related to Disc Protrusions in the Lumbar Spine

- Pain, muscle-guarding
  - Flexed posture and deviation away from (usually) the symptomatic side
  - Neurological symptoms in dermatome and possibly myotome of affected nerve roots
  - Increased symptoms (peripheralization) with sitting, prolonged flexed postures, transition from sit to stand, coughing, straining
  - Limited nerve mobility, such as straight-leg raising (usually between 30° and 60°)
  - Peripheralization of symptoms with repeated forward-bending (spinal flexion) tests
- The patient may have a decrease in or loss of lumbar lordosis and may have some lateral shifting of the spinal column.
  - Forward bending is limited. When repeating the forward-bending test, the symptoms increase or peripheralize. *Peripheralization* means the symptoms are experienced farther down the leg (Fig. 15.2).
  - Backward bending is limited; when repeating the backward-bending test, the pain lessens or centralizes.<sup>140,146,250</sup> *Centralization* means that the symptoms recede up the leg or become localized to the back. If the protrusion cannot be mechanically reduced, backward bending peripheralizes or increases the symptoms.
  - If there is a *lateral shift* of the spinal column, backward bending increases the pain. If the lateral shift is first corrected, repeated backward bending lessens or centralizes the pain (see Figs. 15.6 and 15.7 in the management section of this chapter).
  - Testing passive lumbar flexion in the supine position (double knees-to-chest) and passive extension in the prone position (press-ups) usually produces signs similar to those of the standing tests, but results may not be as dramatic because gravity is eliminated.
  - Pain between 30° and 60° of straight-leg raising is considered positive for interference of dural mobility but not pathognomonic for a disc protrusion.<sup>235</sup>
  - Contained nuclear protrusion can be influenced by movement because the hydrostatic mechanism is still intact. A complete tear of the outer layers of the annulus disrupts the hydrostatic mechanism, so the herniated or prolapsed nuclear material cannot be influenced by movement.<sup>158</sup> Anti-inflammatory intervention by a physician is important during the acute phase. Patients with disc extrusions may respond to conservative measures owing to resolution of the inflammation and resorption of the disc material.<sup>213</sup>

**FIGURE 15.2** Examples of peripheralization and centralization of lower-quarter symptoms. Viewing the images left to right illustrates peripheralization of symptoms; from right to left illustrates centralization.

### Objective Clinical Findings in the Cervical Spine

- Findings are similar to those in the lumbar spine except they are displayed in the respective dermatomes and myotomes of the cervical nerve roots.
- Initially, the patient may present with a faulty forward head posture and may hold the head in a guarded side-bent or rotated position away from the symptomatic side.
- Cervical flexion peripheralizes the symptoms; neck retractions (axial extension) followed by extension may centralize the symptoms of a contained nuclear bulge.
- There may be nerve mobility impairments in the upper extremity.
- Manual distraction may relieve or centralize the symptoms.
- In severe cases, the patient may present with bilateral symptoms or cervical myelopathy characterized by gait abnormalities, upper motor neuron lesions, and/or leg weakness and paresthesia due to pressure on or irritation of the spinal cord.

## Pathomechanical Relationships of the Intervertebral Disc and Facet Joints

The disc and facets make up a three-joint complex between two adjoining vertebrae and are biomechanically interrelated. An asymmetrical disc injury affects the kinematics of the entire unit plus the joints above and below, resulting in

asymmetrical movements of the facets, abnormal stresses, and eventually cartilage degeneration.<sup>188</sup>

### Disc Degeneration

As the disc degenerates, there is a decrease in both water content and disc height. The vertebral bodies approximate, and the IV foramina and spinal canal narrow.<sup>31</sup> This is called degenerative disc disease.

### Initial Changes

Initially, there is increased slack with increased mobility and translation in the spinal segment. Opposition of the facet surfaces changes and the capsules are strained, resulting in irritation, swelling, and muscle spasm.

### Altered Muscle Control

Altered joint receptor function negatively affects muscle recruitment in swollen joints.<sup>212</sup> Pain has also been cited as a factor for altered and diminished recruitment patterns in the stabilizing muscles of the spine.<sup>108,109,112</sup> Increasing shear forces from poor midrange stabilization places increased stresses on the osteoligamentous support structures, which is thought to contribute to segmental hypermobility or instability.<sup>72</sup>

### Progressive Bony Changes

Eventually, with the repeated irritation due to the faulty mechanics, there are progressive bony changes in the facet and vertebral body margins. This is known as spondylosis, osteoarthritis (OA), or degenerative joint disease (DJD). Osteophyte formation along the facets and spondylitic lipping and spurring along the vertebral bodies occur, and hypomobility

develops.<sup>165</sup> These changes lead to additional narrowing of the associated foramina and spinal canal. In the cervical spine, the uncovertebral joints thicken, roughen, and distort.<sup>207</sup>

## Related Pathologies

### Segmental (Clinical) Instability

Segmental instability has been described as poor control in the neutral zones within the physiological range of spinal movement because of a decrease in the capacity of the neuromuscular stabilizing system to control the movement.<sup>72,188</sup> Clinically, patients demonstrate difficulty moving in the midranges of spinal motion and may demonstrate shifting or fluctuation in movement (see the section on pathomechanics of spinal instability in this chapter).

### Stenosis

Stenosis is narrowing of a passage or opening. In the spine, stenosis is any compromise of the space in the spinal canal (central stenosis), nerve root canal, or foramen (lateral stenosis); it can be congenital or acquired and can occur at any age. The narrowing may be caused by soft tissue structures, such as a disc protrusion, fibrotic scars, or joint swelling; by bony narrowing as with spondylitic osteophyte formation or spondylolisthesis; or by faulty posture. With progression, neurological symptoms develop. Extension exacerbates the symptoms.<sup>175</sup>

### FOCUS ON EVIDENCE

The report of a study in which patients with four or more of the following variables identified a specificity of 0.98 for central stenosis: bilateral LE symptoms, leg pain that is worse than back pain, pain during walking and/or standing, pain relief with sitting, and more than 48 years old.<sup>44</sup>

### Neurological Symptoms: Radiculopathy

Spinal nerve root or spinal cord symptoms may occur:

- When protrusion of the disc compresses against the cord or nerve roots.
- When there is decreased disc height due to degenerative changes<sup>196</sup> or excessive translation of the vertebra from shear forces resulting in decreased foraminal space. The nerve root becomes impinged between the tip of the superior articulating facet and the pedicle.
- When there is an inflammatory response due to trauma, degeneration, or disease with accompanying edema and stenosis.
- When spondylosis results in osteophytic growth on the articular facets or along the disc borders of the vertebral bodies that decreases spinal canal or IV foraminal size.
- When there is spondylolisthesis or when there is scarring or adhesion formation after injury or spinal surgery.

### Dysfunction

The cycle of dysfunction caused by injury, pain, and muscle splinting leads to further restriction of movement, pain, and muscle splinting unless appropriate therapy is introduced. There are additional descriptions of facet joint pathologies in the following section.

## Pathology of the Zygapophyseal (Facet) Joints

Facet joints are synovial articulations that are enclosed in a capsule and supported by ligaments; they respond to trauma and arthritic changes similar to any peripheral joint.

Various types of meniscoid-like structures or invaginations of the facet capsules are present in the zygapophyseal joints of the spine. They are synovial reflections containing fat and blood vessels. In some cases, dense fibrous tissue develops as a result of mechanical stresses.<sup>23</sup> Some people describe entrapment of these structures between the articulating surfaces with sudden or unusual movement as a source of pain and limited motion via tension on the well-innervated capsule.<sup>23,228</sup> Bogduk<sup>23</sup> describes the *locked-back mechanism* as being “extrapment” of the meniscoids in the supracapsular or infracapsular folds, which then blocks the return to extension from the flexed position. It is called an “extrapment” because the meniscoid fails to re-enter the joint cavity; consequently, it becomes a space-occupying lesion in the capsular folds, causing pain as it impacts against and stretches the capsules.

## Common Diagnoses and Impairments From Facet Joint Pathologies

The etiology of facet joint pathologies may be a result of trauma, degeneration, or a systemic disease. Box 15.2 summarizes the impairments and functional limitations.

### Facet Sprain/Joint Capsule Injury

There is usually a history of trauma, such as falling or a motor vehicle accident. The joints react with effusion (swelling), limited range of motion (ROM), and accompanying muscle guarding. The swelling may cause foraminal stenosis and neurological signs.

### Spondylosis, Osteoarthritis, and Degenerative Joint Disease

Spondylosis and OA are synonymous terms. This pathology may also be referred to as DJD. Osteoarthritis involves degeneration of the IV disc as well as the facet joints. Usually, there is a history of faulty posture, prolonged immobilization after injury, or severe or repetitive trauma.

- During the early stages of degenerative changes, there is greater play, or hypermobility/instability, in the three-joint

### BOX 15.2 Summary of Common Impairments and Activity Limitations Related to Facet Joint Pathology

- *Pain*: When acute, there is pain and muscle guarding with all motions; pain when subacute and chronic is related to periods of immobility or excessive activity.
- *Impaired mobility*: Usually hypomobility and decreased joint play in affected joints; there may be hypermobility or instability during early stages.
- *Impaired posture*.
- *Impaired spinal extension*: Extension may cause or increase neurological symptoms due to foraminal stenosis; therefore, may be unable to sustain or perform repetitive extension activities without exacerbating symptoms.
- *Any activity that requires flexibility or prolonged repetition of trunk motions*, such as repetitive lifting and carrying of heavy objects, may exacerbate symptoms in the arthritic spine.

complex. Over time, stress from the altered mechanics leads to osteophyte formation with spurring and lipping along the joint margins and vertebral bodies. Progressive hypomobility with bony stenosis results. The encroachment of osteophytes on the spinal canal and IV foramina may cause neurological signs, especially with spinal extension and side bending.

- Usually, when there is hypomobility, compensatory hypermobility occurs in neighboring spinal segments.
- Pain with movement and/or joint stiffness following periods of rest are the primary reasons people seek physical therapy.
- Pain may result from the stresses of excessive mobility or from stretch to hypomobile structures. Pain may also be a result of the encroachment of developing osteophytes against pain-sensitive tissue or of swelling and irritation because of excessive or abnormal mobility of the segments.
- The degenerating joint is vulnerable to facet impingement, sprains, and inflammation, as is any arthritic joint.
- In some patients, movement relieves the symptoms; in others, movement irritates the joints, and painful symptoms increase.

### Rheumatoid Arthritis

Symptoms of rheumatoid arthritis (RA) can affect any of the synovial joints of the spine and ribs. There is pain and swelling.

- RA in the cervical spine presents special problems. There are neurological symptoms wherever degenerative change or swelling impinges against neurological tissue. There is increased fragility of tissues affected by RA, such as osteoporosis with cyst formation, erosion of bone, and instabilities from ligamentous necrosis. Most common of the

serious lesions are atlantoaxial subluxation and C4–5 and C5–6 vertebral dislocations.<sup>163</sup>

- Pain or neurological signs originating in the spine may or may not be related to subluxation. Therefore, these signs should be used as a precaution whenever dealing with this disease because of the potential damage to the spinal cord.<sup>163</sup>
- Radiograph or CT scan examinations are important in ruling out instabilities; signs and symptoms alone are not conclusive.

**PRECAUTION:** Inappropriate movements of the spine in patients with RA, such as performing cervical manipulation, could be life-threatening or extremely debilitating because of the potential to cause damage to the cervical cord or vertebral artery.<sup>163</sup>

### Ankylosing Spondylitis

Ankylosing spondylitis (AS) is a rheumatic disease characterized by chronic inflammation of the ligaments in the lumbar and spinal areas.<sup>80</sup> The inflamed cartilage/bony junction will fuse in approximately 20% of the population.<sup>241</sup>

- The prevalence of this pathology is approximately 1 to 3 per 1,000 people, and the diagnosis peaks in the mid-20s.<sup>59</sup>
- This pathology appears to begin in the lumbar spine and progress cephalad. The sacroiliac (SI) joints are affected nearly 100% of the time, followed by the neck (75%), lumbosacral area (50%), and hips and heels (30%).<sup>80,141</sup>
- There is a gradual loss of motion and the person will complain of general stiffness. The patient may initially complain of bilateral pain in his or her SI joints, thoracic spine, or shoulders. The person will wake up early with pain and stiffness and have difficulty standing up straight.
- In advanced cases, radiographs will reveal a “bamboo” spine. This imaging identifies where the anterior longitudinal ligament has fused to the vertebral bodies. Decreased joint spaces may also be identified on the film.<sup>80,141</sup>

### FOCUS ON EVIDENCE

Rudwaleit and associates<sup>206</sup> identified four variables that were often seen in people with ankylosing spondylitis. The variables were stiffness greater than 30 minutes in duration, back pain that improved with exercise but not rest, back pain that wakes a person up in the second half of the night, and alternating buttock pain. If three or more of these parameters were met, this yielded a positive likelihood ratio of 12.4 and specificity and sensitivity of .97 and .34, respectively.

**PRECAUTION:** Atlanto-axial subluxation is the hallmark of cervical spine involvement. Extreme caution should be used when assessing and manipulating the cervical spine region to avoid causing serious or fatal injury.<sup>80,141,239</sup>

### Facet Joint Impingement (Blocking, Fixation, Extrapment)

With a sudden or unusual movement, the meniscoid of a facet capsule may be extrapped, impinged (entrapped), or stressed, which causes pain and muscle guarding. The onset is sudden and usually involves forward bending and rotation.<sup>23,234</sup>

- There is loss of specific motions and attempted movement induces pain. At rest, the individual has no pain.
- There are no true neurological signs, but there may be referred pain in the related dermatome.
- Over time, stress is placed on the contralateral joint and on the disc, leading to problems in these structures.

## Pathology of the Vertebrae

Axial overload (compression) of the spine may cause end-plate damage or vertebral body fracture. Compression fracture is a complication of osteoporosis.

### Compression Fracture Secondary to Osteoporosis

The prevalence, risk factors, prevention, recommendations for general exercise, and exercise precautions for osteoporosis are described in detail in Chapter 11, with information related to the older population in Chapter 24. Vertebral compression fractures most often occur in the thoracolumbar region as the result of a fall or trauma or from performing basic activities of daily living (ADLs) that require forward bending of the trunk.

- Fractures usually occur during the sixth or seventh decade of life in the anterior vertebral body.
- Pain may be referred to the low back or abdominal region with or without lower extremity radiculopathy.
- Patients present with increased thoracic kyphosis (sometimes called dowager's hump) and lumbar lordosis secondary to instability, bony changes (wedging), and muscle weakness.
- Exercise prescription is based on the person's pain tolerance.
- Surgical interventions, such as vertebroplasty, may be indicated in severe cases or to prevent progression.
- The risk of low back pain (LBP) caused by a serious pathology, in the absence of trauma is less than 1% in the general population.<sup>99</sup> The physical therapist is encouraged to be concerned when multiple red flags are present versus a single outlying sign or symptom.

### FOCUS ON EVIDENCE

Henske et al<sup>98</sup> identified five major factors that may incriminate a spinal fracture. These variables include >50 years old, female gender, history of major trauma, pain and tenderness, and/or co-occurring distraction/painful injury. Additionally, this same study reported that a person with  $\geq 3$  of the following variables

had a posttest probability of 52% for a vertebral compression fracture. The variables were: >70 years old, female gender, significant trauma, and prolonged use of corticosteroids.

### Scheuermann's Disease

Scheuermann's disease is a rare congenital and/or degenerative weakening of the vertebral endplates, typically seen at T10–L2.<sup>149</sup> The nucleus pulposus can protrude vertically into the vertebral end-plate, which can lead to a bony necrosis or Schmorl's nodes. Scheuermann's disease may also be caused by insufficient blood supply to the growing bone. This pathology is usually seen in the second decade of life and may be diagnosed as "growing pains." Intervention should be related to presenting signs with the caution to minimize compressive forces on the vertebrae.

## Pathology of Muscle and Soft Tissue Injuries: Strains, Tears, and Contusions

Common impairments and functional limitations are summarized in Box 15.3.

### General Symptoms From Trauma

Often more than one tissue is injured as a result of trauma. The extent of the tissue involvement may not be detectable during the acute phase.

- There is pain, localized swelling, tenderness on palpation, and protective muscle guarding regardless of whether the injured tissue is inert or contractile. Muscle guarding serves the immediate purpose of immobilizing the region. If the muscle contraction is prolonged, it results in the buildup of metabolic waste products and sluggish circulation. This altered local environment results in irritation of the free nerve endings, so the muscle continues to contract and becomes the source of additional pain (see Fig. 10.1).
- Ligamentous strains cause pain when the ligament is stressed. If torn, there is hypermobility of the segment.
- As healing of the involved structures occurs, there may be adaptive shortening or scar tissue adhering to surrounding tissue and restricting tissue mobility and postural alignment.

### Common Sites of Lumbar Strain

A common site for injury in the lumbar region is along the iliac crest. This is where many forces converge around the attachment of the lateral raphe of the lumbodorsal fascia, quadratus lumborum, erector spinae, and iliolumbar ligament (see Fig. 14.12). Injury to this region frequently occurs with falls and with repeated loading of the region during lifting or twisting motions.

### BOX 15.3 Summary of Common Impairments and Activity Limitations Associated With Muscle and Soft Tissue Injuries

#### Acute Stage

- Pain and muscle guarding
- Pain with contraction of the muscle or stretch on the muscle
- Interference with ADLs (rolling over, turning, sitting, sit to stand, standing, walking)

#### Subacute and Chronic Stages

- Impaired muscle performance
- Impaired mobility—may have contractures in muscle and related connective tissue or may have adhesions at site of tissue injury
- Impaired spinal control and stabilization during functional activities
- Impaired postural awareness
- Limited IADLs, work, and recreational activities (difficulty with repetitive or sustained postures, lifting, pushing, pulling, reaching, and holding loads)

## Common Sites of Cervical Strain

Common injuries in the neck and upper thoracic region occur with flexion/extension trauma. Serious cervical trauma may result in vertebral fractures and spinal cord injury. Discussion of vertebral fractures and spinal cord injury is beyond the scope of this text.

**Extension injuries.** When the head rapidly accelerates into extension, if nothing stops it (such as a headrest in a car), the occiput is stopped by the thorax. The posterior structures, especially the joints, are compressed. The anterior structures (longus colli, suprahyoid, and infrahyoid muscles) are stretched. The mandible is pulled open; the condylar head of the TMJ translates forward, stressing the joint structures, and the muscles (masseter, temporalis, medial pterygoids) controlling jaw elevation are stretched.

**Flexion injuries.** When the head rapidly accelerates into flexion and nothing stops it (such as the steering wheel or air bag in a car), the chin is stopped by the sternum. The mandible is forced posteriorly so the condylar head is forced into the retrodiscal pad in the joint. The posterior cervical muscles, ligaments, fasciae, and joint capsules are stretched.

## Postural Strain

Strain to the posterior cervical, scapular, and upper thoracic muscles and fasciae is common with postural stresses such as prolonged sitting at a computer terminal, a desk, or focused on a tablet or other electronic device. Structures in the low back

region are strained with faulty standing and sitting postures. Postural stresses are described in detail in Chapter 14.

## Emotional Stress

Emotional stress is often expressed as increased tension in the posterior cervical or lumbar region.

## Activity Limitations and Participation Restrictions

Impaired muscle function underlies most spinal problems that demonstrate pain or poor spinal control and stabilization during functional activities.

**Acute.** During the acute phase, muscle guarding interferes with basic activities, such as bed mobility, sitting, standing, and walking, as well as ability to participate in family, work, and recreational demands.

**Subacute and chronic.** With the subacute and chronic conditions, muscle impairments result in poor stabilization and spinal control in prolonged upright postures and activities. Stability of the spine is imperative for most activities and needs to be addressed to minimize restrictions and improve function.

## Pathomechanics of Spinal Instability

Spinal stability was defined and described in Chapter 14. The mechanical model of stability in which stability is maintained over the base of support by the guy wire function of the global and segmental musculature was reviewed, as was the functional model proposed by Panjabi and colleagues<sup>185-187</sup> in which stability is visualized as a three-legged stool that requires not only the active muscle function, but also the passive osteoligamentous structures and neural control from the central nervous system to program muscle response for spinal stability. All three legs of the stool are necessary for stability; instability results when one (or more) of the legs does not function properly.

There are various grades of instability. Patients who have severe symptoms and radiographic evidence of excessive motion and who do not respond to conservative treatment become candidates for spinal fusion.<sup>72</sup> Surgical fusion of the cervical and lumbar regions are discussed later in this chapter. Clinical instability that can be managed by therapeutic exercise interventions is defined by an increase in the neutral zone.

## Neutral Zone

The *neutral zone*<sup>185,186</sup> is the area that is midrange in the ROM of a spinal segment in which no stress is placed on the passive osteoligamentous structures. In the spine, the neutral zone is

relatively small (usually only several degrees of range is possible between any two vertebrae before the elastic zone of the inert tissues is reached) and is controlled by dynamic tension in the deep segmental musculature that attaches to each of the spinal segments.

The neutral zone can be visualized as a ball lying on the bottom of a bowl. The sides of the bowl represent the osteoligamentous structures that provide passive support of the spinal segment. When the ball is disturbed, it rolls back and forth and up against the sides of the bowl and eventually settles back in the middle. A deep bowl has a smaller region in which the ball can roll back and forth and therefore, less motion or more stability; a shallow bowl has a larger region in which the ball can roll, so there is greater displacement or more mobility (less stability) (Fig. 15.3 A and B). Muscles added to this visualization are depicted as bungee cords that are attached to the ball and go outward to the edges of the bowl; they help center the ball in the middle of the bowl when perturbations occur (Fig. 15.3 C). In a structure in which there is less stability (more segmental movement), the muscles have greater responsibility to maintain the neutral zone (ball in the middle of the bowl).

**Neutral spine.** The term neutral spine is used clinically to define the midrange of motion.

## Instability

If there is an increase in the neutral zone, the segment may show signs of instability.<sup>72,185-187</sup> More segmental movement may occur owing to disc degeneration, spondylolysis, spondylolisthesis, or ligamentous laxity; or it may be due to poor neuromuscular control of the deep segmental stabilizing muscles

**FIGURE 15.3** Neutral zone of a spinal segment depicted as a bowl, with the sides of the bowl representing the osteoligamentous tissues and the moving ball representing the segmental mobility. **(A)** In a deep bowl, when perturbations disturb the ball, there is little motion as the ball rolls back and forth and settles in the center of the bowl—representing stability. **(B)** In a shallow bowl, there is greater motion—representing greater segmental mobility or instability. **(C)** Viewing the bowl from above, bungee cords attached to the ball and the sides of the bowl represent the dynamic function of segmental muscles. Appropriately graded tension in the bungee cords stabilizes the ball when perturbations disturb the unit.

in maintaining the neutral zone because of fatigue, altered recruitment pattern, reflex inhibition from pain, or some pathology.<sup>72,186,187,236</sup> The individual may experience neck or back pain when aberrant movement occurs at the segment or stresses are imposed at the end of the range (relaxed postures for a period of time or sudden stress that the muscles cannot control).

## FOCUS ON EVIDENCE

It has been shown that activation and function in the transversus abdominis (TrA) changes (delayed and more phasic) in patients with LBP;<sup>110,111</sup> there may be atrophy, structural change, and altered electromyographic activity in the multifidus at the painful spinal level as well,<sup>46,105,203</sup> possibly indicating less effective stabilizing action from these muscles. Studies have also documented that training the deep segmental muscles for postural control and stability improves the long-term outcome in patient populations with acute<sup>104</sup> and chronic<sup>183</sup> LBP as well as pelvic girdle pain following pregnancy.<sup>223</sup> In the cervical region, studies have documented that training the stabilizing function of the deep cervical musculature for postural control decreases the frequency and intensity of symptoms of cervical headaches.<sup>121</sup>

## Management Guidelines Based on Stages of Recovery and Diagnostic Categories

### Principles of Management for the Spine

At the time of a spinal injury, impairments, activity limitations, and participation restrictions are not known. Up to 60% of acute back injuries resolve within 1 week and up to 90% resolve within 6 weeks<sup>129</sup> with a recurrence rate of less than 25%.<sup>22,222,243</sup> Participation restrictions are dependent on the extent of the injury. If it involves the spinal cord, levels of complete paralysis may occur requiring rehabilitative interventions to develop adaptations for participation in daily activities. If it involves the nerve roots (also the cauda equina), varying degrees of sensory loss in specific dermatomes and muscle weakness in specific myotomes may occur, which may or may not interfere with the individual's daily personal and work-related activities. Upper-quarter nerve roots affect function of the arms and hands; lower-quarter nerve roots affect function of the lower extremities, especially during weight-bearing activities. Studies on chronic pain syndromes as a result of spinal injuries seem to conclude that the degree of participation restrictions is related to psychological, economic, and sociological factors and prior incidence of injury more than the actual tissues involved.<sup>135</sup> Nerve root involvement

and pain provocation with active movements in several directions are more common in patients who develop chronic pain. Discussion of treatment for spinal cord injuries and chronic pain syndromes is beyond the scope of this book.

## Examination and Evaluation

**History, systems review, and testing.** A history and systems review of the patient is conducted to rule out any serious conditions, determine if the patient should be referred to another practitioner, or determine if the patient's condition is appropriate for physical therapy intervention. Then, if it is safe, tests and measures are conducted to determine if the source of symptoms can be influenced by mechanical changes in position or movement and to establish a baseline from which changes can be documented. Examination techniques and procedures are beyond the scope of this text, but a brief summary of concerns in the spinal area is listed to help focus on critical decisions prior to establishing an intervention strategy.

- **Serious “red flag” conditions related to orthopedic conditions** that should be referred to a physician for management include spinal cord symptoms and signs (upper motor neuron lesions), recent trauma in which spinal fracture or instabilities have not been ruled out, and serious pain (especially pain that awakens the individual) that cannot be explained mechanically.
- **Psychological distress** may interfere with a patient's recovery; therefore, referral to an appropriate professional may be indicated for a multidisciplinary approach in the patient's care. Several psychosocial questionnaires, including the Patient Health Questionnaire for Depression and Anxiety (PHQ-4)<sup>138</sup> and the Graded Chronic Pain Scale,<sup>178,237</sup> can be used to determine if referral is indicated.
- **Neurological symptoms** should be explored in an attempt to relate them to spinal cord, nerve root, spinal nerve, plexus, or peripheral nerve patterns. Causes of nerve root signs frequently seen by physical therapists include IV disc protrusions; bony, soft tissue, or vascular stenosis in the spinal canal or IV foramina; facet joint swelling; and nerve root tension from restricted mobility or inflammation.
- **Pain patterns** should be explored to determine if they relate to a known musculoskeletal pattern or signal a medical condition. It should be recognized that pain is interpreted in many ways and has various meanings for different people; therefore, the information is interpreted as only one factor when determining cause of the symptoms.

### FOCUS ON EVIDENCE

Based on strong evidence, the *Clinical Practice Guidelines (CPGs) for Low Back Pain*<sup>48</sup> and for *Neck Pain*<sup>37</sup> support utilizing self-report questionnaires (such as the Oswestry Disability Index or Roland-Morris Disability Questionnaire for the low back and the Neck Disability Index or Patient-Specific Functional Scale for neck pain) for identifying the baseline

status of pain, function, and disability to monitor change. Based on expert opinion, the *CPGs for Low Back* and *Neck Pain* recommend monitoring activity limitations and participation restrictions by using reproducible and validated measures.<sup>37,48</sup>

**Stage of recovery.** Time frames for each recovery stage vary depending on the reference used. In general, the acute stage usually lasts less than 4 weeks, the subacute stage is 4 to 12 weeks, and the chronic stage is greater than 12 weeks.<sup>2</sup> Chronic pain syndromes generally are conditions that extend beyond 6 months.

- **Acute inflammatory stage.** The patient experiences constant pain, and there are signs of inflammation. No position or movement completely relieves the symptoms. Medical intervention with anti-inflammatory medications is usually warranted.
- **Acute stage without signs of inflammation.** Symptoms are intermittent and related to mechanical deformation. There may be signs of nerve irritability when the nerve root or spinal nerve is compressed or placed under tension. The patient may be categorized into an extension bias, a flexion bias, or a nonweight-bearing bias based on the presenting posture, movement impairments, or positions of symptom relief. These categories are described in greater detail in the next section. Delitto and associates<sup>49</sup> classified patients as being at this stage if they cannot stand longer than 15 minutes, sit longer than 30 minutes, or walk more than one-quarter of a mile without their status worsening.
- **Subacute stage.** Usually at this stage, certain movements and postures with some instrumental ADLs (IADLs) still provoke symptoms, such as lifting, vacuuming, gardening, and other activities requiring repetitive movement of loads, so a basic lifestyle cannot fully be resumed. A more thorough examination is conducted to identify specific impairments, activity limitations, and participation restrictions that could be interfering with recovery.
- **Chronic stage.** When this stage is reached, emphasis is placed on returning the patient to high-level demand activities that require handling repetitive loads on a sustained basis over a prolonged period of time (from heavy material handling, to repetitive household activities that include lifting small children, to strenuous athletic activities).

**Diagnosis, prognosis, and plan of care.** As mentioned in the introduction to this chapter, specific pathologies and medical diagnoses often do not guide the therapist when choosing appropriate treatment interventions, and various systems of patient classification for treating musculoskeletal impairments and functional limitations are present in the literature.<sup>2,49,50,73,158,204,214</sup> Several validation studies supporting clinical prediction rules are available to assist the therapist in making decisions when developing and modifying interventions.<sup>14,38,41,42,75,103,145,200,233</sup> In addition, the *CPGs for Neck Pain*<sup>37</sup> and for *Low Back Pain*<sup>48</sup> have organized recommendations in relation to the International Classification of

Functioning, Disability, and Health (ICF) categories. These classifications are available in ONLINE Box 15.1 on the FA Davis website associated with this text.

The material in the remainder of this section is organized to integrate impairment-based diagnostic categories with the medical model of spinal pathologies in order to help the therapist choose an intervention strategy that best enhances the patient's recovery. Specific medical diagnoses with unique regional features and interventions are described in the last section of this chapter. A table that summarizes the interventions for the spinal and related pathologies described in this chapter is available on the FA Davis website associated with this text (ONLINE Table 15.1)

The decisions concerning the approach to treatment are determined by the patient's responses to the examination maneuvers and the maneuvers that provide the greatest relief of symptoms. Adjustments in the intervention occur as the patient progresses through the healing process. The categories described in this and the following sections are summarized in Box 15.4.

### FOCUS ON EVIDENCE

In two separate, but similar systematic reviews, using directional preference for treatment (the direction of movement that decreased symptoms at the initial evaluation) was shown to be an effective approach when centralization occurred<sup>154</sup> or when compared with other treatment options.<sup>224</sup> This approach was further substantiated in a study by Donelson et al<sup>55</sup> that

included 71 patients with acute to chronic LBP with and without leg radicular pain. Each person was treated for 2 weeks according to their directional preference. At the follow-up, 91% to 100% of participants reported significant improvement or complete resolve in their pain location, pain duration, or neurological status.

Based on strong evidence for patients with acute LBP and related lower extremity pain, the *CPGs for Low Back Pain* recommend utilizing repeated movements, exercises, or procedures that promote centralization of symptoms.<sup>48</sup>

## General Guidelines for Managing Acute Spinal Impairments: Maximum Protection Phase

Use of modalities, myofascial release, and massage to decrease pain and swelling from acute symptoms is appropriate during this stage. It is also important that the patient becomes an active participant in his or her program. Kinesthetic training of neutral or functional spinal posture, nondestructive movements in the pain-free range, awareness and activation of deep segmental musculature, and basic functional training maneuvers are taught if they do not exacerbate the symptoms. Specific interventions for various impairments, specific biases, or syndromes and common pathologies in the spinal region are described in the remaining sections of this chapter. Specific techniques for kinesthetic training, deep segmental muscle

### BOX 15.4 Impairment-Based Diagnostic Categories That Direct Intervention<sup>49,73,158,204</sup>

#### General: Stage of Recovery

- Acute with inflammation (0–4 weeks).
- Acute without inflammation (0–4 weeks): intermittent symptoms with acute nerve root symptoms.
- Subacute (4–12 weeks).
- Chronic (>12 weeks).
- Chronic pain syndrome (>6 months).

#### Nonweight-Bearing Bias: Traction Approach

- Patient does not tolerate being upright for basic ADLs and IADLs.
- Movement testing makes symptoms worse.
- Traction (or other nonweight-bearing procedures) relieves symptoms.

#### Extension Bias: Extension Approach

- Patient usually presents with flexed posture—a *lateral shift* may also be present.
- Extension tests decrease or centralize symptoms.
- Diagnosis may include intervertebral disc lesions, impaired flexed posture, fluid stasis.

#### Flexion Bias: Flexion Approach

- Patient usually presents with flexed posture and is more comfortable when flexed.
- Extension tests exacerbate or peripheralize symptoms.

- Diagnoses may include spondylosis, stenosis, extension load injuries, swollen facet joints.

#### Hypermobility/Functional Instability: Stabilization/Immobilization Approach

- Patients present with hypermobile spinal segment(s); poor spinal stability (segmental or global).
- Diagnoses may include trauma, ligamentous laxity, spondylolysis, or spondylolisthesis.

#### Hypomobility: Mobilization/Manipulation Approach

- Restricted mobility in one or more spinal segments.

#### Muscle and Soft Tissue Lesions: Exercise Approach

- Patient usually presents with guarded posture or increased muscle tension.
- Diagnoses may include strains, tears, contusions, or overuse.

#### Postural Pain Syndrome: Exercise and Conditioning Approach

- Patient presents with faulty posture; symptoms increase with sustained position.
- Diagnoses may include postural strain, cervico-genic headache, thoracic outlet syndrome, poor physical condition
- Movement, posture correction, and exercise decrease symptoms

activation, stabilization training, joint manipulation, and functional training activities for the acute stage in the cervical and lumbar spinal regions are described in Chapter 16. Management guidelines for treating the patient with acute symptoms are summarized in Box 15.5. The following points are fundamental to all interventions.

### Patient Education

It is important to engage patients in all aspects of intervention, including information about anticipated progress and outcome, the healing time of inflamed tissues or reduction of symptoms due to nerve root pressure (if indicated), and precautions and contraindications.

### FOCUS ON EVIDENCE

Based on moderate evidence, the *CPGs for Low Back Pain* recommend providing education and counselling that includes promoting the importance of remaining active (including resumption of normal and vocational activities), self-care options, and avoiding bed rest during the acute phase, as well as an explanation of the natural history of back pain, the inherent strength of the spine, and use of pain coping strategies.<sup>48</sup>

### Symptom Relief or Comfort

If a patient is experiencing acute inflammation from a traumatic injury, there is constant pain; yet, often an optimal position of comfort or symptom reduction can be determined in which there is the least amount of stress on the inflamed, irritated, or swollen region. The terms *functional position* or *functional range* are used to describe this position.<sup>167</sup> (Neutral position is midrange.) The functional range may change for the individual as the tissues heal and the person gains mobility and strength in the region. Some pathological conditions typically tend to cause symptoms in one portion of the range and are relieved in another range.<sup>167</sup> The following terms, describing subcategories of diagnoses or syndromes, have been popularized based on the work of Morgan,<sup>167</sup> Saal and associates,<sup>209,211</sup> Delitto and colleagues,<sup>49</sup> and Fritz and George.<sup>73</sup>

### CLINICAL TIP

For patients with acute or chronic LBP with or without leg radicular pain, utilizing exercises that emphasize directional preference (flexion, extension, or side glide rotation) results in greater improvement in outcome than using nondirectional or general exercises.<sup>14,55,224</sup>

## BOX 15.5 MANAGEMENT GUIDELINES— Acute Spinal Impairments/Protection Phase

### Impairments, Activity Limitations, and Participation Restrictions

Pain and/or neurological symptoms  
Inflammation  
Guarded posture (prefers flexion, extension, or nonweight bearing)  
Limited ability to perform ADLs and IADLs

#### Plan of Care

#### Intervention

- |  |   |
|--|---|
| 1. Educate the patient.  | 1. Engage patient in all activities to learn self-management. Inform patient of anticipated progress and precautions.   |
| 2. Decrease acute symptoms.  | 2. Modalities, massage, traction, or mobilization/manipulation as needed. Rest only for first couple days if needed.  |
| 3. Teach awareness of neck and pelvic position and movement.             | 3. Kinesthetic training: cervical and scapular motions, pelvic tilts, neutral spine.  |
| 4. Demonstrate safe postures.  | 4. Practice positions and movement and experience effect on spine. Help patient find the functional spinal position of comfort in supine, sitting, standing.  |
| 5. Initiate neuromuscular activation and control of stabilizing muscles. | 5. Deep segmental muscle activation techniques: <ul style="list-style-type: none"> <li>■ Lumbar spine: drawing-in maneuver, multifidus contraction.</li> <li>■ Cervical spine: gentle head nods</li> </ul> Basic stabilization: with arm and leg motions (passive support if needed, progress to active control). |
| 6. Teach safe performance of basic ADLs; progress to IADLs.              | 6. Roll, sit, stand, and walk with safe postures. Progress tolerance to sitting longer than 30 minutes, standing longer than 15 minutes, and walking > 1 mile.  |

**Extension bias-extension syndrome.** The patient's symptoms are lessened in positions of extension (lordosis). Sustained flexed postures or repetitive flexion motions load the anterior disc region, causing fluid redistribution from the compressed areas and swelling and creep in the distended areas. This is frequently the mechanism of symptom production with posterior or posterolateral IV disc lesions or injury to the posterior longitudinal ligament. Whether the pathology is an injured disc or stressed and swollen tissues, repeated extension motions and positions relieve the symptoms by moving the fluid to reverse the stasis (these techniques are described in the Extension Bias section of this chapter). Some patients present with a lateral shift, which usually requires correction before extension relieves the symptoms.<sup>158-160</sup>

**Flexion bias-flexion syndrome.** The patient's symptoms are lessened in positions of spinal flexion and provoked in extension. This is often the case when there is compromise of the facets, IV foramen, or spinal canal, as in bony spinal stenosis, spondylosis, and spondylolisthesis (these techniques are described in the Flexion Bias section of this chapter).

**Nonweight-bearing bias-traction syndrome.** The patient's symptoms are lessened when in nonweight-bearing positions, such as when lying down or in traction. Symptoms also lessen when spinal pressure is reduced by leaning on the upper extremities (using arm rests to unweight the trunk), by leaning the trunk against a support, or when in a pool. The condition is considered *gravity sensitive* because the symptoms worsen during standing, walking, running, coughing, or similar activities that increase spinal pressure. Often, traction and aquatic therapy are the only interventions that minimize symptoms during the acute phase.

### Kinesthetic Awareness of Safe Postures and Effects of Movement

The patient is taught how to identify and assume the spinal position that is most comfortable and reduces the symptoms, using pelvic tilts for lumbar positioning and head nods and chin tucks for cervical spine positioning, and is taught how to use passive positioning to help maintain the functional position during the acute state (Box 15.6). If necessary (usually only in severe cases for a limited time or following surgery), a corset or cervical collar may be used to provide support.

### Muscle Performance: Deep Segmental Muscle Activation and Basic Stabilization

Whether the patient has a cervical or lumbar problem, as soon as tolerated, the patient is taught how to activate the deep segmental muscles.

#### Lumbar Region: Deep Segmental Muscle Activation

For the lumbar region, the “drawing-in” maneuver is used to activate the TrA and a gentle bulging contraction of the multifidus muscle. Facilitation techniques, which are described in detail in the Segmental Activation section of Chapter 16, may be necessary.

#### Cervical Region: Deep Segmental Muscle Activation

For the patient with cervical pain, gentle head nods and slight flattening of the cervical lordosis in the supine position are used for activation of the longus colli and multifidus.

#### Basic Stabilization

Once the patient learns to activate the segmental muscles, simple upper and lower extremity motions with the spine stabilized are added to the intervention to initiate training of the global stabilizers. *Passive prepositioning* is used if the patient is unable actively to maintain his or her functional position, as described in Box 15.6. For both cervical and lumbar problems, the patient is instructed first to do the drawing-in maneuver followed by gentle arm motions within a range that does not exacerbate symptoms. Leg motions require greater lumbopelvic control and are introduced if the patient is able to demonstrate pelvic control and the symptoms are not exacerbated with the movements. Suggestions for determining the exercise progressions are detailed in the Stabilization section of Chapter 16.

#### Basic Functional Movements

The patient is taught to perform simple movements for ADLs while protecting the spine in the functional position. These movements include rolling from prone to supine and reverse, lying to sitting and reverse, sitting to standing and reverse, and walking. Descriptions of these maneuvers are in the Functional Activities section of Chapter 16.

**PRECAUTIONS:** Review any special precautions for the condition with the patient. Condition-specific precautions are described in the remaining sections of this chapter.

#### BOX 15.6 Examples of Passive Positioning of the Spine

- **Supine:** Hook-lying flexes the lumbar spine; extended legs extends the lumbar spine. A pillow under the head flexes the neck; a small roll under the neck stabilizes a mild lordosis with the head neutral.
- **Prone:** Use of a pillow under the abdomen flexes the lumbar spine; no pillow extends the spine. To maintain the cervical spine in neutral alignment without rotation, a split table or a small towel roll placed under the forehead provides space for the nose, so the patient does not turn the head.
- **Sitting:** Usually causes spinal flexion, especially if the hips and knees are flexed. To emphasize flexion, the feet are propped up on a small footstool; to emphasize extension, a lumbar pillow or towel roll is placed in the low-back region. To unweight the spine, the arms are placed on an armrest, or a reclining chair is used.
- **Standing:** Usually causes spinal extension; to emphasize flexion, one foot is placed on a small stool.

## General Guidelines for Managing Subacute Spinal Impairments: Controlled Motion Phase

When the signs and symptoms of the inflammatory process are under control and pain is no longer constant, the patient is progressed through a program of safe muscle endurance and strengthening exercises to prepare the tissue for functional activities and rehabilitation training. Functional activities that can be performed safely are resumed. Pain may still interfere with some daily activities, but it should no longer be constant. Poor neuromuscular control and stabilization, poor postural awareness and body mechanics, decreased flexibility and strength, and generalized deconditioning may be the underlying impairments at this stage. Intervention during this

stage is critical, because either the patient feels good and tends to overdo activities and reinjures the tissues or the patient is fearful and does not adequately resume safe movements, leading to further participation restrictions. Either extreme may slow down the recovery process.

Management guidelines for cervical and lumbar problems that require controlled motion interventions are summarized in Box 15.7. The specific techniques and progressions of intervention outlined here are described in detail in Chapter 16.

### Pain Modulation

At this stage, use of modalities to modulate pain is not recommended. Emphasis is placed on increasing patient awareness of posture, strength, mobility, and spinal control and their relationship to modulating pain.

#### BOX 15.7 MANAGEMENT GUIDELINES—

#### Subacute Spinal Problems/Controlled Motion Phase

##### Impairments, Activity Limitations, and Participation Restrictions

Pain: only when excessive stress is placed on vulnerable tissues  
 Impaired posture/postural awareness  
 Impaired mobility  
 Impaired muscle performance: poor neuromuscular control of stabilizing muscles; decreased muscle endurance and strength  
 General deconditioning  
 Limited ability to perform IADLs for extended periods of time  
 Poor body mechanics

##### Plan of Care

##### Intervention

- |   |   |
|---|---|
| 1. Educate the patient in self-management and how to decrease episodes of pain. | 1. Engage patient in all activities emphasizing safe movement and postures.<br>Home exercise program.<br>Ergonomic adaptation of work or home environment.                      |
| 2. Progress awareness and control of spinal alignment.                          | 2. Practice active spinal control in pain-free positions and with all exercises and activities. Practice posture correction.  |
| 3. Increase mobility in restricted muscles/joint/fascia/nerve.                  | 3. Joint mobilization/manipulation, neuromobilization, muscle inhibition, self-stretching.  |
| 4. Teach techniques to develop neuromuscular control, strength, and endurance.  | 4. Progress stabilization exercises; increase repetitions (emphasize muscle endurance).<br>Initiate extremity-strengthening exercises in conjunction with spinal stabilization. |
| 5. Develop cardiopulmonary endurance.   | 5. Low to moderate intensity aerobic exercises; emphasize spinal bias.  |
| 6. Teach techniques of stress relief/relaxation.                                | 6. Relaxation exercises and postural stress relief.   |
| 7. Teach safe body mechanics and functional adaptations.                        | 7. Practice stable spine lifting, pushing/pulling, and reaching practice activities specific to desired outcome emphasizing spinal control, endurance, and timing.              |

### Kinesthetic Training

Kinesthetic training is progressed by using reinforcement techniques. Feed-forward control of the deep segmental musculature, active control of the spinal position, and correct posture are reinforced in a variety of ways until activation and control become habitual. Kinesthetic training overlaps the stabilization exercises.

### Stretching/Manipulation

Decreased flexibility in joints, muscles, and fascia may restrict the patient's ability to assume normal spinal alignment. Manual techniques and safe self-stretching techniques are used to increase muscle, joint, and connective tissue mobility.

### Muscle Performance

Exercises are progressed with increased challenges for control, muscular endurance, and strength in the spinal stabilizing muscles; these exercises include activities that increase control and strength in the extremity musculature in conjunction with spinal stabilization.

#### CLINICAL TIP

If a patient continues to display a flexion or extension bias, adapt exercises to emphasize that particular bias and prevent stresses in the symptom-producing direction.

- Stabilization exercises are used to emphasize movement and resistance to the extremities while maintaining control of the spinal position. Increasing the time and number of repetitions builds muscle endurance at each level of performance.
- Wall slides, partial squats, partial lunges, pushing, and pulling against resistance are used to strengthen the extremities to prepare for lifting, reaching, pushing, and pulling activities.
- When the patient learns effective spinal control with the stabilizing muscles in a variety of stabilization exercise routines, dynamic trunk and neck strengthening exercises, such as curl-ups, back extension, and cervical motions, are introduced. Care is taken to monitor symptoms and modify any activities that exacerbate the problem.

### Cardiopulmonary Conditioning

Aerobic capacity is usually compromised after injury. It is important to guide the patient in the initiation of or safe return to an aerobic conditioning program. Help the patient identify activities that do not exacerbate spinal symptoms and set goals and progressions to achieve desired outcome.

### Postural Stress Management and Relaxation Exercises

It is common that a patient's symptoms are exacerbated with sustained postural stresses such as sitting at a computer,

talking on the phone (head tilted), utilizing a digital mobile device, or repetitive forward bending (shoe salesman); therefore, analysis of work, home, or recreational postures and activities is a necessary component of the patient's program. The patient is then advised about methods to correct the sustained or repetitive postural stresses. In addition, frequent changes of position and movement through the pain-free ROMs should be encouraged. It may be necessary to teach the patient how to consciously relax tension in muscles to relieve stress. Relaxation exercises are described in Chapter 14.

### Functional Activities

Once the patient has learned spinal control and stabilization and has developed adequate flexibility and strength for specific tasks, components of the task are incorporated into the exercise program and then into the patient's daily lifestyle. Safe body mechanics are included in all aspects of care.

## General Guidelines for Managing Chronic Spinal Impairments: Return to Function Phase

Patients who have been treated through the acute and subacute phases of healing with appropriately graded exercises should have minimal structural or functional impairments that prevent or restrict daily activities. Individuals who must do heavy material handling (e.g., a manual laborer, firefighter, or caregiver of patients or of small children) or who participate in high-demand sports activities may require additional rehabilitative training to return safely to these high-demand activities and to avoid further injury. Impairments in strength, endurance, neuromuscular control, and skill are related to the functional goals of the individual. At this stage, conditioning and spinal control during high-intensity and repetitive activities are emphasized. Any underlying impairments that interfere with the desired outcomes must be remediated. Management guidelines for return to function are summarized in Box 15.8. Suggestions for progressing exercise intervention techniques from the subacute through chronic stages are described in Chapter 16.

### Management Guidelines: Nonweight-Bearing Bias

During examination, some patients do not respond to extension, flexion, or even midrange spinal positions or motions due to the acuity of or mechanical stimuli from their condition. The person is often more comfortable lying down and may have partial or full relief with a traction test maneuver to the painful region of the spine.

For these patients, use of traction procedures or unweighting the body in a pool may be the interventions of choice until the symptoms stabilize.

### BOX 15.8 MANAGEMENT GUIDELINES— Chronic Spinal Problems/Return to Function Phase

#### Impairments, Activity Limitations, and Participation Restrictions

Pain: only when excessive stress is placed on vulnerable tissues in repetitive or sustained nature for prolonged periods  
 Poor neuromuscular control and endurance in high-intensity or destabilized situations  
 Flexibility and strength imbalances  
 Generalized deconditioning  
 Limited ability to perform high-intensity physical demands for extended periods of time

Plan of Care	Intervention
1. Emphasize spinal control in high-intensity and repetitive activities.	1. Practice active spinal control in various transitional activities that challenge balance.
2. Increase mobility in restricted muscles/joints/fascia/nerve.	2. Joint mobilization/manipulation, neuromobilization, muscle inhibition, self-stretching.
3. Improve muscle performance; dynamic trunk and extremity strength, coordination, and endurance.	3. Progress dynamic trunk and extremity resistance exercises emphasizing functional goals.
4. Increase cardiopulmonary endurance.	4. Progress intensity of aerobic exercises.
5. Emphasize habitual use of techniques of stress relief/relaxation and posture correction.	5. Motions and postures to relieve stress.
6. Teach safe progression to high-level/high-intensity activities.	6. Apply any ergonomic changes to work/home environment.
7. Teach healthy exercise habits for self-maintenance.	7. Progressive practice using activity-specific training consistent with desired functional outcome, emphasizing spinal control, endurance, balance, agility, timing, and speed.

## Management of Acute Symptoms

### Traction

- Various references have reported the benefits of traction in patients meeting this criteria,<sup>27,40,74,193,217</sup> Traction has the mechanical benefit of temporarily separating the vertebrae, causing mechanical sliding of the facet joints in the spine, and increasing the size of the IV foramina. If done intermittently, this motion may help reduce circulatory congestion and relieve pressure on the dura, blood vessels, and nerve roots in the IV foramina. Improving circulation also may help decrease the concentration of noxious chemical irritants due to swelling and inflammation.
- There may be a neurophysiological response via stimulation of the mechanoreceptors that may modulate the transmission of nociceptive stimuli at the spinal cord or brain stem level.

### Pool

If a person is not fearful of being in a pool, supporting the individual with a buoyant life belt in deep water reduces the effects of gravity on the lumbar spine. If symptoms are reduced, it may be possible to begin and progress gentle stabilization exercises

in this buoyant environment to meet some of the goals during the acute and subacute phases. Exercises can also be progressed by using the properties of water for resistance and stretching (see description of aquatic exercises in Chapter 9).

### Progression

As healing occurs, the patient should begin to tolerate weight bearing. After re-examination and assessment, identify the impairments and activity and participation restrictions. If a bias toward flexion or extension is determined, or if there are areas of hypermobility or hypomobility, plan the interventions accordingly.

## Management Guidelines: Extension Bias

Patients with an extension bias often assume a flexed posture or a flexed posture with lateral deviation of the trunk or neck, but during the examination, sustained or repetitive extension maneuvers reduce or relieve their symptoms. These patients

would benefit from early interventions that emphasize extension of the involved segments. The impairments may be due to a contained IV disc lesion, fluid stasis, a flexion injury, or muscle imbalances from a faulty flexed posture. McKenzie<sup>158-160</sup> developed a method of categorizing these patients based on the extent of their pain and/or neurological symptoms. He also described the phenomena of peripheralization and centralization that accompany an expanding and receding lesion, frequently attributed to IV disc lesions (see Fig. 15.2).

Many of the techniques that were originally described by McKenzie<sup>158-160</sup> to manage a patient with an acute disc lesion have been found to be beneficial in the management of patients who have a cluster of signs and symptoms that categorize them into the extension bias (extension syndrome) category.<sup>71,73,145,211</sup>

## Principles of Management

Because patients with signs and symptoms of a bulging IV disc often fit into the “extension bias” category, a brief discussion of the response of the IV disc is presented here.

### Effects of Postural Changes on IV Disc Pressure

Relative changes in posture and activities affect intradiscal pressure. When compared to the level of pressure when standing, intradiscal pressure is least when lying supine, increases by almost 50% while sitting with hips and knees flexed, and almost doubles if leaning forward while sitting.<sup>217</sup> Sitting with a back rest inclination of 120° and lumbar support 5 cm in depth provides the lowest load to the disc while sitting.<sup>11</sup> Therefore, sitting with the hips and knees flexed or leaning forward should be avoided when there is an acute disc lesion. If sitting is necessary, there should be support for the lumbar spine by reclining the trunk 120°.

### Effects of Bed Rest on the IV Disc

When a person is lying down, compression forces to the disc are reduced, and with time, the nucleus potentially can absorb more water to equalize pressures (imbibition). When lying down with the spine in flexion, the imbibed fluid accumulates posteriorly in the disc where there is greater space. Then, upon rising, body weight compresses the disc with the increased fluid, and intradiscal pressure greatly increases. The pain or symptoms from a disc protrusion are accentuated. To avoid exacerbating symptoms, absolute bed rest during the acute phase should be avoided.<sup>48</sup> Bed rest during the first 2 days (when symptoms are highly irritable) may be needed to promote early healing, but it should be interspersed with short intervals of standing, walking, and appropriately controlled movement.<sup>242</sup>

### Effects of Traction on the IV Disc

Traction may relieve symptoms from a disc protrusion, although there is conflicting evidence as to whether traction

in general is beneficial.<sup>40,48</sup> It is proposed that separating the vertebral bodies may have the effect of placing tension on the annular fibers and posterior longitudinal ligament, thus having a flattening effect on the bulge; or it may decrease the intradiscal pressure.<sup>217</sup> If traction relieves symptoms, the time of application must be short because with the reduced pressure fluid imbibition may occur to equalize the pressure. Then, when the traction is released, the pressure increases and symptoms are exacerbated.

### Effects of Flexion and Extension on the IV Disc and Fluid Stasis

Rest in a slightly forward-bent position often lessens pain because of the space potential for the nucleus pulposus of the IV disc. The patient may also deviate laterally to minimize pressure against a nerve root. Movement into extension initially causes increased symptoms. With acute disc lesions in which there is protective lateral shifting and lumbar flexion, techniques that cause lateral shifting of the spine opposite to the deviation followed by passive spinal extension (sustained or repetitive) to compress the protrusion mechanically have been found to relieve the clinical signs and symptoms in many patients.<sup>133,159</sup>

Patients experiencing pain due to fluid stasis after being in a sustained flexed posture also experience relief with movement into extension.

### FOCUS ON EVIDENCE

In a study of 20 subjects with LBP who were candidates for extension-based treatment, those who experienced an immediate decrease in pain intensity (N = 10) of at least 2/10 after treatment (posterior to anterior mobilization followed by prone press-ups) demonstrated a mean increase in diffusion coefficient of 4.2% of the nuclear region of the L5-S1 IV disc measured by MRI. Those who did not experience pain reduction (N = 10) did not have a change in diffusion (mean decrease of 1.6%; P < .005).<sup>18</sup>

### Effects of Isometric and Dynamic Exercise

Isometric activities (resisted pelvic tilt exercises, straining, Valsalva maneuver) and active back flexion or extension exercises increase intradiscal pressures above normal. They therefore must be avoided during the acute stage of a disc lesion. Strong muscle contractions also exacerbate symptoms if a muscle has been injured. Therefore, active and resistive extension exercises are avoided during the acute stage.

### Effects of Muscle Guarding

Reflex muscle guarding or splinting often accompanies an acute disc lesion and adds to the compressive forces on the disc. Modalities and gentle oscillatory traction to the spine may help decrease the splinting.

## Indications, Precautions, and Contraindications for Interventions: Extension Approach

**Indications.** Extension is used if pain and/or neurological symptoms centralize (decrease or move more proximally) during repeated extension testing maneuvers and peripheralize (worsen) during flexion.<sup>158</sup> Extension is also indicated for flexed postural dysfunctions with limited range into extension. If no test movements decrease the symptoms, this mechanical approach to treatment should not be used. This was illustrated in a randomized control trial by Hosseinifar et al,<sup>114</sup> where patients with nonspecific LBP were placed into either a McKenzie (extension) or stabilization exercise group. After 18 visits, the stabilization group reported a significant decrease in their pain and functional outcomes compared with the McKenzie group.

**PRECAUTION:** A patient with acute pain in the spinal region that is not influenced by changing the patient's position or by movement must be screened by a physician for signs of serious pathology.

**CONTRAINDICATIONS:** When there is an acute disc lesion, any form of exercise or activity that increases intradiscal pressure, such as the Valsalva maneuver, active trunk flexion, or trunk rotation, is contraindicated during the protection phase of treatment. Any movement that peripheralizes the symptoms signals a movement that is contraindicated during the acute and early subacute period of treatment. Peripheralization with extension motions may indicate stenosis, a large lateral disc protrusion, or pathology in a posterior element.<sup>210</sup> Contraindications to specific movements are summarized in Box 15.9.

## Interventions Using an Extension Approach in the Lumbar Spine

### Management of Acute Symptoms

If symptoms are severe, bed rest is indicated with short periods of walking at regular intervals. Walking usually promotes lumbar extension and stimulates fluid mechanics to help reduce swelling in the disc or connective tissues. If the patient cannot stand upright, he or she should use crutches or a walker to help relieve the increased pressure of the forward-bent posture.

If repeated flexion test movements increase the symptoms and if repeated extension test movements decrease or centralize the symptoms, all flexion activities should be avoided during the early phases of intervention. Treatment begins with the following maneuvers.

#### Extension

**Patient position and procedure:** Prone. If the flexion posture is severe, place pillows under the abdomen for support. Gradually increase the amount of extension by removing the pillows, and then progress by having the patient prop himself or herself up on the elbows, allowing the pelvis to sag (Fig. 15.4 A). When

### BOX 15.9 Contraindications to Specific Spinal Movements

*Extension* of the spine is contraindicated:<sup>100</sup>

- When no position or movement decreases or centralizes the described pain
- When saddle anesthesia and/or bladder weakness is present (could indicate spinal cord or cauda equina lesion)
- When a patient is in such extreme pain that he or she rigidly holds the body immobile with any attempted correction

*Flexion* of the spine should be avoided:

- When extension relieves the symptoms
- When flexion movements increase the pain or peripheralize the symptoms

propping, pillows placed under the thorax help take strain off the shoulders. Wait 5 to 10 minutes between each increment of extension to allow reduction of the water content and the size of the bulge. There should be an accompanying centralization of or decrease in symptoms. Progress to having the patient prop himself or herself up on the hands, allowing the pelvis to sag (Fig. 15.4 B).

If the sustained position of prone propping is not well tolerated, have the patient perform passive lumbar extension intermittently by repeating the *prone press-ups*, at least 10 times, attempting to go into greater extension with each repetition. If possible, have the patient maintain the end position (as in Fig. 15.4 B) after the 10th repetition as long as tolerated.

**PRECAUTION:** Carefully monitor the patient's symptoms. They should lessen peripherally (i.e., decreased foot and leg symptoms or decreased thigh and buttock symptoms) but may increase (centralize) in the low back. If the symptoms progress down the lower extremity (peripheralize), immediately stop the exercises and reassess.<sup>159</sup>

**Alternate positions and procedure:** if the patient does not tolerate the prone position, alternate positions may be effective:

- Sitting with a lumbar roll (or towel roll) placed behind the low back. Include repetitive extension motions while sitting, either with pelvic rocking or by extending the thorax over the stable pelvis.
- Standing and performing repetitive back extensions (Fig. 15.5).
- Standing with hands placed on a counter or table and then sagging the pelvis forward to create lumbar extension. This can be a sustained posture or performed repetitively

#### Lateral Shift Correction

If the patient has lateral shifting of the spine (Fig. 15.6), extension alone cannot reduce a nuclear protrusion of the disc

**FIGURE 15.4** Lumbar extension is accomplished (A) by having the patient prop up on the elbows and (B) by propping on hands and allowing the pelvis to sag.

**FIGURE 15.5** Standing back extension.

until the shift is corrected. Once the shift is corrected, the patient must extend (as described above) to maintain the correction.

**Patient position and procedure:** Standing with flexed elbow against the side of the deviated rib cage. Stand on the side to which the thorax is shifted and place your shoulder against the patient's elbow. Then wrap your arms around the patient's pelvis on the opposite side and simultaneously pull the pelvis toward you while pushing the patient's thorax away (Fig. 15.7).

**FIGURE 15.6** Patient with lateral shift of the thoracic cage toward the right. The pelvis is shifted toward the left.

This is a gradual maneuver. Continue with the lateral shifting if centralization of the symptoms occurs. If there is overcorrection, the pain and lateral shift may move to the contralateral side, which is corrected by shifting the thorax back. The purpose is to centralize the pain and correct the lateral shift. Once the shift is corrected, *immediately* have the patient backward-bend (see Fig. 15.5). Again, allow time. Progress to passive extension with prone propping and prone press-ups as previously described.

**FIGURE 15.7** A lateral gliding technique used to correct a lateral shift of the thorax is applied against the patient's elbow and thoracic cage as the pelvis is pulled in the opposite direction.

### Alternate patient positions and procedures:

- Side-lying on the side to which the thorax is shifted. Place a small pillow or towel roll under the thorax. The patient remains in this position until the pain centralizes; he or she then rolls prone and begins passive extension with prone propping and prone press-ups.
- Prone-lying. Attempt to side-glide the thorax and pelvis toward the midline with manual pressure. The forces are in equal and opposite directions. Once the symptoms centralize, instruct the patient to begin passive extension with prone propping and prone press-ups.

Teach self-correction of the lateral shift. The patient places the hand on the side of the shifted rib cage on the lateral aspect of the rib cage and places the other hand over the crest of the opposite ilium and then gradually pushes these regions toward the midline and holds (Fig. 15.8).

### Patient Education

- Help the patient recognize what positions and motions increase or decrease the pain or other symptoms by performing them under supervision. Teach safe movement patterns to protect the back as described in the guidelines for treating acute spinal problems (see Box 15.5).
- Instruct the patient to repeat the extension activities frequently, such as 10 times every hour with lateral shift correction if necessary, during the first couple of days. The more severe the symptoms, the more frequently the extension exercises should be completed. In addition, they should be performed immediately upon waking up and after periods of prolonged sitting and/or bending.
- Caution the patient to stop the activity immediately if the pain worsens or peripheralizes during exercises.
- Instruct the patient to maintain an extended posture with passive support while the lesion is healing. For example,

**FIGURE 15.8** Self-correction of a lateral shift.

have the patient use a towel roll or lumbar pillow while sitting. This is especially important when riding in a car or sitting in a soft chair. When going to bed, have the patient pin a towel, folded lengthwise four times, around the waist.

Instruct the patient to use extreme caution if needing to perform flexion activities, such as lifting, or during any other functions that increase intradiscal pressure such as straining.

### CLINICAL TIP

If your patient must do an activity that requires flexion or straining, instruct them to first preset the spine in extension by extending the spine, and then after completing the activity to do repeated extensions.

### Lumbar Traction

Traction may be tolerated by the patient during the acute stage and has the benefit of widening the disc space and possibly reducing the nuclear protrusion by decreasing the pressure on the disc or by placing tension on the posterior longitudinal ligament.<sup>217</sup>

- Time of the traction should be short; osmotic forces soon equalize. However, upon release of the traction force, there could be an increase in disc pressure, leading to increased pain. Use less than 15 minutes of intermittent traction or less than 10 minutes of sustained traction.
- High poundage; more than half the patient's body weight is necessary for separating the lumbar vertebrae.
- If there is complete relief initially, often there is an exacerbation of symptoms later.
- If the symptoms are relieved with mechanical traction, instruct a family member or caregiver in the application of a unilateral leg pull of the involved extremity for home treatment. This manual traction technique is applied intermittently for 10 to 15 seconds with enough force to decrease symptoms and may be performed throughout the day.

### Joint Manipulation

Grades I through IV joint mobilization/manipulation may be utilized preceding the prone press ups, but high-velocity thrust (HVT) should not be performed as this may promote inflammation at the segment. HVTs also require a rotation component, and this may place further stress on the disc.

### Kinesthetic Training, Stabilization, and Basic Functional Activities

Once the patient learns to control the symptoms, the following should be emphasized.

- Teach simple spinal movements in pain-free ranges using gentle pelvic tilts. The patient is taught to be aware of how far forward and backward he or she can rock the pelvis and move the spine without increasing the symptoms. The pelvic rocking is done in supine, sitting, hand-knee

all-fours (quadruped), prone-lying, side-lying, and standing positions. It is important to stay within the patient's ability to control the symptoms.

- Instruct the patient to finish all exercise routines with the pelvis tilted anteriorly and the spine in extension.
- Teach the patient basic stabilization techniques utilizing the deep trunk muscles while maintaining control of the extended spinal position and performing simple extremity motions. It is important to caution against holding the breath and causing the Valsalva maneuver, which would excessively increase the intradiscal pressure.
- Encourage activities, such as walking or swimming, within the tolerance of the individual.
- Initiate passive, straight-leg raising with intermittent dorsiflexion and plantarflexion to maintain mobility in the nerve roots of the lumbar spine.

## Management When Acute Symptoms Have Stabilized

### Signs of Improvement

Improvement is noted with loss of spinal deformity, increased motion in the back, and negative dural mobility signs. Loss of back pain with an increase in true neurological signs is an indication of worsening. The patient is tested to determine that the symptoms have stabilized; this is accomplished by performing repeated flexion and extension tests with the patient standing and then lying supine and prone as done initially. The tests may be positive for structural impairments (restricted motion, weakness, and tension), but should not cause peripheralization of the symptoms, as when the condition was acute.<sup>159</sup>

### Intervention

The emphases during this stage are *recovery of function*, *development of a healthy back care plan*, and *teaching the patient how to prevent recurrences*. The pain from adaptive shortening decreases as normal flexibility, neural mobility, strength, and endurance are restored.

In addition to general exercise instruction, teach the patient these principles:

- Following any flexion exercises, perform extension exercises, such as prone press-ups or standing back extension (see Figs. 15.4 and 15.5).
- If being in a prolonged flexed posture is necessary, interrupt the flexion with backward bending at least once every hour. Also, perform intermittent pelvic tilts every hour throughout the day.
- If symptoms of a protrusion develop and are felt, immediately perform press-ups in the prone position, anterior pelvic tilts in the quadruped position, or backward bending while standing to prevent progression of the symptoms.

## CLINICAL TIP

It is important that the patient understands they should continue with their daily activities and that symptoms can often

be managed with lumbar extension postures and pelvic tilt motion. Instruct them to perform repeated lumbar extension in sitting, standing, or prone position every hour that they are awake, in addition to lumbar ROM via pelvic tilting.

## Interventions to Manage a Disc Lesion in the Cervical Spine

Disc lesions in the cervical spine are less common than in the lumbar spine. Herniated discs are most common between the C6 and C7 vertebrae; this is likely due to the increased mobility at this transitional section between the cervical lordosis to the thoracic kyphosis. It may also be the result of degeneration, osteophytes, or poor posture. Patients may present with peripheral neuropathy and forward-head posture without a diagnosis of disc pathology. Symptoms increase with activities and postures that increase flexion in the lower cervical and upper thoracic spine and decrease with extension in that region (axial extension or neck retraction).<sup>1</sup>

Conservative management is similar to that in the lumbar spine and follows the same principles described in the previous section. Medical management includes pharmacological pain and inflammation control measures. Often disc extrusions are an indication for surgery because of potential compromise of the spinal canal and pressure on the spinal cord.<sup>213</sup> These procedures are described in the next section.

### Acute Phase

#### Passive Axial Extension (Cervical Retraction)

**Patient position and procedure:** Begin with the patient supine, with no pillow under the head or neck. Gently nod the patient's head and allow the neck to flatten against the treatment table. If the neck is deviated or rotated to one side, moving the head and neck back toward the midline must be done first. This may require gentle, progressive positioning and may take 10 to 20 minutes to accomplish.

**Progression:** Progress the retraction to hyperextension of the cervical spine and then progress to rotation. Use caution and carefully monitor the signs and symptoms; do not progress if symptoms peripheralize down the arm.

#### Patient Education

Teach the patient to retract his or her head and neck in the sitting position. The patient may gently push against the chin (caution not to push so hard as to cause joint compression of the TMJ) to direct the motion. This technique has been shown to improve the H-reflex amplitude and may be useful for improving mobility and decreasing symptoms of radiculopathy by decompressing nerve roots in the lower cervical spine.<sup>1</sup>

#### Traction

Cervical traction may relieve the patient's symptoms. As described for lumbar traction, during the acute phase, sustained traction should be no longer than 10 minutes and intermittent traction no longer than 15 minutes in duration. The dosage is at an intensity that causes vertebral separation (at least 15 lb).

### CLINICAL TIP

A family member or caregiver may be instructed in performing home traction. The provider gently cradles the patient's head and applies enough distraction force to decrease the symptoms. This can be done in increments of 10 to 30 seconds and can be performed throughout the day.

### Kinesthetic Training for Posture Correction

Instruct the patient in safe mechanics for maintaining the head position. It is important to help the patient identify the posture that centralizes the symptoms and to adjust the collar to maintain that position.

### Progression as Symptoms Stabilize

Follow the guidelines described in Box 15.7. Faulty cervical, thoracic, and scapular posture may be present. Emphasize kinesthetic training for postural awareness, stabilization exercises for postural control with emphasis on the scapular and shoulder muscles, environmental adaptations to reduce postural stresses, and functional activities with safe spinal mechanics.<sup>89,139</sup>

### FOCUS ON EVIDENCE

Kjellman and Oberg<sup>130</sup> randomly placed 77 people with neck pain into one of the following three groups: general exercise, McKenzie extension exercise, and a control group (ultrasound and education). Outcome measures were pain intensity and the Neck Disability Index. After 12 months, all groups showed significant improvement with no significant difference between the three groups, with nearly 70% of patients reporting they were better or completely restored. The authors did note, though, that in the short term (during the first 3 weeks of treatment), those in the extension exercise group had more favorable response to treatment than the general exercise group or the control group, and there was a tendency that those in the extension exercise group used the health-care system less frequently during the 6- to 12-month period. Analysis showed significant improvement between the extension exercise group and control group at 3 weeks and at 6 months ( $P < 0.05$ ).

## Disc Lesions: Surgery and Postoperative Management

### Indications for Surgery

Patients with upper or lower extremity radiculopathy caused by nerve root irritation and who have failed conservative measures, including physical therapy, medications, and steroid injections, may be appropriate surgical candidates.<sup>33,34,36,78,131,151,184,194,240</sup>

### Common Surgeries

The two most common surgical procedures in the spine are laminectomy and fusion of one or more vertebrae.<sup>152</sup>

**Laminectomy.** A laminectomy is the removal of the lamina. A partial or hemi-laminectomy is a removal of only part of the lamina; a complete laminectomy is the excision of the entire lamina, the spinous process, and the ligamentum flavum that attached to the lamina. The primary disadvantage to a complete laminectomy is that the surgical segment loses its anatomical stabilization.<sup>34,36,100</sup> A laminectomy is typically indicated over a fusion in patients with a small unilateral disc protrusion. The benefits of a laminectomy are that the patients retain segmental mobility while experiencing symptom relief.

**Fusions.** Fusions are indicated when the patient presents with axial pain combined with instability, severe arthritic degenerative changes, or peripheral pain that is not controlled.<sup>33,36,78,94,131,151,184,194,240</sup> The advantages of a spinal fusion are that it reduces or eliminates segmental motion, reduces mechanical stress at the degenerated disc area, and reduces the incidence of additional herniations at the affected disc site.<sup>240</sup> However, effects of a fusion may expedite the degenerative processes, create a hypermobility at adjacent spinal segments, and alter overall spinal mechanics.<sup>19,62,100,106</sup>

### Procedures

**Anterior cervical disc fusion.** Anterior cervical disc fusion (ACDF) involves a horizontal incision at the level(s) of the cervical vertebrae that are to be fused. Both the platysma and longus coli muscles are interrupted during this procedure. Once the disc is excised, the adjacent vertebrae are then internally fixated with a single unilateral plate and screws attaching directly to the vertebral bodies. Although complications are rare, they can include sore throat, hoarseness, and difficulty swallowing.<sup>81</sup> Medical complications involving the heart, lungs, and other organs affect approximately 5% of surgical patients following ACDF.<sup>152</sup> Neurological or more serious complications, including myelopathy, radiculomyelopathy, and recurrent laryngeal nerve palsy, have been reported as ranging from 1% to 4% of the postsurgical population.<sup>20,33,69</sup> Complications are more likely in elderly patients ( $\geq 65$  years old).<sup>30</sup>

### Outcomes

Pain has been reported to significantly decrease following ACDF.<sup>78,107,131,144,168,184,247</sup> Good to excellent outcomes have been reported as high as 92%.<sup>100</sup>

**Transforaminal lumbar interbody fusion.** Transforaminal lumbar interbody fusion (TLIF) involves a vertical incision centrally along the posterior spine.<sup>94</sup> The paraspinal muscles, including the multifidi, are retracted prior to the removal of the lamina, spinous process, and ligamentum flavum. The vertebrae are fused together using bone from the facetotomy and autologous bone from the iliac crest.<sup>94</sup> Complications, occurring in 2% to 5% of patients, include infection, epidural

bleeding, neural injury, postsurgical instability, epidural fibrosis, and arachnoiditis.<sup>19,76,86,194,246</sup> Surgical site infection and wound complications have been cited as the most common complications after surgery.<sup>6</sup> Hayashi et al<sup>96</sup> reported adjacent segment degeneration in 40% of people at 121 month follow-up. Re-operation rates range from 8% to 14%.<sup>96,216</sup> The fusion rate has been reported to range from 70% to 96%.<sup>76,143,170</sup>

### Outcomes

Significant improvement in VAS, Oswestry Disability scores, and other functional outcomes have been reported.<sup>12,76,86,90,102,216</sup> Berg and associates<sup>19</sup> identified that 84% of people reported improvement and/or complete resolution of pain at 1 year postoperative and 86% at 2 years. The authors also reported that 71% of people returned to work after 1 year. In a similar study, Fujimori and colleagues<sup>76</sup> reported a 3.4 point decrease in pain on the visual analogue scale and a 14 point improvement in the Oswestry Disability Index at 1.3 years postoperative.

**Laminectomy.** Laminectomies can be performed in either the lumbar or cervical spine regions. Both involve a posterior approach and are performed similarly to a posterior fusion with the exception that the vertebrae are not internally fixated to each other. The recovery time and return to work time are usually much quicker as compared with a fusion. However, similar rehabilitation guidelines are followed as described in the next section. The need for re-operation following a laminectomy has been reported to range between 14% and 33.8%,<sup>32,216</sup> and lifetime risk of fusion after laminectomy is 8%.<sup>32</sup>

## Postoperative Management

Postoperative management is similar for all of these surgical procedures.

### Maximum Protection Phase

- **Patient education.** Educate the patient on the expectations of the surgeon, the surgical procedure, and the rehabilitation involved in the process. Also, instruct the patient on any restrictions as detailed by the surgeon. These restrictions typically include no heavy lifting (>10 lb) for up to 3 months. Limitations in active motions may also be imposed depending on the surgeon's preference and type of procedure.
- **Wound management and pain control.** Teach the patient to look for signs of inflammation such as redness, swelling, or nonclosure of the wound.
- **Bed mobility.** The patient must relearn how to perform bed mobility as they may be wearing a spinal orthosis that prevents normal movement.
- **Bracing.** To promote healing, patients who have undergone either an ACDF or TLIF are typically placed in a Philadelphia collar and then a soft collar or a chairback brace, respectively, for up to 3 months. The patient may be allowed to remove the brace to shower but must immediately don the orthosis upon getting dressed.

- **Exercises.** Encourage walking and gentle ROM exercises (assisted if necessary) that can be completed in the supine position. Include heel slides, short-arc quads, quad and gluteal isometrics, and ankle pumps. Patients who have undergone a laminectomy are instructed to avoid excessive spinal extension due to the weakened bony neural arch.

**CONTRAINDICATIONS:** Patients are to avoid a shower or getting the incision wet until it is completely closed. This is usually 1 to 2 weeks following surgery. As described above, the patient is instructed to follow the surgeon's guidelines regarding limitations with movement and lifting.

### Moderate and Minimum Protection Phases

- **Scar tissue mobilization.** After the incision site is healed, initiate scar mobilization to improve connective tissue mobility and decrease pain at the surgical site.
- **Progressive stretching and joint mobilization/manipulation of restricted tissue.** Gentle (grade I to II) joint techniques at adjacent segments are indicated for pain modulation and improved ROM.
- **Muscle performance**
  - Initiate segmental and progress to global stabilization exercises to patient tolerance.<sup>97</sup>
  - Address patient goals directed at minimizing specific activity restrictions and impairments.
  - Begin with single plane exercises and progress complexity as patient tolerates.
- **Gait training.** Once the patient is allowed to ambulate, an assistive device is usually indicated to facilitate an erect posture and unload some of the stress to the surgical area.

### CONTRAINDICATIONS:

- The patient must continue to follow the surgeon's contraindications to promote optimal healing.
- Joint manipulations at the level(s) of the fusion are contraindicated.
- Extension exercises, including prone press-up, are contraindicated in patients who have undergone a laminectomy.

### FOCUS ON EVIDENCE

Multiple research studies report improved functional status in patients who begin rehabilitation at 12 weeks following lumbar spine surgery (with or without fusion).<sup>157,176,177,208</sup> Several authors report that beginning rehabilitation at 6 weeks has inferior outcomes compared to waiting until 12 weeks.<sup>176,177,208</sup>

## Management Guidelines: Flexion Bias

Patients may present with a flexed posture and be unable to extend because of increased neurological symptoms and decreased mobility; these patients would benefit from early

interventions that emphasize flexion of the involved segments to relieve symptoms. The patients may have a medical diagnosis of spondylosis or spinal stenosis (central or lateral), an extension load injury, or capsular impingement or swollen facet joints, so symptoms increase with extension. The flexed position reduces or relieves the symptoms.

**NOTE:** Cervical radiculopathy is discussed in the section on Management of Regional Diagnoses later in this chapter.

## Principles of Management

Physical therapy interventions focus on increasing the diameter of the foramen and minimizing nerve root irritation.

**Effect of position.** Flexion widens the IV foramina, whereas extension decreases the size of the foramina. Any compromise of the foraminal opening, such as encroachment from bony spurs or lipping or swollen tissue, reduces the space. The patient may describe intermittent nerve root symptoms (intermittent numbness or tingling) whenever the involved segment extends, indicating mechanical compression. Constant nerve root symptoms could be caused by inflammation and swollen tissue.

**Effect of traction.** Traction has been demonstrated to widen the IV foramina. Positioning the spine in flexion prior to the application of traction provides the greatest increased space.<sup>145,193</sup> Positional traction, in which the patient is placed in side bending away from the side of pain and rotation toward the pain, may also be beneficial to increase the diameter of the lateral foramen.

**Effect of trauma and repetitive irritation.** Swelling in the facet joints from macrotrauma or microtrauma leads to a compromised foraminal space. With degeneration and increased mobility in a spinal segment, instability could be the cause of repetitive microtrauma, leading to swelling and pain.

**Effect of meniscoid tissue.** The meniscoid tissue of the joint capsule may become impinged with sudden movements. This blocks specific movements, such as extension and side bending to the involved side. Manipulation and traction usually relieve the symptoms.

## Indications and Contraindications for Intervention: Flexion Approach

**Indications.** Flexion is used if neurological and/or pain symptoms are eased with flexion and worsened with extension positions or motions.

**CONTRAINDICATIONS:** Extension and extension with rotation positions, motions, and exercises are contraindicated if neurological symptoms or pain worsen with these motions. Flexion exercises are contraindicated if neurological or pain symptoms peripheralize with flexion or repeated flexion maneuvers (see Box 15.9).

## Techniques Utilizing a Flexion Approach

In general, spinal flexion postures and exercises are taught following the guidelines described in Boxes 15.5, 15.7, and 15.8. The following suggestions should also be considered for special conditions.

### Management of Acute Symptoms

#### Patient Education

- As described in the general acute section earlier in this chapter, once the functional position for comfort is identified, encourage the patient to move within pain-free ranges and maintain daily activities that do not exacerbate the symptoms.
- Passive support, such as use of a cervical collar or lumbar corset, is typically not utilized or discussed with the patient except when managing patients with RA or other disorders associated with hypermobility or instability.

#### Functional Position for Comfort

- For flexion bias in the lumbar spine, the position is usually with the hips and knees flexed so the lumbar spine flexes.
- In the cervical spine, the position is toward axial extension (upper cervical flexion) with some flexion also in the lower cervical region.
- If there are neurological signs, the position provides maximal opening of the IV foramina to minimize impingement of the nerve root.

#### Traction

- Gentle intermittent joint distraction and gliding techniques may inhibit painful muscle responses and provide synovial fluid movement in the joint for healing.
- Dosages must be very gentle grade I or II to avoid stretching the capsules and are best applied with manual techniques during the acute stage.
- With spondylosis or stenosis, if a patient does not have signs of acute joint inflammation but does have signs of nerve root irritation, stronger traction forces may be beneficial to cause opening of the IV foramina, which helps relieve the pressure.

**CONTRAINDICATION:** If a patient has RA, traction and joint mobilizations/manipulations in the spine are potentially dangerous because of ligamentous necrosis and vertebral instability; therefore, they should not be performed.<sup>163</sup>

#### Correction of Lateral Shift

If the patient has a lateral shift of the thoracic region along with symptom relief when in flexion, he or she may be taught self-correction.

**Patient position and procedure:** Standing with the leg opposite the shift on a chair so the hip is in about 90° of flexion. The leg on the side of the lateral shift is kept extended. Have the patient then flex the trunk onto the raised thigh and apply pressure by pulling on the ankle (Fig. 15.9).

**FIGURE 15.9** Self-correction of a lateral shift when there is deviation of the trunk as it flexes.

### Correction of Meniscoid Impingements

If there is entrapped synovial or meniscoid tissue in a facet joint that blocks motion into extension, release of the trapped meniscoid relieves the pain and the accompanying muscle guarding. The joint surfaces need to be separated and the joint capsules made taut.<sup>23</sup> General techniques include traction and manipulation.

- Traction to the spine may be applied manually or mechanically. The patient also can be taught self-traction and positional traction techniques. Traction applied longitudinally along the axis of the spine has the effect of sliding the facets' joint surfaces and thus placing tension on the facet capsules. Traction with contralateral side bending and rotation of the spine has the effect of distracting the facet joint surfaces as well as placing tension on the capsules.
- Techniques of manual traction, self-traction, and positional traction with rotation and manipulations are described in the stretching section of Chapter 16.

### Management When Acute Symptoms Have Stabilized

General guidelines for subacute and chronic spinal problems are summarized in Boxes 15.7 and 15.8. Specific emphasis when treating patients with mobility impairments due to hypomobile or hypermobile facet joints should include the following:

- Hypomobile joints require stretching but not if the techniques stress a hypermobile region. Traction techniques may be effective if the hypermobile region is stabilized during stretching. For those trained in joint mobilization/manipulation techniques, these techniques are effective for selective facet joint stretching and have been found to be an effective part of a total treatment approach when there is instability in specific areas and restricted mobility in neighboring facet joints.<sup>182</sup> Emphasis is on developing dynamic stability through muscle control in the hypermobile regions while gaining mobility in the restricted regions.

- Strength and flexibility of the trunk, hip, and shoulder girdle musculature require selective stretching and strengthening.
- If there are bony changes and osteophytic spurs, the patient should avoid postures and activities of hyperextension, such as reaching or looking overhead for prolonged periods of time. Adaptations in the environment might include using a stepstool so reaching is at shoulder level. Postures and motions emphasizing flexion of the spine that increase the size of the IV foramina are usually preferred.
- For patients with RA, emphasis is on stabilization and control. Because of the potential instabilities from necrotic tissue and bone erosion, subluxations and dislocations may cause damage to the spinal cord or vascular supply and can be extremely debilitating or life-threatening.

## Management Guidelines: Stabilization

Patients with segmental instability—including hypermobility; ligamentous laxity; and diagnoses such as spondylolysis, spondylolisthesis, or poor neuromuscular control of the deep segmental and global stabilizing musculature—require interventions that improve stability. Some of the patients may have a history of trauma, repeated manipulations, or early signs of spondylosis. Mobility testing of the spinal segments reveals increased mobility at one or more segments. There may be decreased activity in the stabilizing musculature, particularly in response to postural perturbations, and there may be faulty respiratory patterns. (Additional information on spondylolisthesis is in the final section of this chapter.)

### Identification of Clinical Instability

Stress radiographs are typically used by the medical profession to identify instability. Those with more than 4 mm of translation or 10° of rotation are considered candidates for surgery.<sup>72</sup> Radiographs can identify problems only in the passive structures. To identify impairments in the musculature and the ability to control movement, techniques have been developed that specifically address deep segmental muscle activation and endurance and global muscle stabilization. The following may be used:

- *Quality of movement.* Observe spinal ROM (standing) and note if there is a catch or aberrant movement. Patients may demonstrate difficulty moving smoothly in the midranges as well as a shifting or fluctuation in movement.<sup>75</sup>
- *Control of deep segmental musculature.* In the lumbar region, palpate the TrA and multifidus muscles while the patient attempts to contract them. Devices to measure activation, such as using a biopressure feedback unit or ultrasound imaging, have been developed for both research and clinical usage<sup>113</sup> (see the next section titled Principles of Management as well as Chapter 16).

- *Control of the global musculature.* Several protocols have been developed to test the stabilizing function of the global musculature.<sup>79,92,203</sup> They primarily challenge the isometric holding capability of the anterior, posterior, and lateral trunk musculature under various loads. The passive lumbar extension test, the lumbar extension load test, and the active straight leg raise test have all been shown to be good predictors of patients that may need lumbar stabilization exercises.<sup>199</sup>

## Principles of Management

### Passive Support

Although not usually recommended, braces or corsets may be necessary for support to provide stability and reduce pain when instability is significant.<sup>72</sup> If needed, these devices should be used in conjunction with training the deep segmental musculature for dynamic control.

### Deep Segmental Muscle Activation

Activation of segmental musculature may not be automatic in patients with pain or instability. In addition to verbal and tactile cues, techniques used to instruct patients include use of a biofeedback pressure cuff (Chattanooga®) and ultrasound imaging. Ultrasound imaging is primarily used in research settings because of the cost of the units. The pressure cuff has been shown to have clinical relevance in providing immediate feedback to patients.<sup>113</sup> Use of the cuff for testing and instruction in deep segmental muscle activation of the cervical and lumbar regions is described in detail in the Muscle Performance section of Chapter 16.

Once the patient learns to activate the segmental muscles, emphasis is placed on sustaining the contraction over a period of time and on increasing the repetitions of the static hold to reinforce the postural function. These contractions are of low-intensity to minimize the compressive activity of the global muscles.<sup>83</sup>

### CLINICAL TIP

“Strengthening the core” has become a popular phrase in general exercise programs, with its meaning being applied to any exercise that focuses attention on the trunk musculature (usually the abdominals). For *therapeutic purposes* when managing patients with segmental instability, the emphasis is initially directed toward training activation of the deep segmental muscles, followed by the global trunk muscles, and helping the patient become aware of the difference in the actions and functions of these muscles. These techniques are described in detail in Chapter 16.

### Lumbar Region

Initially, the patient is taught to find and maintain a neutral spinal position using pelvic tilts (midrange). The patient is

then instructed in the “drawing-in maneuver” to activate the TrA, and he or she learns to contract the multifidus by bulging out the muscle. Gentle co-activation of the muscles of the perineum facilitates contraction of these segmental muscles.<sup>173</sup>

### FOCUS ON EVIDENCE

A review of systematic reviews from 2000 to 2011 on core stabilization exercises for chronic LBP summarized that stabilization exercise programs benefit people with nonspecific LBP.<sup>93</sup> Additionally, it is reported that core stabilization is more effective in reducing LBP and improving functional outcomes when compared with conventional exercises.<sup>29,119</sup>

### Cervical Region

The patient is taught to activate the segmental musculature with gentle capital nodding and slight flattening of the cervical lordosis.<sup>83</sup>

### Progression of Stabilization Exercises

- Progress from segmental muscle activation to general stabilization exercises using the global musculature to emphasize cervical and pelvic control while superimposing extremity motions. Include weight-bearing activities, such as wall slides, partial lunges, and partial squats, with emphasis on the “drawing-in” maneuver and spinal control in the neutral spinal position while doing the activities.
- Incorporate functional activities into the stabilization exercise routines. Encourage the patient to activate the segmental musculature consciously and maintain a neutral spinal position until it becomes habitual.

## Management Guidelines: Mobilization/Manipulation

**NOTE:** The terms *manipulation* and *mobilization* are currently being used interchangeably, with a trend toward using the term *manipulation* (see Chapter 5). The authors of this chapter are using *manipulation* to mean graded oscillation techniques and *HVT* to mean high-velocity, small-amplitude motion performed at the end of the pathological limit of the joint. When describing or documenting manipulation techniques used, the clinician is reminded to define the intensity (grade I–IV or HVT) as well as spinal level (target), direction of force application, and patient position.

Some patients benefit from spinal manipulation during the early stages of intervention.<sup>39,43,161</sup> Hypomobile spinal segments may add to stress of hypermobile segments and require a combined approach of manipulation as well as stabilization

exercises.<sup>116,182</sup> Manipulation techniques for the cervical, thoracic, and lumbar spines are described in Chapter 16.

## Management: Lumbar Spine

Following determination of a hypomobile segment in the lumbar spine, perform the general manipulation (using the lumbar roll technique) up to two times followed by instruction in ROM exercises. This is repeated for two sessions, after which the patient is instructed in stabilization exercises and progressed through treatment as summarized in Boxes 15.7 and 15.8.

The lumbopelvic technique used in validation studies<sup>38,39</sup> as well as an alternate technique<sup>43</sup> are described in Chapter 16. The traction procedures described in the nonweight-bearing section earlier in this chapter may also be beneficial.

### FOCUS ON EVIDENCE

In a randomized controlled trial of 71 subjects with LBP, Flynn and associates<sup>68</sup> determined that patients most likely to benefit from spinal manipulation prior to stabilization exercises were those who met four of five of the following criteria: symptom duration less than 16 days; no symptoms distal to the knee; score less than 19 on a fear-avoidance measure; at least one hypomobile lumbar segment; and at least one hip with more than 35° internal rotation. This was validated by Childs and colleagues<sup>38</sup> in a multicenter randomized, controlled trial of 131 consecutive patients.

Fritz and associates<sup>75</sup> reported that those who had positive tests for spinal hypomobility had more successful outcomes if manipulation was included in the interventions and those with hypermobility were more successful if stabilization was included.

The *CPGs for Low Back Pain*<sup>48</sup> cite strong evidence for use of manipulation procedures when treating patients with mobility deficits and acute, subacute, and chronic LBP and back-related buttock or thigh pain in order to reduce pain and improve mobility.

## Management: Cervical Spine

Cervical manipulation, in combination with exercise, has been shown to significantly decrease neck pain<sup>7,63,64,87</sup> as well as increase ROM, upper extremity and neck strength, and endurance.<sup>27</sup> Gross and associates<sup>87</sup> completed a Cochrane review and identified strong evidence in favor of manipulation combined with exercise to decrease pain when compared with a control group.

**NOTE:** The risk of serious or life-threatening injuries has been reported from 1 in 20,000 to 5 in 10 million.<sup>88</sup> In spite of the potential risks,<sup>53,118</sup> many authors have reported there is no risk to damage of the vertebra-basilar artery as a result of cervical thrust joint manipulation.<sup>15,35,101,227</sup> Additionally, cervical thrust

joint manipulation has been shown to decrease pain when compared with traction,<sup>251</sup> to decrease pain and disability, and to improve patient outcomes when compared with nonthrust manipulations.<sup>58,225</sup>

It is important that the thoracic spine is assessed in patients with cervical impairments.<sup>120,132</sup> Not only does the thoracic spine move during cervical motion, but it is prone to mobility impairments. In addition, there are common muscle attachments in both regions. Performing joint manipulation and HVT of the thoracic spine often improves outcomes in patients with cervical complaints.<sup>41,42,120,132,153</sup>

### FOCUS ON EVIDENCE

Cleland and Childs<sup>41</sup> performed thoracic manipulation, exercise, and patient education on 78 patients with neck pain. An 86% success rate was found for patients with three or more of the following criteria: symptoms <30 days; no symptoms distal to the shoulder, cervical extension did not aggravate the symptoms; Fear-Avoidance Belief Questionnaire-Physical Activity Score of <12; diminished upper thoracic kyphosis (T3–5); and cervical extension <30°.

Puentedura and associates<sup>198</sup> identified four clinical variables that predicted success following cervical thrust joint manipulation. The variables were symptom duration less than 38 days, patient expectation that thrust manipulation would be effective, rotation left and right had a difference of greater than or equal to 10°, and pain with posterior to anterior midcervical mobility testing. If three or more variables were identified, there was a 90% chance of short-term success. Additionally, Bishop and associates<sup>21</sup> found that patients who believed manipulation would be successful had better outcomes.

## Management Guidelines: Soft Tissue Injuries

As previously described, symptoms in soft tissues, including muscles, can occur as a result of direct trauma (tears/contusions), strain from sustained or repetitive activities, or as a protective mechanism (guarding/spasm) from injury to joints or other tissues. General guidelines for management are summarized in Boxes 15.5, 15.7, and 15.8. In addition, specific considerations when treating muscle injury are described in this section.

### Management During the Acute Stage: Protection Phase

#### Pain and Inflammation Control

Use appropriate modalities and myofascial release techniques to control pain and inflammation.

### Cervical Region

For serious injuries, cervical collars provide passive support to relieve the muscles from the job of supporting or controlling the injured part. Cervical collars are usually reserved for severe and acute whiplash injuries or postoperative intervention per the physician's recommendations. The length of time a collar is worn during the day relates to the severity of the condition and the amount of protection required. Wean the patient from this form of passive support as soon as possible to minimize dependency on its use.

### Lumbar Region

Corsets provide passive support of the lumbar region and may be used following serious injury or postsurgically. As with the cervical region, the length of time that a corset is worn should be related to the amount of protection required. Some patients tend to become dependent on the corset and continue to wear it even after healing when it no longer serves its intended purpose. During healing, it is better to strengthen the body's natural corset (deep abdominal muscles) and develop effective spinal mechanics (see Chapter 16) than to have the patient rely on passive support.

### Muscle Function

When evaluating muscle function, identify the functional position in which the patient has a decrease in the intensity of symptoms. With a muscle injury, this is often with the muscle in its shortened position. In this position, begin gentle muscle-setting techniques. Dosage is critical; resistance is minimal. Use only enough to generate a setting contraction.

### Cervical Region

**Patient position and procedure:** Supine. Stand at the head of the treatment table, supporting the patient's head with your hands. Start with the guarding muscle in its shortened position. Ask the patient to hold as you apply gentle resistance (light enough to barely move a feather). Both the contraction and the relaxation should be gradual. There should be no neck movement or jerky resistance.

- If there has been muscle injury, the technique is repeated with the muscle kept in the shortened range for several days before beginning to lengthen it.
- As the muscle heals or if there is no muscle injury, progress the treatment by gradually lengthening the guarding muscle after each contraction and relaxation. Movement is performed only within the patient's pain-free range; no stretching is performed when there is muscle guarding.

**Alternate procedure:** Reverse muscle action. These exercises are valuable for gentle muscle performance activity when neck motions cause pain and muscle guarding. The neck is not moved, but the muscles are called on to contract and relax. The motions include active scapular elevation, depression,

adduction, and rotation. If symptoms are not exacerbated, active shoulder flexion, extension, abduction, adduction, and rotation are used to stimulate the stabilizing function of the cervical musculature.

### Lumbar Region

**Patient position and procedure:** Prone, with arms resting at the side. Have the patient lift the head. This initiates a setting (stabilizing) contraction of the lumbar erector spinae muscles. A stronger contraction of the lumbar extensor muscles occurs if the head and thorax are extended. Alternate hip extension also causes a setting contraction of the lumbar extensor muscles.

- When there is muscle injury, the muscle is kept in this shortened range for several days.
- For progression as the muscle heals or if there is no muscle injury, gradually allow the muscle to elongate after each contraction by putting a pillow under the abdomen and having the patient extend the thorax on the lumbar spine through a greater range. Elongation is performed only within tolerance during the early healing phase. There should be no increase in symptoms.

**Alternate position and procedure:** Supine. Have the patient gently press the head and neck into the bed, causing a setting contraction of the spinal extensors.

### Traction

Gentle oscillating traction may reflexively inhibit the pain and help maintain synovial fluid and joint-play motion during the acute stage when the muscles do not allow full ROM. Gentle techniques are most effectively applied using manual traction. Position the part with the injured tissue in a shortened position and use a dosage less than that which causes vertebral separation.

**PRECAUTION:** Traction techniques may aggravate a muscle or soft tissue injury if the tissue is placed in a lengthened position during the setup or with a high dosage of pull during treatment.<sup>169</sup>

### Environmental Adaptation

If there are activities or postures that caused the trauma or are continuing to provoke symptoms, identify the mechanism and modify the activity or environment to eliminate the potential of recurrence of the problem.

## Management in the Subacute and Chronic Stages of Healing: Controlled Motion and Return to Function Phases

Once acute symptoms are under control, re-examine the patient and determine the impairments and activity limitations. Refer to the general guidelines for management as presented in Boxes 15.7 and 15.8.

## Management of Regional Diagnoses

Most spinal pathologies may affect any region in the spine and tend to cluster in the diagnostic categories that are described in the previous section. There are several pathologies unique to the thoracic and lumbopelvic region and several unique to the craniocervical and upper thoracic region; the interventions for these pathologies are described in this section.

### Lower Thoracic and Lumbopelvic Region

#### Compression Fracture Secondary to Osteoporosis

As described earlier in this chapter, compression fractures of the vertebral bodies, secondary to osteoporosis, commonly occur in the thoracolumbar region as a result of axial loading or trunk flexion. Symptoms are provoked with flexion activities.

#### Interventions

- Teach stabilization exercises to promote a neutral thoracolumbar junction and develop spinal stability.
- Teach scapular stabilization exercises to assist with correct posture and decrease the progression of a thoracic kyphosis, commonly seen in people with osteoporosis.
- Stretch the antagonist muscles. These muscles include the shoulder horizontal adductors, internal rotators, hip flexors, and internal rotators.
- Instruct in correct lifting techniques and advise to avoid extreme and prolonged trunk flexion when possible.
- Whenever possible, instruct patients who have osteoporosis in preventative measures and safe exercises as described in the osteoporosis section of Chapter 11.

**CONTRAINDICATIONS:** Avoid trunk flexion activities and exercises, such as bending forward to lift heavy objects and performing toe touch and sit up (crunch) exercises.

#### Spondylolisthesis

Spondylolisthesis is defined as an anterior slippage of one vertebra on the one directly below it. It is graded according to the amount the superior vertebra moves in relation to the one directly below it as identified on a radiograph. Grade I includes all films that demonstrate up to a 25% slippage, grade II is reserved for patients who have a slippage from 26% to 50%, grade III indicates a 51% to 75% slip, and grade IV is more than 75% slippage.<sup>85,245</sup> This pathology can occur at any age and is associated with instability at the involved segment. Spondylolisthesis can be the result of either a congenital

malformation in the pars interarticularis, a traumatic fracture of the vertebral arch, or degenerative changes associated with age or obesity.

#### Physical Therapy Interventions

- Use the flexion approach described in the previous section.
- Stabilization exercises: include both segmental and global stabilization.
- Stretch the hip flexors.
- Gentle manipulations (grades I and II) for pain modulation. Avoid HVT techniques, as they may further exacerbate the symptoms or instability.

#### Ankylosing Spondylitis

This is a rheumatic disorder that results in the eventual ossification of both the anterior and posterior longitudinal spinal ligaments and the facet joints. Ankylosing spondylitis first appears in adolescence and “peaks” in the mid-20s.<sup>80,120,239,241</sup> People with this pathology complain of pain at the bilateral SI joints, thoracic or lumbar spine, shoulder, or foot regions.

Rudwaleit and associates<sup>206</sup> identified the following characteristics in people with ankylosing spondylitis: stiffness >30 minutes of duration, back pain that improves with exercise but not rest, back pain that wakes a person up only during the second half of the night, and alternating buttock pain. It was determined, that if at least three of four of these were present, the positive likelihood ratio was 12:4.

#### Interventions

The primary physical therapy intervention for this pathology is patient education. Patients must have a good understanding of the disease progress (may require a referral to a rheumatologist).

- Educate the patient about the proper, or “functional,” posture before the spine becomes ankylosed. An exaggerated lumbar lordosis is required to facilitate a functional thoracic kyphosis and prevent the person from fusing in a posture in which the entire spine is in a kyphotic posture. This can be accomplished by instructing patients to sleep in a prone position and to use a pillow or towel roll behind their lumbar spine during all sitting activities.
- Gentle manipulations (grades I and II) for pain modulation at the non-ankylosed segments
- Segmental and global trunk stabilization and scapular stabilization exercises are mandatory to strengthen the muscles surrounding the spine.
- Stretch to maintain hip extension and shoulder flexion, as lumbar and thoracic extension may eventually be lost.

#### Scheuermann’s Disease

This pathology is similar to HNP except the nucleus pulposus migrates either superior or inferior versus posterior or posterolateral. Scheuermann’s disease is the result of a weakened vertebral end-plate. This weakness causes a crack and a breakdown

in the weight-bearing ability of the vertebra. The nucleus pulposus then travels to the path of least resistance. Typically, patients with Scheuermann's disease do not have any radicular symptoms as the nerve roots are not involved.

### Interventions

- Segmental and global stabilization exercises
- Stretching of tight muscles
- Posture education
- Joint manipulation may be used either for pain modulation or to improve ROM.<sup>125</sup> However, use caution with high-velocity techniques.

## Rib Subluxation

The ribs articulate with the thoracic spine and move with all arm and thoracic activities. The place/location where the rib articulates with the thoracic spine is called a costovertebral joint. These joints can become sprained, or displaced, during twisting activities (unloading the trunk of a car or swinging a golf club), trauma (motor vehicle collision or fall), or following a period of prolonged sickness in which repetitive or aggressive coughing was involved. Radicular pain (intercostal nerve) may or may not be involved depending on the mechanism and severity of the injury. Muscle energy (ME) techniques may be used to correct either a posterior or anterior rib hypomobility.

### Interventions VIDEO 15.1

**ME technique to correct a rib that has been forced and stuck in a posterior position.**

- **Patient position:** sitting.
- **Technique:** Stand on the involved side. Place one hand lateral to the rib angle while resisting horizontal adduction (isometrically) with the other hand (Fig 15.10). During the isometric contraction, elicit an anteromedial force at the rib, attempting to improve movement. Hold the contraction and force for 3 to 5 seconds and repeat three to five times.

**FIGURE 15.10** ME technique to correct a posterior rib.

**ME to correct a rib that has been forced and stuck in an anterior position.**

- **Patient position:** sitting.
- **Technique:** Stand on the uninvolved side. Place hand medial to the rib angle while resisting horizontal abduction with the other hand (Fig. 15.11). During the isometric contraction, elicit a posterolateral force at the rib attempting to improve movement. The contraction and force are held for 3 to 5 seconds and repeated three to five times. A thorough assessment of the thoracic facet and IV facet joints is also indicated.

### CLINICAL TIP

In addition to ME techniques to correct rib dysfunctions, examine thoracic IV mobility and scapular muscular strength since the function of these areas may also be affected with impairments of the costovertebral joints. Thoracic IV manipulations are described in Chapter 16; scapular stabilization exercises are presented in Chapter 17.

## Sacroiliac Joint Dysfunction

SI joint sprain has been shown to occur in 10% to 33% of the patient population.<sup>8,23,56,57,150,219</sup> Impairments can be either traumatic or insidious onset. Patients will frequently complain of pain localized to the SI joint region with or without radiculopathy depending on the involvement of the sciatic nerve. Pain is usually relieved with rest and/or by unweighting the joint. Unresolved inflammation or a traumatic etiology may yield a hypomobile SI joint. It is beyond the scope of this textbook to discuss all the hypomobility impairments as they pertain to the sacrum and innominate. Four common impairments include pubic symphysis hypomobility, an anterior rotated innominate, a posterior rotated innominate, and an upslipped innominate (Fig. 15.12). The first three can be corrected with ME techniques, while the fourth may require a HVT.

**FIGURE 15.11** ME technique to correct an anterior rib.

**FIGURE 15.12** (A) Normal relationship of the sacrum and innominate, (B) anterior rotated innominate showing the ASIS inferior and PSIS superior, (C) posterior rotated innominate showing the ASIS superior and PSIS inferior, (D) upslipped innominate showing ASIS and PSIS superior on the right compared to contralateral side.

### Identification of SI Joint Impairments

- **Observation and findings.** With the patient standing, view from the posterior aspect. Look for symmetry in the heights of the iliac crests, posterior superior iliac spines, and anterior superior iliac spines. With your hands on these bony landmarks, have the patient march in place (March Test) and observe movement of the innominate. If there are positive signs, conduct additional tests, supine and prone lying, to verify SI joint involvement.<sup>56,149,197</sup>
- **General SI joint hypomobility.** The pelvis will “rise up” on the restricted side during the March Test.
- **Anterior rotated innominate.** The posterior superior iliac spine (PSIS) will be higher and the anterior superior iliac spine (ASIS) will be lower on the involved side.
- **Posterior rotated innominate.** The PSIS will be lower and the ASIS will be higher on the involved side.
- **Upslipped innominate.** All bony landmarks of the pelvis will be higher on the side of the upslip.

### Interventions VIDEO 15.2

**“Shot-gun” technique.** The “shot-gun” technique is used to treat both pubic symphysis and general SI joint hypomobility. The idea used to describe the mechanics of this technique is that it creates a gapping followed by a compression of the pubic symphysis joint to improve mobility, although no known studies have confirmed this concept.

- **Patient position:** Supine in a hook-lying position.
- **Technique:** Instruct the patient to contract against your resistance to submaximal contractions, alternating between hip

abduction and adduction for a series of three to five repetitions holding each contraction for 3 to 5 seconds (Fig. 15.13).

#### ME techniques to correct an anterior rotated innominate.

ME techniques to correct an anterior rotated pelvis use the force generated by the contracting gluteus maximus to rotate the innominate posteriorly.

- **Patient position:** Supine.
- **Technique:** Flex the involved hip to the point of pain and/or restriction, then resists a series of submaximal isometric hip extension contractions (Fig. 15.14).

#### ME technique to correct a posterior rotated innominate.

A patient that has a posterior rotated innominate can be treated with ME techniques using the rectus femoris muscle.

- **Patient position:** Prone.
- **Technique:** Passively extend the involved extremity to the restriction or point of pain, then resists a series of submaximal isometric hip flexion contractions (Fig. 15.15). With one hand on the pelvis, assist gliding the pelvis anteriorly by pushing on the posterior superior iliac spine when the other hand lifts the femur.

**HVT to treat an upslipped innominate.** An upslip is usually the result of trauma (such as a fall) or scoliosis. Treatment utilizes a HVT rather than an ME technique. VIDEO 15.3

- **Patient position:** Supine.
- **Technique:** Hold the ankle on the side of the involved pelvis. Place the extremity in slight hip extension, abduction, and internal rotation. This will place the SI joint in a loose pack

**FIGURE 15.13** “Shot-gun” ME technique.

**FIGURE 15.14** ME technique of the gluteus maximus to correct an anteriorly rotated innominate bone.

**FIGURE 15.15** ME technique of the rectus femoris to correct a posteriorly rotated innominate bone.

position while providing maximum stability to the hip joint. After a series of two to three inhalations and exhalations by the patient, provide a quick “tug” during the final exhalation (Fig. 15.16).

**FIGURE 15.16** HVT to correct an upslip of the innominate bone.

## Cervical and Upper Thoracic Region

The anatomy and arthrokinematics of the craniocervical region are described in Chapter 14, and physical therapy interventions are discussed in Chapter 16. It is, however, necessary to discuss the significance of this region as both a transitional area from the neck to the head and the precautions needed with respect to the vertebral artery as it courses through this region.

This region is important because the *greater occipital nerve* (sensory branch of C2) pierces the semispinalis capitis muscle prior to providing innervation to the posterior scalp. Irritation of this nerve can be a major cause of headaches.

This craniovertebral area is also important, as it pertains to the vulnerability of the *vertebral artery*. The two vertebral arteries arise from the subclavian arteries prior to entering the transverse foramen of C6, bilaterally, and traveling up through C1. These arteries are responsible for providing 20% of the blood to the brain. After they pass through C1, the arteries travel along the superior surface of the atlas before entering the brain through the foramen magnum.

**PRECAUTIONS AND CONTRAINDICATIONS:** Extreme caution should be used during grade IV manipulations, HVT, ME techniques, and manual traction so as not to occlude these arteries. Only 45° of rotation is enough to “kink” the artery, and the lumen can narrow up to 90% of its original size with contralateral side bending.<sup>85,192</sup> This can be exaggerated when coupled with backward bending. If the patient has a history of instability, such as RA or long-term steroid use, or complains

of dizziness or balance impairments, manipulative movements of the cranio-vertebral region should not be done.

Additional risk factors include cervical trauma in the past month, recent infection, hypertension, migraine headaches without aura, low cholesterol, and low body mass index.<sup>47</sup> Cervical arterial dissection, which is a tear or hematoma in the wall of the vertebral or internal carotid artery, has been reported as a potential complication in a very small population of individuals. Early warning signs of dissection were summarized in a prospective case control study; they include transient ischemic neurological features, blurred vision, and imbalance, as well as dizziness, dysphasia, and paresthesia and weakness in the arm.<sup>230</sup>

### CLINICAL TIP

If a patient reports dizziness that is associated with movement, be cautious with examination and intervention techniques that use rotation or extension of the upper cervical spine.

Specific treatment of headaches and selected cervical impairments are discussed in the following sections.

## Tension Headache/Cervical Headache

According to the International Headache Society, the three categories of headaches are primary (migraine, cluster, or tension), secondary (headaches caused by another disorder), and cranial neuralgias.<sup>229</sup> Secondary headaches include those that result from cervical spine impairments (musculoskeletal) or temporomandibular dysfunction (TMD). Musculoskeletal headaches are a common complaint with impaired posture. About 15% to 20% of chronic and recurrent headaches are diagnosed as cervical headaches and are related to musculoskeletal impairments.<sup>122</sup> Often, there is associated tension in the posterior cervical muscles and pain at the attachment of the cervical extensors, at the cervicothoracic junction, and/or radiating across the top, side, or back of the scalp.

### Etiology

There are many factors that may cause a cervical headache.<sup>156</sup> Headaches may follow soft tissue injury or may be caused by faulty or sustained postures, greater occipital nerve irritation or impingement, or sustained muscle contraction (from faulty posture or emotional tension) leading to ischemia. Cervical muscle trigger points can all contribute to pain in the craniofacial region.<sup>10,123,142,232,244</sup> With cervical headaches, the joints, ligaments, and neuronal structures of the upper cervical spine are often inflamed or in dysfunction.<sup>13,61,77,181</sup> This includes inflammation of cranial nerves V, VII, IX, X, and XI as they descend into the grey matter of C1–3 and provide sensation to the face, forehead, orbit, sinuses, and TMJ region.<sup>192</sup>

Headaches may be related to TMJ dysfunction<sup>147,180</sup> or other conditions, including cardiovascular,<sup>70,136</sup> systemic inflammation,<sup>24,137,205</sup> allergies, or sinusitis.<sup>5</sup> Cervical impairments, which may lead to headaches, can also arise from faulty thoracic joint mobility.<sup>120,132</sup> Whatever the cause, there usually is a cycle of pain, muscle contraction, decreased circulation, and more pain, which leads to decreased function and potential soft tissue and joint impairments.

### Presenting Signs and Symptoms

Therapists can effectively treat headaches if they were caused by trauma or stress or if function triggers the onset and/or pain begins in the neck and becomes a headache.<sup>218</sup> Differentiating cervical headaches and related impairments in the musculoskeletal system from other kinds of headaches, such as cluster or migraine headaches, is important for developing a plan of care that effectively manages the headaches. Box 15.10 identifies common history and symptoms associated with cervical headaches as well as red flags that require referral to a physician.<sup>122</sup>

#### BOX 15.10 History and Symptoms of Cervical Headaches

- Unilateral headaches or bilateral headaches with one side predominant
- Pain in the neck or suboccipital region that spreads into the head
- Intensity can fluctuate between mild, moderate, or severe
- Precipitated by sustained neck postures or movements
- May be precipitated by stress (also common with other types of headache)
- May be related to trauma, DJD, or a sedentary lifestyle and postural stresses
- More prevalent in females but no familial tendency
- Pain or altered sensation in the face or TMJ region

#### Red Flags and Precautions

A referral to a physician is indicated if the patient complains of any of the following, as the headache is probably not of musculoskeletal origin.

- States this is either the first or worst headache they have ever experienced
- Reports sharp pain or spikes in intensity
- Reports headaches come in bunches; i.e., throughout the day or over several hours, the headaches come and go
- A change in personality or behavior is reported

#### Refer to a specialist with the following reported history and headache<sup>88</sup>

- Positive cardiac history or signs, send to a cardiologist
- Bilateral pain or in multiple joints, send to a rheumatologist
- Sinusitis, facial pain, nasal congestion or pressure, send to ENT
- Vision loss/disturbances or pain with eye movement, send to ophthalmologist
- TMD symptoms, send to pain center or dentist

### Musculoskeletal Impairments

Musculoskeletal impairments include:

- Joint impairments in the upper cervical spine and craniovertebral region (pain and motion restrictions).
- Impaired muscle performance (impaired tonic postural control and endurance in upper and deep cervical flexors and possibly multifidus and small posterior suboccipital muscles).<sup>122</sup>
- Impaired shoulder girdle/scapular posture with related muscle imbalances.
- Impaired lumbar posture with related muscle imbalances.<sup>156</sup>
- Impaired neural tissue from pressure or inflammation in the upper cervical/craniovertebral region.
- Impaired neuromotor control.
- Impaired upper thoracic mobility.

### General Management Guidelines

Management is directed toward reversing physical impairments, including posture correction, stress management, and prevention of future episodes.<sup>122</sup>

#### Pain Management

Modalities, massage, and muscle-setting exercises are used to break into the cycle of pain and muscle tension.

**Soft tissue techniques and myofascial release.** Various forms of soft tissue mobilization, myofascial release, and trigger point release have been reported to decrease pain intensity and improve cervical ROM.<sup>67,115,117,166</sup>

**Dry needling.** This manual therapy intervention has been reported to decrease pain both immediately and for a 4-week follow-up.<sup>124,128</sup>

**NOTE:** The inclusion of soft tissue, myofascial release, and dry needling techniques are beyond the scope of this textbook.

#### Mobility and Muscle Performance

Examine the flexibility and strength of the muscles in the cervical, upper thoracic, shoulder girdle, and lumbar spine and design an exercise program to regain a balance in flexibility and neuromuscular control in conjunction with posture correction and training as described in Chapter 14 (see Boxes 14.2 and 14.3). Interventions that have been reported to decrease the intensity and incidence of cervical headaches include the following.<sup>28,67,115,117,122,124,128,156,166</sup>

**Mobility and flexibility.** Increase joint mobility in the cervical spine and flexibility in the suboccipital muscles to relieve tension in that region as well as to activate and train the deep cervical flexors for control of capital flexion and cervical retraction (described in Chapter 16). Control and support from the deep segmental muscles are the foundation of management.

**Cervical stabilization.** Utilize cervical stabilization exercises as described in detail in Chapter 16, emphasizing tonic

holding of the deep segmental muscles in isolation from the global muscles.<sup>122</sup>

**Scapular stabilization and posture.** Train the lower trapezius, rhomboids, and serratus anterior muscles in tonic holding postures to improve control of scapulothoracic posture (described in Chapter 17). Exercise prescription should focus on the endurance aspects of these muscles.<sup>28</sup>

#### Stress Management

If the person is in tension-producing situations, relaxation techniques, ROM and muscle-setting techniques, and proper spinal mechanics are taught.

### FOCUS ON EVIDENCE

Jull and associates<sup>121</sup> conducted a multicenter, randomized, controlled study of 200 individuals with cervicogenic headache. They looked at the effectiveness of manipulative therapy and a low-load exercise program alone and in combination compared to a control group and found that both interventions reduced headache frequency and intensity and reduced neck pain compared to that in the control group and that the effects were maintained at the 12-month follow-up. The exercise intervention primarily consisted of training postural control of the longus colli and other deep neck flexors as well as the serratus anterior and lower trapezius muscles and increasing muscular endurance. (See Chapter 16 for a description of the cervical stabilization exercises and Chapter 17 for a description of the scapular stabilizing exercises.) Postural correction exercises were also performed throughout the day and progressed to isometric resistance and flexibility exercises.

**Prevention.** Underlying the prevention of future episodes of cervical headaches is the education of the patient to correct postural stresses; maintain a healthy balance in the length and strength of the postural muscles; and adapt the home, work, or recreational environment to minimize sustained or repetitive faulty postural alignment.

### Neck Pain

It is estimated that 22% to 70% of the American population will have neck pain in their life. Prevalence increases with age, and nearly 37% of people have neck pain that lasts longer than 12 months. Almost 25% of all patients seen in outpatient physical therapy clinics have this complaint.<sup>37</sup>

Therapy interventions for cervical pain follow the same guidelines described earlier (see Management Guidelines in Boxes 15.5, 15.7, and 15.8). As identified in the Hypomobility: Manipulation section, it is important to assess and treat the thoracic spine in people with cervical impairments<sup>132</sup> because not only does the thoracic spine move

during cervical motions, influence cervical posture, and have common muscle attachments, but also because the thoracic spine is prone to hypomobility impairments. Performing joint manipulation and HVT to the thoracic spine will often improve outcomes in people with cervical symptoms.<sup>41,120,132</sup> Patients with neck pain also report more symptoms of TMJ dysfunction than healthy controls (see management guidelines for TMJ Dysfunction later in this chapter).<sup>52</sup>

### FOCUS ON EVIDENCE

The summary recommendations for interventions in the treatment of neck pain published in the *CPGs for Neck Pain*<sup>37</sup> include:

- cervical mobilization/manipulation based on strong evidence;
- thoracic mobilization/manipulation based on weak evidence;
- targeted stretching exercises based on weak evidence;
- coordination, strengthening, and endurance exercises based on strong evidence;
- upper quarter and nerve mobilization based on moderate evidence;
- traction based on moderate evidence; and
- patient education and counselling based on strong evidence.

Raney and colleagues<sup>200</sup> applied mechanical traction to 68 patients with neck pain for 15 minutes each session. Mechanical traction was found to be 90% successful in 90% of the patients if they met four of the five following criteria: (1) patient reported peripheralization with C4–7 mobility testing; (2) patient had a positive abduction sign; (3) patient was age 55 years or older; (4) patient returned a positive median nerve tension test; and (5) patient experienced relief of symptoms with manual distraction.

Tseng<sup>233</sup> followed 100 patients with neck pain and identified six variables for patient success with manipulation. The authors concluded that if the patients met four of the following criteria their chance for success using cervical manipulation was 89%. The variables were (1) initial Neck Disability index <11.5, (2) bilateral involvement pattern, (3) not performing sedentary work >5 hours each day, (4) feeling better while moving neck, (5) did not feel worse with neck extension, and (6) diagnosis of spondylosis without radiculopathy.

## Cervical Radiculopathy

Neck pain with pain and/or neurologic symptoms extending into the arm can be the result of several pathologic conditions, including narrowing of the IV foramen from inflammation and/or degenerative changes in the facets or the IV discs. Thus, foraminal stenosis with accompanying neurologic signs require

careful examination as to what positions, motions, and activities lead to symptom production as well as symptom relief. Interventions are then directed toward relieving the symptoms. Interventions typically include:

- Cervical traction
- Cervical stabilization exercises that emphasize training, strengthening, and developing endurance in the deep cervical flexors, axial extension/cervical retraction, and scapular posture (these are described in detail in Chapter 16)
- Posture training with emphasis on postures that relieve symptoms (Chapter 14)

### FOCUS ON EVIDENCE

Fritz and associates<sup>74</sup> randomized 86 people with cervical radiculopathy into three different intervention groups for 4 weeks of treatment and followed them for 12 months after the conclusion of therapy. All patients were told to remain active and perform exercises every day. The groups were: exercise alone, exercise with intermittent mechanical traction (performed supine, and exercise with over the door traction (for home use). The mechanical traction group had significantly improved Neck Disability Index scores at both 6 and 12 months with respect to the other groups. The exercises used in the study included scapular strengthening and cervical stabilization exercises to the deep cervical flexors.

A systematic review<sup>231</sup> summarized that patients with cervical radiculopathy have a favorable natural course of recovery. The review identified that use of a collar was no more effective than physical therapy or traction. It was also reported that traction was no more effective than placebo traction.

Cleland and associates<sup>42</sup> identified 96 consecutive patients with cervical radiculopathy. Patients had a 90% success rate using an intervention manual therapy, traction, and deep neck flexor strengthening exercises if they met the following criteria: <54 years old; dominant hand not affected; looking down did not worsen the symptoms; and ME and/or thrust, traction, and deep neck flexor muscle strengthening used  $\geq 50\%$  of the time during PT sessions.

## Cervical Myelopathy

Cervical myelopathy is a disease of the spinal cord.<sup>192</sup> It results from degeneration or stenosis of the central spinal canal. The prevalence of this disease is unknown. A person with cervical myelopathy may experience neurological symptoms in both his hands and feet. In addition to an uncoordinated gait, people who have cervical myelopathy may experience a variety of upper motor neuron lesions, including bowel and bladder impairments. Myelomalacia, seen on a MRI film, is the gold standard for the accurate diagnosis of this pathology.<sup>45</sup> There are no neurologic tests or signs that offer both a high sensitivity and specificity.<sup>45</sup>

Therapy interventions are based on the associated impairments and identifying the cause. As this pathology is caused by degeneration, stenosis, or spondylosis, the intervention sequence for cervical myelopathy will follow the same guidelines as described under those pathologies. This includes scapular stabilization, posture education, and cervical and thoracic joint manipulations.

### FOCUS ON EVIDENCE

Rhee and associates<sup>202</sup> conducted a systematic review of the literature from January 1956 through November 2012 that compared conservative treatment with surgery for outcomes of patients with myelopathy. Only 1 randomized control trial was identified that favored conservative care over surgery in patients with mild myelopathy. Since cervical myelopathy is typically a progressive disorder, the overall recommendation is that patients need to be monitored for neurological deterioration. Additionally, patients with moderate to severe symptoms need to be counselled that even a minor traumatic event could significantly worsen their neurological status.

## Temporomandibular Joint Dysfunction

The function of the TMJ is closely related to the function of the upper cervical spine and posture. In 44% of patient cases, neck pain is associated with TMD.<sup>238</sup> Because of this close relationship and co-occurrence of neck pain and jaw dysfunction, a brief description of the structure, function, impairments, and interventions related to the TMJ are included.

### Structure and Function

Each TMJ is described as a ginglymoarthrodial joint (combination of a hinge and plane joint), consisting of the mandibular condyle articulating with the TM disc and glenoid fossa of the temporal bone (Fig. 15.17). Together, these joints perform tasks such as chewing, talking, and yawning.

**Motions of the TMJs.** The motions available at the TMJs include mandibular depression (mouth opening), lateral deviation, and protrusion.

- During mandibular depression, the condyle both rolls and slides anterior on the TM disc while the disc also slides anterior to maintain a congruent surface with the fossa (Fig. 15.18). Mouth opening is primarily facilitated by gravity with minimal assistance from the anterior digastric and the lateral pterygoid muscles.
- Protrusion occurs when both TMJs slide anteriorly.
- Lateral excursion involves the ipsilateral TMJ spinning in place with the contralateral TMJ sliding anterior. Both protrusion and lateral excursion are needed when grinding small foods, like lettuce.

FIGURE 15.17 Structure of the TMJ.

### Signs and Symptoms

The three cardinal (main) signs of TMJ impairments are:<sup>51,60,82,162,171,172,179</sup>

- Pain in the TMJ region that is affected by movement.
- Joint noise during movement.
- Restrictions or limitations with jaw movement.

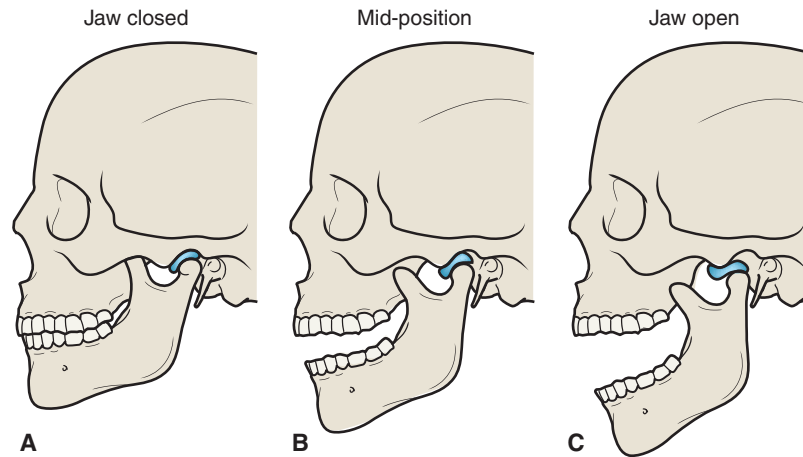

Pain from a variety of sources is often cited as part of the TM joint syndrome.<sup>174</sup>

- Pain may occur locally in the TMJ, in the richly vascularized and highly innervated retrodiscal pad located in the posterior region of the joint or in the ear.
- Pain from muscle spasm or myofascial pain in the masseter, temporalis, or the medial or lateral pterygoid muscles may be described as a headache or facial pain.
- Tension in the muscles of the cervical spine may itself be painful or cause referenced pain from irritation of the greater occipital nerve that may be described as a tension headache.

### Etiology of Symptoms

TM joint impairments and pain are usually the result of trauma, poor posture, or faulty movement patterns. Additionally, symptoms can result from:

- Poor oral hygiene
- Gum chewing
- Heavy kissing
- Bruxism (grinding the teeth)
- Smoking

**FIGURE 15.18** Mandibular depression: (A) relationship of the condyle, TM disc and glenoid fossa with jaw closed; (B) as the jaw opens the condyle rolls on the TM disc, then (C) the disc and condyle slid anterior on the articular eminence.

- Inflammatory conditions such as RA
- Open mouth breathing

### Relationship to Neck Pain

Two theories have been proposed as to why neck pain may cause TMJ discomfort.<sup>215</sup> Causes may be:

- A result of the neurophysiological influences from pain in masticatory muscles via the tonic neck reflex and/or the agonist/antagonist relationship of the anterior and posterior cervical muscles.
- Patients with neck pain respond by bruxing (grinding the teeth), which may lead to muscle or TMJ pain.

### Mechanical Imbalances

Imbalance that occurs between the head, jaw, neck, and shoulder girdle may also precipitate TMD signs and symptoms. Causes may be:

- Malocclusion, decreased vertical dimension of the bite, or other dental problems.<sup>134</sup>
- Faulty joint mechanics from inflammation, subluxation of the meniscus (disc), dislocation of the condylar head, joint contractures, or asymmetrical forces from jaw and bite imbalances. Restricted motion results from periods of immobilization after reconstructive surgery or fracture of the jaw.
- Muscle spasm in the muscles of mastication, causing abnormal or asymmetrical joint forces. Muscle spasm can be the result of emotional tension, faulty joint mechanics, direct or indirect injury, or a postural dysfunction.
- Sinus problems, resulting in mouth breathing, which indirectly affects posture and jaw position.
- Forward-head posture resulting in retraction of the mandible, which places the anterior throat muscles in a lengthened position. Consequently, there is increased activity in the muscles that close the jaw to counter the mandibular depression force caused by the digastric muscles. Extension

of the head on the upper cervical spine places the muscles and soft tissue in the suboccipital region in a shortened position, so they lose flexibility. Also, the nerves and joints in the upper cervical region become compressed or irritated.

- Sudden trauma, such as a flexion/extension accident in which the jaw forcefully opens when the head whips back into hyperextension; a direct blow from an auto accident, boxing, a fall, or similar trauma.
- Sustained trauma associated with prolonged dental surgery in which the mouth is held open for a lengthy period of time may initiate symptoms in the TMJ or supporting tissue. Excessive stresses, such as biting or chewing on large pieces of hard food, may also traumatize the joints.

### Principles of Management and Interventions

The approach to management depends on the cause of symptoms and/or functional limitations. It is important to remember that “aggressive and irreversible treatments” should be avoided if possible.<sup>84</sup> In simple cases in which posture, joint dysfunction, or muscle imbalances are the source of the problem, intervention with therapeutic exercise can directly address the impairments. In most cases, a dental referral, otolaryngology referral, or psychological support may be necessary to deal with related pathology.<sup>95</sup> A complete evaluation is necessary prior to initiation of any treatment. Successful management of TMJ impairments is directly related to the accuracy of diagnosing the underlying pathology.<sup>54</sup>

### Reduction of Pain and Muscle Guarding

Use of modalities for pain modulation and relaxation are often indicated during acute and painful episodes. Extra- and intra-oral myofascial techniques are indicated to improve joint and muscle mobility and decrease pain. In addition, the person should eat soft foods and avoid items requiring excessive jaw opening (i.e., apple, corn on the cob, large sandwich)

or firm biting (i.e., carrots) and repetitive chewing motions (i.e., gum).

### Soft Tissue Techniques

The following soft tissue techniques can be performed by the therapist and/or incorporated into a home exercise regimen. These techniques are suggested to reduce muscle tension and/or improve mobility in the TMJ region:

- *Extra-oral massage.* Perform using a circular motion technique in the region of either the masseter or temporalis muscle. Use a gentle massaging motion to facilitate muscle relaxation.
- *Intra-oral trigger point release.* Identify a point of muscle tension within either the temporalis or masseter tendons. Maintain gentle finger point pressure until the muscle is felt to relax. Repeat at multiple areas of the muscle where muscle tension is identified.
- *A petrous sinus release.* This technique is indicated in patients with TMJ pain and limitations due to muscle guarding and/or sinus involvement. Place one finger on the buccal side of the maxillary teeth and move posterior and cephalad. Once resistance is met, then maintain pressure until a “release” or softening of the muscle occurs. It is judicious to advise the patient that this technique may be a little uncomfortable.

### Fascial Muscle Relaxation and Tongue Proprioception and Control

The following are suggested techniques:

- Place the tip of the tongue on the hard palate behind the front teeth and draw little circles or letters on the palate. For additional stimulus, place a Lifesaver® between the tongue and palate; then follow the circular edge with the tip of the tongue.
- Place the tip of the tongue on the hard palate and blow air out to vibrate the tongue, making an “r r r” sound.
- Fill the cheeks with air (mouth closed); then let the air out in a puff.
- Make a “clicking” sound with the tongue on the roof of the mouth. When doing so, the jaw drops open quickly and returns with the teeth slightly apart, and the tongue usually rests on the hard palate behind the front teeth. This is the resting position of the jaw and is also the first step in teaching relaxation exercises. (Relaxation exercises are described in Chapter 14.)

### Control of Jaw Muscles and Joint Proprioception

First, teach recognition of the resting position of the jaw. The lips are closed, teeth slightly apart, and tongue resting lightly on the hard palate behind the front teeth. The patient should breathe in and out slowly through the nose, using diaphragmatic breathing. Resting position of the jaw should be maintained throughout the day.

- Teach control while opening and closing the jaw through the first half of the ROM. With the tongue on the roof of

the mouth, the patient opens the mouth, trying to keep the chin in the midline. Use a mirror for visual reinforcement. The patient is also taught to lightly palpate the lateral pole of each condyle of the mandible bilaterally and attempt to maintain symmetry between movement of the two sides when opening and closing the mouth.

- An alternative for training joint proprioception is to have the patient place one finger on a maxillary canine tooth (i.e., cuspid). The patient slowly opens and closes his or her mouth, attempting to bring the corresponding mandibular canine in contact with his or her finger during end-range mandibular elevation. The technique can be advanced by instructing the patient to begin in lateral excursion and then attempt to return his or her mandible to the correct position.
- If the jaw deviates while opening or closing, have the patient practice lateral deviation to the opposite side. The lateral motion should not be excessive or cause pain.
- Progress to applying gentle resistance with the thumb against the chin. Do not overpower the muscles.

### Stretching Techniques

If there is restricted jaw opening, determine if it is from hypomobile tissues or a dislocated meniscus. Passive stretching and joint mobilization/manipulation are used to stretch tight tissues. Joint distraction can be used to reposition a meniscus that is blocking opening.

#### Passive Stretching

Stretch to increase jaw opening if indicated. Begin by placing layered tongue depressors between the central incisors. The patient can gradually work to increase the amount of tongue depressors used until he or she can open approximately far enough to insert the knuckles of the index and middle fingers.

- Self-stretching is carried out by placing each thumb under the upper teeth and the index or middle fingers over the lower teeth and pushing the teeth open.

#### Joint Manipulation Techniques **VIDEO 15.4**

**Patient position and procedures:** Supine or sitting, with the head supported and stabilized. Perform joint techniques with a gloved hand or hands. Determination of dosages and precautions for administration of manipulative techniques are described in Chapter 5.

- *Unilateral distraction* (Fig. 15.19 A). Use the hand opposite the side on which you are working. Place your thumb in the patient’s mouth on the back molars; the fingers are outside and wrapped around the jaw. The force is in a downward (caudal) direction.
- *Unilateral distraction with glide* (Fig. 15.19 B). After distracting the jaw as described above, pull it in a forward (anterior) direction with a tipping motion. The other hand can be placed over the TMJ to palpate the amount of movement.
- *Bilateral distraction* (Fig. 15.20). If the patient is supine, stand at the head of the treatment table. If the patient is

**FIGURE 15.19** Unilateral mobilization of the temporomandibular joint. **(A)** Distraction is in a caudal direction. **(B)** Arrow indicates distraction with glide in a caudal, then anterior direction.

**FIGURE 15.20** Bilateral distraction of the temporomandibular joint with the patient supine.

sitting, stand in front of the patient. Use both thumbs, placing them on the molars on each side of the mandible. The fingers are wrapped around the jaw. The force from the thumbs is equal in a caudal direction.

- *Self-manipulation.* Place cotton dental rolls between the back teeth and have the patient bite down. This distracts the condyles from the fossae in the joints.

### Reduction of Upper Quarter Muscle Imbalances

Identify flexibility and strength imbalances in the upper quarter. Stretch restricting postural muscles, teach relaxation, and then retrain for proper muscle control. Cervical and shoulder postural stretching and retraining exercises are described in Chapters 16 and 17, respectively.

## Independent Learning Activities

### Critical Thinking and Discussion

1. What are the functional differences between the way the cervical spine and lumbar spine are used in daily activities?
2. Explain how different individuals who sustain back injuries can experience different symptoms of radiating pain down the leg, numbness and tingling into the foot, deep aching down the leg, or no leg symptoms at all. What does each of these symptoms mean?
3. Explain why some people experience diminished symptoms and improved function if the emphasis of intervention is spinal extension, whereas others improve if the emphasis of intervention is spinal flexion.
4. Identify three common causes of musculoskeletal headaches. What are the indications of headaches that could be identified that would warrant a referral to a medical physician?

### Laboratory Practice

1. Practice identifying cervical and lumbar spine positions when in the supine, prone, side-lying, sitting, and standing

positions. Determine what is needed to change the position. For instance, if flexion is emphasized, what is needed to cause extension?

2. Identify and feel what happens to the various portions of the spine when moving from one position to another, such as rolling supine to prone and return, moving from supine to sit, moving from sit to stand, and reverse.
3. Practice methods for developing gentle isometric muscle contractions that could be used during the acute phase of treatment for both the cervical and lumbar spines.
4. Practice the various proprioceptive exercises and manipulation techniques for the TMJ region.
5. Create a list of pros/cons comparing and contrasting cervical mobilizations with high velocity thrust techniques. What are the safety precautions associated with these techniques? Perform the vertebral artery test on a lab partner. Given a low sensitivity, how does this affect your interpretation of the test results?

## Case Studies

### Case 1

A 45-year-old man sustained injuries in a rear-end collision 4 days ago (a car hit him going approximately 45 mph while he was stopped at a stop light). He was in an older car without an air bag or properly positioned headrest, although he was wearing a seatbelt. Initially, he hit the headrest at the mid-cervical spine as his neck extended, and then his head flexed forward but did not hit anything. He has been cleared of cervical fractures or instability. Medical history is unremarkable; he is a social drinker and gave up smoking 5 years ago. He is an accountant and usually works long hours at a computer but has been unable to work since the accident. He presents wearing a cervical collar and has a facial expression of distress. He states he has had difficulty sleeping because the pain wakes him whenever he moves.

**Pain:** constant posterior cervical pain, headaches, and pain radiating into the shoulder region bilaterally; intermittent tingling in the right thumb, index, and middle finger. Pain rated at 8/10 when at rest, 10/10 when attempting to move.

**Positive findings:** guarded forward-head posture. He is unwilling to move more than 10° into flexion or extension, 25° into side bending bilaterally; minimal rotation. Gentle traction to the head relieves the neurological symptoms. Palpation tenderness in upper trapezius and posterior cervical and anterior throat muscles bilaterally. Increased tenderness along facet margins of C4–5, 5–6 and 6–7, right > left.

- Based on the above impairments and functional limitations, identify goals and interventions for this patient. Describe the techniques you would use and practice them on a lab partner.
- How long do you anticipate the patient will have these symptoms? At what point will you change your goals?

### Case 2

Assume you did not see the patient described in Case Study 1 until 4 weeks after the accident. He no longer has constant pain and has returned to work. His complaints are an inability to sit at the computer for more than 30 minutes before his hand starts to tingle. Numbness occurs after 1 hour of work. Headaches begin within 2 hours of work. Neck and shoulder pain is 6/10 by midday at which time he takes NSAIDs so he can continue working. Positive tests include forward-head posture with forward shoulders; decreased flexibility in the suboccipital muscles, anterior thorax, and internal rotators of the shoulder. Cervical flexion is 75%, extension 50%, and side bending and rotation 75% bilaterally. Sustained extension of the cervical spine causes tingling in the thumb, index, and middle finger of the right hand. Strength of scapular adductors and lateral rotators of the shoulder is 4/5; myotome testing is normal bilaterally.

- What are your goals and interventions for this patient at this stage?

- After studying the techniques described in Chapter 16, describe the techniques you would use with this patient and practice them on a laboratory partner.
- For each therapeutic exercise technique, practice progressions and determine how you would progress this patient so he could work without exacerbation of symptoms.

### Case 3

A 55-year-old woman presents with early signs of degenerative joint disease of the lumbar spine. She has been an active runner since college. Occasionally, she has participated in aerobic dance classes. Her history is unremarkable. She has three grown children and had no complaints of back pain related to the pregnancies.

**Current symptoms:** intermittent periods of pain extending from the mid-lumbar spine, through the right buttock and posterior thigh. The pain begins 15 minutes into her running and progresses to an 8/10 by 25 to 30 minutes. She also complains of increased stiffness after sitting > 1 hour, standing > 15 minutes, as well as when waking in the morning and getting out of bed. She is a middle-school teacher and track coach for a girls' high school team.

**Key findings:** lordotic posture, with tight low back, hip flexors, and tensor fasciae latae. Strength of lower abdominals is 4/5. Forward bending of the spine increases tension in low back, repeated backward bending and prone press-ups increase buttock pain. Side bending is decreased 25%, with some discomfort with overpressure into right side bending.

- Based on these impairments and limitations, identify the irritability of the condition and determine goals and intervention.
- What are the most important factors to emphasize with this individual to help her manage her symptoms?
- After studying the exercises in Chapter 16, practice the techniques you would have this patient do. Also, practice how you would progress the techniques and what criteria you would use for progressions.

### Case 4

A 42-year-old man presents with a medical diagnosis of HNP at the L5–S1 area. Present symptoms began 4 days ago when rising out of bed. He is a sedentary person who plays social golf on the weekends (rides in a cart) and is 50 lb overweight. He has had occasional episodes of LBP over the past 15 years, but “nothing like this.”

**Medical history:** smokes one pack of cigarettes per day and is on blood pressure medication. He describes the symptoms as a sharp pain beginning in the left buttock region and radiating down the back of the thigh; there is intermittent paresthesia along the lateral border of his foot, which is noticeable when sitting. He describes a considerable increase in symptoms when attempting to rise from bed or from a chair or when straining. He has been unable to walk because he cannot stand upright. On

observation, you note that the patient is standing with a posterior pelvic tilt and forward-bend of the trunk and the thorax is deviated to the right.

Examination maneuvers: all spinal flexion motions increase symptoms; side gliding of the thorax to the left followed by lumbar extension centralizes the symptoms primarily to buttock and LBP.

- Based on this information, identify the impairments and functional limitations. What type of intervention should be used?
- Develop a sequence of treatment techniques that you would use during the first visit. Include instructions and precautions. Practice the techniques.

### Case 5

A 61-year-old male underwent a transforminal lumbar interbody fusion at the levels of L4–S1 approximately 8 weeks ago. He is a retired high school teacher and would like to return to working in his yard and playing golf. He states his pain is localized to his low back region with a 3/10 with activity. His current complaints include difficulty standing from low surfaces, such as the commode and the couch. He also feels he has decreased endurance, as he is unable to walk his dog more than 10 minutes in the morning. He would like to be able to walk for up to 1 hour.

Medical history: patient reports he drinks one glass of wine with dinner and does not smoke. He has a positive history for hypertension. All other medical history is unremarkable.

Examination: patient has full trunk ROM with pain reported at end-range in all directions. Patient has bilateral 4/5 knee extension and 3+/5 hip flexion strength. Abdominals are 3/5. Sensation is intact to light touch bilaterally throughout his lower extremities. Patient ambulates without an assistive device but is still wearing a removable lumbar orthotic (chair-back brace) for the next 4 weeks. The physician has told the patient not to lift anything heavier than 20 pounds.

- What are your goals and interventions for this patient at this stage?

- After studying the techniques described in Chapter 16, describe what you would use with this patient at his current level of function and practice the regimen on a lab partner. What criteria would you use to progress his exercises? How would you incorporate functional progressions in his exercise routines?
- How would you discuss with your patient the resumption of his activities of yard work and golf? What modifications/precautions should he make?

### Case 6

A 22-year-old female presents with left side TMJ pain with an onset of approximately 6 months ago. She is a graduate student (law school) and reports she has been extremely busy in school. She also reports she is planning her wedding, which will occur in 3 months. She cannot recall any previous trauma. She has been to the dentist, and he cleared her from any dental pathologies (abscess, fracture, etc.). The current complaint is pain with chewing and limited opening, especially with yawning. Her past medical history is unremarkable.

Examination: she has forward head posture with increased cervical lordosis and no deviation in the frontal plane. Bilateral upper extremity strength and sensation are normal and symmetrical. Cervical range of motion is approximately 25% limited with flexion and bilateral rotation. Patient demonstrates TMJ opening 50% of normal and lateral excursion 75% of normal. There is pain with palpation at the muscle bellies of the masseter and temporalis.

- Based on this information, identify the impairments and functional limitations. What type of intervention should be used?
- Develop a sequence of treatment techniques that you would use during the first visit. Include instructions and precautions. Practice the techniques.
- Identify methods the patient can use to manage and/or decrease her stress.

Basic spinal anatomy, mechanics, and posture are presented in Chapter 14. In Chapter 15, the pathomechanics, common pathologies, and management guidelines related to the spine are presented. The management guidelines are outlined based on stages of healing as well as subgroupings based on diagnostic categories that reflect impairments and movement disorders. Chapter 16 is a continuation of this material in which the techniques of intervention using therapeutic exercise and mobilization/manipulation for management of neck and trunk impairments are described.

This chapter is divided into six main sections. The first section describes the underlying concepts and approaches to exercise interventions for spinal impairments. Each of the remaining five sections describes components of exercise interventions for the neck and trunk. The topics covered include exercises for kinesthetic awareness, mobility/flexibility (including manipulation), muscle performance (including stability, muscle endurance, and strength), cardiopulmonary endurance, and functional activities. Stress relief and relaxation principles and techniques, important components of total rehabilitation, are covered in detail in Chapter 14.

## Basic Concepts of Spinal Management With Exercise

It is important to recognize that even though the material in this chapter is presented in separate sections, there is an overlap in the use of the techniques described in each section, and there are fundamental interventions basic to all exercise programs.

## Fundamental Interventions

When patients seek treatment from a physical therapist, they come with different diagnoses, impairments, and activity limitations and are at different stages of tissue healing. Yet the treatment plan for each patient must begin with fundamental interventions in order to lay the foundation on which to build an effective therapeutic exercise program. *Fundamental interventions* are defined as exercises or skills that all patients with

spinal impairments should learn regardless of their functional level at the time of examination and initial treatment. The interventions include basic kinesthetic training, basic spinal stabilization training, and functional training of basic body mechanics. These interventions are summarized in Box 16.1.

### BOX 16.1 Fundamental Exercise Interventions for Spinal Rehabilitation

These fundamental interventions are adapted or modified based on patient abilities and responses.

#### Kinesthetic Training

- Awareness and control of safe spinal motion: head nodding and pelvic tilts
- Awareness of neutral spinal position (if needed begin in the patient's spinal bias) while supine, prone, sitting, and standing
- Awareness of effects of activities of daily living and extremity motion on the spine (see Functional Training)

#### Stabilization Training

- *Deep segmental muscle* activation and sustained contraction
  - Cervical region: controlled axial extension (cervical retraction) with craniocervical flexion and lower cervical/upper thoracic extension
  - Lumbar region: drawing-in maneuver and multifidus muscle activation techniques
- *Superficial multi-segmental (global) muscle* control of spinal posture with extremity loading
- Passive support of spinal posture only if needed; progress to active control
- Coordinate segmental muscle activation with maintenance of a stable spine in neutral spinal position (or position of bias) with all arm and leg motions

#### Functional Training (Basic Body Mechanics With Stable Spine)

- Log roll supine to prone, prone to supine
- Transition from supine to side-lying to sitting and return
- Transition from sit to stand and return
- Walking

Once the fundamental skills are learned, exercise interventions then progress on a continuum at the level of the patient's abilities and willingness to learn. For example, a patient beginning treatment with chronic symptoms several months after the onset of symptoms must first become aware of positions or activities that increase the symptoms and then learn how to move the spine safely as well as learn what effects the various postures and movements have on symptoms (*fundamental* kinesthetic awareness). The patient must learn how to activate the deep segmental stabilizing musculature and then how to use the deep stabilizers with the global musculature to stabilize the spine against various extremity loading exercises (*fundamental* muscle performance). Finally, the patient must learn basic body mechanics (*fundamental* functional activities) in order to minimize stresses to the spine during daily activities before progressing to exercises that can be tolerated at the chronic stage of healing and returning to desired functional activities.

The fundamental exercises are described in detail preceding the exercise progressions in each of the respective sections of this chapter. The principles of management are similar for the cervical and lumbar spinal regions, and many of the same techniques may be used or modified for both regions.

## Patient Education

Patient education is the key component of every goal and intervention. It encompasses several ideas. First, the patient is an active participant in identifying the desired goals; education as to potential outcomes is part of this process. Second, the patient may need to be informed about limitations at each stage of healing, so he or she will not become concerned that the acute symptoms will be forever disabling, but also will not “overdo” exercises and activities during the early subacute phase that cause exacerbation of symptoms. The patient may then need to be challenged to progress beyond perceived limitations during the later stages of recovery.

To ensure that each individual develops control over and learns to manage the symptoms and any impairments, it is important that the patient is engaged in all activities at each stage of recovery and is not just a passive recipient of “treatment.” Instruct the patient on how to safely progress self-management beyond the time spent under professional supervision so he or she can reach the maximum level of functional return with minimal activity or participation restrictions.

Finally, the patient needs instruction in prevention. This includes safe ways to exercise, safe body mechanics for return to high-intensity activities, modification of the work and home environment, and activities to minimize stresses.

### FOCUS ON EVIDENCE

The *Clinical Practice Guidelines (CPGs) for Low Back Pain*, based on moderate evidence, recommend patient education

and counselling to include promoting the inherent anatomical/structural strength of the spine, the explanation of pain, the favorable prognosis of low back pain (LBP), use of pain coping strategies, early resumption of normal activities, and improvement of activity levels.<sup>17</sup>

## General Exercise Guidelines

Therapeutic exercise is an important intervention in the management of impairments in the spinal region. Although this text does not deal with specific examination techniques, it is critical to emphasize the importance of identifying each patient's structural and functional impairments, their activity and participation restrictions, and the stage of tissue healing or stage of rehabilitation in order to establish a baseline for the initiation of intervention techniques and to measure progress toward the outcome goals.

In general, the following components of physical function are used in all intervention programs for spinal problems. These five areas are listed in Table 16.1 with interventions outlined for each phase of rehabilitation. The interventions are described in detail in the remaining sections of this chapter. Prior to developing an exercise program, it is important that the reader has knowledge of various spinal pathologies and the special precautions and contraindications (see Chapter 15), so each patient can safely achieve his or her maximum potential.

### Kinesthetic Awareness

One of the fundamental interventions for spinal rehabilitation is for the patient to develop awareness of safe spinal positions and spinal movement as well as what effect the supine, prone, side-lying, sitting, and standing positions have on the spine. Awareness of what postures make the symptoms better or worse and identifying the neutral spinal position or position of bias are important in helping patients manage their symptoms. Awareness and control of spinal posture and movement are progressed and incorporated into all the exercises described in the remaining sections of this chapter and underlie exercises for the extremities as well.

### Mobility/Flexibility

Stretching and flexibility exercises as well as mobilization/manipulation techniques are used to increase mobility of restricting tissues so the patient can assume an effective position of the spine when exercising to improve muscle performance and functional outcomes. For patients who fit the Mobilization/Manipulation diagnostic category (described in Chapter 15), spinal manipulation techniques or specific high-velocity thrust (HVT) techniques may be indicated during the early intervention period and then followed with stretching exercises. Nerve mobilization may be indicated in either the cervical/upper

**TABLE 16.1** Intervention for Each Phase of Rehabilitation

Phases of Rehabilitation	Phase I: Early Training	Phase II: Basic Training:	Phase III: Intermediate to Advanced Training Return to function with minimum to no protection

<b>Five components of exercise intervention</b>			
<b>Kinesthetic awareness</b> ■ Proprioception training of safe movement and postures	<ul style="list-style-type: none"> <li>■ Pelvic tilt /cervical retraction: passive → active assist → active in comfortable positions*</li> <li>■ Awareness of what makes symptoms better vs. worse*</li> <li>■ Learn neutral spine (or bias)*</li> </ul>	<ul style="list-style-type: none"> <li>■ Active spinal control in supine, prone, quadruped, sitting, standing</li> <li>■ Dynamic maintenance of pain-free position with activities</li> </ul>	<ul style="list-style-type: none"> <li>■ Habitual use of neutral spine in all functional activities</li> </ul>
<b>Mobility/flexibility</b> ■ Move, stretch, manipulate restricting tissues	<ul style="list-style-type: none"> <li>■ Movement to relieve fluid stasis</li> <li>■ Trunk stretching: only in pain-relieving positions</li> <li>■ Extremity stretching: stretch U/LE if no stress to the spine</li> <li>■ Manipulation: grades I and II</li> <li>■ High-velocity thrust if indicated</li> </ul>	<ul style="list-style-type: none"> <li>■ Gentle spinal movement into painful range</li> <li>■ Stretch U/LE muscles; stabilize spine in position of bias</li> <li>■ Manipulation: progress to grade III</li> </ul>	<ul style="list-style-type: none"> <li>■ Move into painful ranges to stretch and manipulate as indicated</li> </ul>
<b>Muscle performance</b> ■ Stabilization training (deep muscles for segmental stability, global muscles for general stability) ■ Muscle endurance ■ Strength and power	<ul style="list-style-type: none"> <li>■ Activation of deep musculature*</li> <li>■ Stabilization exercises with extremity loading (use of passive positioning of spine with pillows, splints, corsets if necessary)*</li> </ul>	<ul style="list-style-type: none"> <li>■ Stabilization exercises with extremity loading (active control of spine position)</li> <li>■ Emphasize muscle endurance</li> <li>■ Perturbation training</li> <li>■ Low-intensity dynamic spinal exercises</li> </ul>	<ul style="list-style-type: none"> <li>■ Stabilization with transitional motions and functional activities; emphasize strength</li> <li>■ Progression to dynamic trunk strengthening</li> <li>■ Progress trunk and extremity strengthening exercises in patterns that reinforce activity goals</li> </ul>
<b>Cardiopulmonary Endurance</b> ■ Aerobic training	<ul style="list-style-type: none"> <li>■ Only if tolerated with maximum protection in position of comfort</li> </ul>	<ul style="list-style-type: none"> <li>■ Low to moderate intensity with moderate to minimal protection.</li> <li>■ Use activities that emphasize spinal bias</li> </ul>	<ul style="list-style-type: none"> <li>■ High-intensity (target heart rate), multiple times per week</li> </ul>
<b>Functional Activities</b> ■ Body mechanics ■ Skill in home, community, work, recreation, sport activities	<ul style="list-style-type: none"> <li>■ Safe postures for recumbent, sitting, and standing*</li> <li>■ Stable-spine techniques while rolling over, moving supine to sit, sit to stand*</li> </ul>	<ul style="list-style-type: none"> <li>■ Strengthen U/LE while stabilizing spine</li> <li>■ Stable spine body mechanics</li> <li>■ Environmental and ergonomic adaptations</li> </ul>	<ul style="list-style-type: none"> <li>■ High-intensity functional activities</li> <li>■ Endurance and strengthening activities that replicate return to desired activities</li> <li>■ Practice prevention</li> </ul>

\*Fundamental interventions for all patients.

extremity or lumbar/lower extremity regions. Indications and techniques are described in Chapter 13.

**NOTE:** The terms *mobilization* and *manipulation* are used interchangeably (see Chapter 5). The authors of this chapter are using *manipulation* to refer to graded oscillation techniques and HVT to refer to high-velocity, small-amplitude techniques performed at the end of the pathological limit of the joint.

## Muscle Performance

In the spine, muscle performance involves not only strength, power, and endurance, but also stability. Activation of the deep segmental muscles as well as the superficial/global multi-segmental muscles of the neck and trunk are fundamental techniques for developing spinal stability. Initially, emphasis is placed on awareness of muscle contraction and control of spinal position while moving the extremities and performing basic functional activities. Exercises are then progressed to challenge the holding capacity of the stabilizing muscles, emphasizing muscle endurance, balance, and strength. Once the individual learns effective stabilization and management of symptoms, dynamic neck and trunk strengthening exercises are initiated to emphasize strength in the full range of motion (ROM). Most people are familiar with trunk curls, “crunches,” and back lifts. The emphasis of therapeutic exercise is safe execution of the exercises combined with respect of the biomechanics of the spine. Exercises should be chosen with the functional outcome goals in mind and integrated with the principles discussed in the Functional Activities section of this chapter.

## Cardiopulmonary Endurance

Aerobic conditioning exercises are initiated as soon as the patient tolerates repetitive activity without exacerbating symptoms. Emphasis is placed on using safe spinal postures while exercising. Aerobic activity increases the patient’s feeling of well-being and improves cardiovascular and pulmonary fitness. Principles of aerobic conditioning are detailed in Chapter 7 and summarized in this chapter, along with suggestions for safe application of aerobic exercises when there are spinal impairments.

## Functional Activities

Fundamental functional activities include training the basic body mechanics of rolling, supine to sit, sit to stand (and reverse), and walking. These activities are coordinated with kinesthetic training and segmental muscle activation and stabilization exercises. When the patient is able, stabilization exercises, muscle endurance, and strengthening exercises are integrated with skills for body mechanics (lifting, pushing, pulling, carrying), safe work habits (ergonomic adaptations), and effective recreational or sport activities to meet the goals of the individual.

## FOCUS ON EVIDENCE

The *CPGs for Neck Pain*<sup>12</sup> and for *Low Back Pain*<sup>17</sup> identify strong evidence for manipulation and thrust techniques to reduce pain and disability with mobility impairments; strong evidence for trunk coordination, strengthening, and endurance exercise; and strong evidence for progressive endurance and fitness activities when treating patients with back and neck pain. There is also strong evidence supporting interventions for subgroups that respond with centralization and directional preference exercises.

## Kinesthetic Awareness

**Goal.** To develop proprioception of spinal positioning, safe movement, and postural control.

## Elements of Functional Training: Fundamental Techniques

### Position of Symptom Relief

It is important that the patient learn how to move the spine and find the range or position in which symptoms are minimized. The position of symptom relief is called the *position of bias* or the *resting position*. The *neutral* spine position is midrange; the patient may or may not feel most comfortable in that position initially. See Chapter 15 for a discussion on spinal bias as it relates to relief of symptoms and common pathologies.

### Cervical Spine

**Patient position and procedure:** Begin supine; progress to sitting and other functional postures as tolerated.

- If the patient is experiencing a lot of pain and is not able to, or not wanting to, move their head, begin with passive movements. Passively move the head and neck with gentle nodding motions of the head into flexion and extension, side bending, and/or rotation to find the most comfortable position for the patient. If necessary, prop the head and neck with pillows.
- Describe the mechanics of what you are doing to the patient.
- Have the patient identify the change in symptoms as movement occurs in and out of the position of bias.
- Have the patient practice moving into and out of that position to develop control.
- If the patient cannot maintain this position while sitting and standing, wearing a cervical collar may be appropriate during the acute stage following an injury or postsurgically, but it is important to use judiciously, so the patient does not become dependent on it.

## Lumbar Spine

**Patient position and procedure:** Begin supine or hook-lying, then sitting, standing, and quadruped.

- Teach the patient to move his or her pelvis into an anterior and posterior pelvic tilt through the range that is comfortable.
- Once the patient has moved the pelvis and spine through a safe range of motion (ROM), instruct him or her to find the position of greatest symptom relief.
- If active movement and control are not possible, teach *passive positioning* (see Chapter 15, Box 15.6). Have the patient assume each of the following positions, and draw the association between the spinal position and what is felt. While supine, passively position the pelvis in posterior tilt and lumbar spine in flexion by placing the lower extremities in the hook-lying position or anterior tilt and lumbar spine extension by placing a small pillow or folded towel under the lumbar spine. If prone lying is tolerated, position the lumbar spine in extension when lying flat or in flexion by placing one or two pillows under the abdomen. Sitting encourages spinal flexion; if extension is more comfortable, instruct the person to use a lumbar pillow for support. Standing usually causes spinal extension; if flexion is desired, instruct the person to place one foot up on a stool while standing.

## Effects of Movement on the Spine

Once the functional spinal position is determined, it is important for the patient to feel and learn what motions make the symptoms better or worse. In general, movement of the extremities away from the trunk (shoulder flexion and abduction, hip extension and abduction) causes spinal extension; movement of the extremities toward the trunk (shoulder extension and adduction, hip flexion and adduction) causes spinal flexion.

- Have the patient find the neutral or functional spine position (bias); then move the arms and then the legs to feel the effect on the spine. Control of the spinal position is emphasized; have the patient practice the arm and leg motions and attempt to maintain control of the spinal position. These motions are the same as the basic stabilization exercises and are described in detail in the muscle performance section.
- If the patient cannot maintain control or the symptoms are made worse, he or she requires passive support or passive positioning when initiating the stabilization exercises.

## Blending of Kinesthetic Training, Stabilization Exercises, and Fundamental Body Mechanics

Once awareness of safe positions and movement is learned, teach the patient the fundamental stabilization techniques for developing neuromuscular control of the position (see the Muscle Performance section of this chapter) and teach the fundamental body mechanics of rolling, moving supine to sit, sit to stand, and ambulation (see the Functional Activities section of this chapter).

## Progression to Active and Habitual Control of Posture

Awareness and control of posture is described in detail in Chapter 14 (see General Management Guidelines for Impaired Posture and Box 14.1). The use of reinforcement techniques (verbal, visual, tactile) is described, as are activities to train cervical, scapular, thoracic, and lumbopelvic alignment and control. It is important to reinforce the relationship between faulty posture and the development of painful symptoms and to identify a need for postural support (temporary or long term).

Integrate the awareness of posture and control of the spinal segments into all stabilization exercises, aerobic conditioning, and functional training activities. Observe the patient as greater challenges to activities are performed and, if necessary, provide reminders to find the neutral spinal position and to initiate contraction of the stabilizing muscles prior to the activity. For example, when reaching overhead, help the patient become aware of the need to contract the abdominal muscles to maintain a neutral spine position and not allow the spine to extend into a painful or unstable range; this is practiced until the stabilization becomes habitual. This principle is also incorporated into body mechanics, such as when going from picking up and lifting to placing an object on a high shelf, or into sport activities when reaching up to block or throw a ball.

## Mobility/Flexibility

**Goal.** To increase ROM of specific structures that affect alignment and mobility in the neck and trunk.

In general, stretching is contraindicated in the region of inflamed tissue. However, if there are postures that relieve symptoms but are difficult to assume because of tissue restriction or fluid stasis, stretching or repetitive movement into the restricted range may be appropriate. For example, repetitive lumbar extension has been shown to relieve symptoms of fluid stasis or a disc lesion, yet a patient may not be able to get into an extended posture because of flexed postural dysfunction or swollen tissue. Prone propping and press-ups may stretch the tight tissue or may compress and massage swollen disc material or fluid stasis to reduce symptoms (see Fig. 15.4 and the section on Management Guidelines: Extension Bias in Chapter 15.)

Acute nerve root irritation from bony spurs or lipping in an arthritic spine is another situation in which acute symptoms may be relieved with stretching. Reducing pressure on the nerve roots with a stretch traction force, which widens the intervertebral foramina, or with procedures that help position the spine in its optimal spinal position may relieve the symptoms.<sup>1</sup>

Decreased mobility in structures in the upper and lower extremities that restrict normal postural alignment may be stretched or mobilized if the techniques do not stress the area of inflammation.

Stretching is done on a continuum. Critical judgment is used to determine the intensity and duration of stretch based

on proximity to the healing tissue and the integrity and tolerance of the tissue. Principles of stretching for impaired mobility are described in Chapter 4.

Joint manipulation techniques and specific HVT techniques may be used to stretch a hypomobile facet joint capsule. Principles of joint manipulation are described in Chapter 5; indications for their use in the spine are identified in Chapter 15 in the Management Guidelines: Mobilization/Manipulation section.

If indicated, the patient is also taught general stress-relieving movements to reduce fluid stasis after being in prolonged postures. These movements are described in Chapter 14 in the Management of Impaired Posture section.

### CLINICAL TIP

In general, stretching is contraindicated in the region of inflamed tissues.

Exceptions:

- Fluid stasis that restricts movement may respond to repetitive motion or sustained positioning into restricted range.
- Acute nerve root impingement may be relieved with traction or flexion to widen the intervertebral foramina.

Use clinical judgment to determine intensity and duration of stretch based on proximity to healing tissue, integrity, and tolerance of the tissue.

## Cervical and Upper Thoracic Region: Stretching Techniques

### Techniques to Increase Thoracic Extension

#### Self-Stretching

- *Patient position and procedure:* Hook-lying, with the hands behind the head and the elbows resting on the mat. Progress with both arms elevated overhead while maintaining back flat on the mat. To increase the stretch, place a pad or rolled towel lengthwise under the thoracic spine between the scapulae. Incorporate breathing exercises to increase mobility of the rib cage and assist with thoracic extension. Have the patient start with the elbows together in front of the face and then inhale as the elbows are brought down to the mat; hold the stretch position; then exhale as the elbows are brought together again.
- *Patient position and procedure:* Supine, with a foam roll placed longitudinally down the length of the spine. If the patient cannot balance on the roll or experiences tenderness along the spinous processes from pressure, tape two foam rolls together. The patient elevates both arms overhead in a “touchdown” position and allows gravity to apply the stretch force (Fig. 16.1 A). The patient then abducts and

laterally rotates both shoulders (90/90 position) so the hands are facing the ceiling (Fig. 16.1 B). This position also stretches the pectoralis major and subscapularis muscles. Breathing exercises can be added to mobilize the ribs.

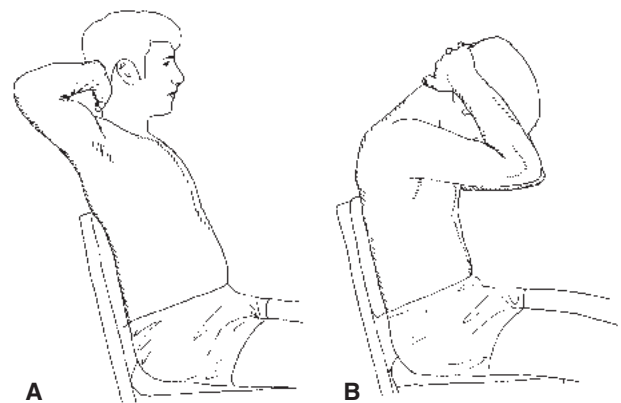

A

B

**FIGURE 16.1** Foam roll stretch to increase flexibility of anterior thorax. (A) In the “touchdown” position, the shoulder extensors are also stretched. (B) With the shoulders abducted and laterally rotated, the pectoralis major and other internal rotators are also stretched. For a less intensive stretch, use a rolled towel placed longitudinally under the spine.

- *Patient position and procedure:* Sitting on a firm, straight-backed chair with the hands behind the head or held abducted and externally rotated 90°. The patient then brings the elbows out to the side as the scapulae are adducted and the thoracic spine is extended (head held neutral, not flexed). To combine with breathing, have the patient inhale as he or she takes the elbows out to the side and exhale as the elbows are brought in front of the face (Fig. 16.2).

A

B

**FIGURE 16.2** (A) Increase flexibility of anterior thorax and pectoralis muscles by adducting the scapula and extending the thoracic spine against the back of the chair. Inspiration increases the stretch; (B) facilitate expiration by bringing the elbows together and flexing the spine.

## Techniques to Increase Cervical Retraction (Axial Extension): Scalene Muscle Stretch

### CLINICAL TIP

Because the scalene muscles are attached to the transverse processes of the upper cervical spine and the upper two ribs, they either flex the cervical spine or elevate the upper ribs when they contract bilaterally. Unilaterally, the scalenes side bend the cervical spine to the same side and rotate it to the opposite side. To effectively stretch this muscle, stabilize the head and apply the stretch force against the upper portion of the rib cage.

### Manual Stretching

**Patient position and procedure:** Sitting. The patient first performs axial extension (tucks the chin and straightens the neck) and then side bends the neck opposite and rotates it toward the tight muscles. Stand behind the patient and stabilize the head with the one hand around the side of the patient's head and face, holding the head against your trunk or shoulder. Place the other hand across the top of the rib cage on the side of tightness (Fig. 16.3). Instruct the patient to inhale and exhale; apply a downward pressure (resisting elevation of the rib cage) as the patient inhales again. As the patient relaxes (exhales), take up the slack. Repeat. This is a gentle, hold-relax stretching maneuver. This technique can also be done in supine.

**FIGURE 16.3** Unilateral active stretching of the scalenus muscles (manual stretch). The patient first performs axial extension, then side-bends the neck opposite and rotates it toward the tight muscles. The therapist stabilizes the head and upper thorax as the patient breathes in, contracting the muscle against the therapist's resistance. As the patient relaxes, the rib cage lowers and stretches the muscle.

### Self-Stretching

**Patient position and procedure:** Standing next to a table and holding onto its underside. The patient positions the head in axial extension, side bends opposite, and rotates toward the same side as the muscle being stretched. To stretch, he or she leans away from the table, inhales, exhales, and holds the stretch position.

## Techniques to Increase Upper Cervical Flexion: Suboccipital Muscle Stretch

### Manual Stretching

**Patient position and procedure:** Sitting. Identify the spinous process of the second cervical vertebra and stabilize it with your thumb or with the second metacarpophalangeal joint (and the thumb and index finger around the transverse processes). Have the patient slowly nod, doing just a tipping motion of the head on the upper spine (Fig. 16.4). Guide the movement by placing the other hand across the patient's forehead.

**FIGURE 16.4** Stretching the short suboccipital muscles. The therapist stabilizes the second cervical vertebra as the patient slowly nods the head.

### Self-Stretching

**Patient position and procedure:** Supine or sitting. Instruct the patient to first perform a chin tuck (axial extension), then nod the head, bringing the chin toward the larynx until a stretch is felt in the suboccipital area.

- Have the patient put a light pressure under the occipital region with the palm of his or her hand while tipping the head forward to reinforce the motion.
- For a *unilateral stretch*, instruct the patient to first perform a chin tuck, rotate slightly (up to 45°) to the left or right, and then nod.

**NOTE:** The weight of the head is enough stretch force in these exercises; the patient should not pull on the head when there is cervical pathology.

### CLINICAL TIP

Shoulder girdle posture is directly related to cervical and thoracic posture. Techniques to increase flexibility in the shoulder girdle muscles are described in Chapter 17. Of primary importance:

- Pectoralis major (see Figs. 17.30 to 17.32)
- Pectoralis minor (see Fig. 17.33)
- Levator scapulae (see Figs. 17.34 and 17.35)
- Shoulder internal rotator muscles (see Fig. 17.26)

## Traction as a Stretching Technique

### Manual Traction: Cervical Spine

Traction techniques can be used for the purposes of stretching the muscles and the facet joint capsules and widening the intervertebral foramina.<sup>72</sup> The value of manual traction is that the angle of pull, head position, and placement of the force (via specific hand placements) can be controlled by the therapist; thus, the force can be specifically applied with minimum stress to regions that should not be stretched.

**Patient position:** Supine on a treatment table. The patient should be as relaxed as possible.

**Therapist position and hand placement:** Standing at the head of the treatment table, supporting the weight of the patient's head in the hands. Hand placement depends on comfort, the size of the patient's head and the therapist's hands. Suggestions include:

- Place the fingers of both hands under the occiput (Fig. 16.5 A), or with the hands on the sides of the face (not covering the ears).

- Place one hand over the forehead and the other hand under the occiput (Fig. 16.5 B).
- Place the index fingers around the spinous process above the vertebral level to be moved. This hand placement provides a specific traction only to the vertebral segments below the level at which the fingers are placed. A belt around the therapist's hips can be used to reinforce the fingers and increase the ease of applying the traction force (Fig. 16.5 C).

**Procedure:** Vary the patient's head position in flexion, extension, side bending, and side bending with rotation until the tissue to be stretched is taut; then apply a traction force by assuming a stable stance and leaning backward in a controlled manner. If a belt is used, the force is transmitted through the belt. The force is usually applied intermittently with smooth and gradual building and releasing of the force. The intensity and duration are usually limited by the therapist's strength and endurance.

### CLINICAL TIP

When applying cervical traction, the more a person's head is flexed, the lower in the cervical spine the traction force is directed. When side bending, caution should be used because the position may cause facet and foramen approximation on the side of the concavity, which, in turn, may cause radicular or facet joint symptoms on that side.

### Self-Traction: Cervical Spine

**Patient position and procedure:** Sitting or lying down. Have the patient place his or her hands behind the neck with the fingers interlocking; the ulnar border of the fingers and hands are under the occiput and mastoid processes. The patient then gives a lifting motion to the head. The head and spine may be placed in flexion, extension, side bending, or rotation for more isolated effects. He or she may apply the traction intermittently or in a sustained manner throughout the day.

**FIGURE 16.5** Manual cervical traction: (A) with the fingers of both hands under the occiput; (B) with one hand over the frontal region and the other hand under the occiput; and (C) using a belt to reinforce the hands for the traction force.

**NOTE:** Various forms of mechanical traction can be used in the clinical setting and at home. The position, dosage, and duration of traction are determined by the therapist. Instruction for use of the equipment is not described in this text.

## Cervical Joint Manipulation Techniques

As previously noted, the principles of joint mobilization/manipulation are discussed in detail in Chapter 5 and their indications for use with specific impairments are identified in Chapter 15. Spinal manipulative techniques are indicated for pain modulation and to improve joint motion.

### CLINICAL TIP

Spinal manipulations are graded I–V. All spinal and rib manipulations, with the exception of HVT techniques, are performed for 1 to 2 minutes and then reassessed for increased motion or decreased pain. Intervention is terminated once the desired result is achieved or to patient tolerance.

- Grade I—small-amplitude oscillations are used for pain modulation, typically during the acute stage following injury.
- Grade II—large-amplitude oscillations are also used for pain modulation. Dosage and indications are similar to grade I manipulations.
- Grade III—large-amplitude oscillations that go up to the restrictive joint barrier are designed to improve joint ROM and can be used during the subacute or chronic stages of healing.
- Grade IV—small-amplitude oscillations that go through the restrictive joint barrier. These manipulations are designed to improve joint ROM and should be used only during the chronic stages of healing.
- Grade V (HVT)—high-velocity and low-amplitude thrust applied at the physiologic limit of joint motion. These manipulations are performed only one time and designed solely to improve ROM.

### PRECAUTIONS:

- If a manipulation procedure causes a change in sensation or an increased pain to radiate down an extremity, or if a patient reports a feeling of dizziness or light-headedness, do not perform additional manipulations.
- Use extreme caution if the patient reports either a current history of corticosteroid use or excessive pain.

### CONTRAINDICATIONS:

- Unhealed fracture
- History of joint or ligamentous laxity caused by trauma or systemic diseases, such as rheumatoid arthritis
- Vertebral artery disease or occlusion

- Acute joint inflammation/irritation
- Cauda equina symptoms

## Manipulation to Increase Cervical Flexion (Fig. 16.6)

**FIGURE 16.6** Cervical Flexion Manipulation—prone

**Patient position:** Prone with arms resting comfortably at patient's side. Place a pillow under the clavicular region for patient comfort and to promote a neutral cervical-thoracic curve.

**Therapist position and hand placement:** Stand on one side of the patient with your body facing toward his or her head. Use a two-thumb contact on the spinous process of the superior restricted segment of the three-joint complex.

**Manipulation force:** Using force through the thumbs, slide the superior vertebra in a cephalad-anterior direction.

## Manipulation to Increase Cervical Extension (Fig. 16.7)

**FIGURE 16.7** Cervical Extension Manipulation—prone

**Patient position:** Prone with arms resting comfortably at patient's side, use a pillow for patient comfort and to promote a neutral cervical-thoracic curve.

**Therapist position and hand placement:** Stand at the head of the patient with your body facing toward his or her feet. Use a two-thumb contact on the spinous process of the superior restricted segment of the restricted three-joint complex.

**Manipulation force:** Using force through the thumbs, slide the superior vertebra in a caudal-posterior direction.

## Manipulation to Increase Cervical Rotation (Fig. 16.8)

**FIGURE 16.8** Cervical Rotation Manipulation—prone

**Patient position:** Prone with arms resting comfortably at patient's side, use a pillow for patient comfort and to promote a neutral cervical-thoracic curve.

**Therapist position and hand placement:** Stand on one side of the patient with your body facing toward their head. Use a two-thumb contact on the transverse process on the superior restricted vertebrae of the three-joint complex to cause rotation toward the direction of restriction.

**Manipulation force:** Using force through the thumbs, slide the superior vertebra in a cephalad-anteromedial direction.

## Manipulation to Increase Cervical Rotation and Side Bending (Fig. 16.9)

**VIDEO 16.1** 🌐

This technique increases the diameter of the ipsilateral foramen, as seen with contralateral rotation and side bending.

**Patient position:** Supine.

**Therapist position and hand placement:** Stand at the head of the patient with one hand (the hand opposite the side of restriction) supporting the head and the other hand in contact with the lateral aspect of the vertebra to be manipulated.

**FIGURE 16.9** Cervical Rotation and Side-Bending Uplide Manipulation—supine

The medial side of the second MCP joint should be in contact with the edge of the facet and pillar to be manipulated and the rest of your hand relaxed on the postero-lateral portion of the patient's neck. Passively place the patient's head and neck into flexion, contralateral rotation, and side bending to take up the slack until the segment to be treated is identified.

**Manipulation force:** Using force through the metacarpal joint of the second digit, slide (or upglide) the cervical facet in an anterior-superior-medial direction at a 45° angle.

## Manipulation to Increase Cervical Rotation and Side Bending: Alternate Technique (Fig. 16.10) **VIDEO 16.1** 🌐

**FIGURE 16.10** Cervical Rotation and Side-Bending Downglide Manipulation—supine

This technique decreases the diameter of the ipsilateral foramen, as seen with ipsilateral rotation and side bending.

**Patient position:** Supine.

**Therapist position and hand placement:** Stand at the head of the patient with one hand (the hand opposite the side of

restriction) supporting the patient's head and the other hand in contact with the vertebra to be manipulated. The medial side of the second MCP joint should be in contact with the edge facet and pillar to be manipulated and the rest of your hand relaxed on the postero-lateral portion of the patient's neck. Passively place the patient's head and neck into extension, ipsilateral rotation, and side bending to take up the slack until the segment to be treated is identified.

**Manipulation force:** Using force through the MCP joint of the second digit, slide (or downslide) the cervical facet in an inferior-medial direction at a 45° angle.

## Muscle Energy Techniques to Increase Craniocervical Mobility

Muscle energy (ME) uses the application of submaximum, isometric contractions of muscles whose line of pull can cause the desired accessory motion of a joint; ME techniques are designed to improve joint mobility (see Chapter 5). The patient holds the gentle muscle contraction against the therapist's graded resistance for 3 to 5 seconds and then relaxes. This process is repeated for three to five repetitions. When performed correctly, ME techniques are extremely safe and are indicated for most joint restrictions resulting from musculoskeletal disorders at any stage of healing.

**PRECAUTION:** Great care should be used when applying the following techniques so as not to occlude the vertebral artery. The therapist should test the integrity of the vertebral artery prior to performing the following ME techniques. Do not perform ME techniques if the patient reports an altered sensation in either upper extremity or a feeling of dizziness or lightheadedness during the set-up of these techniques.

### Techniques to Increase Craniocervical Flexion (Fig. 16.11) VIDEO 16.2

**FIGURE 16.11** Muscle Energy: Craniocervical Flexion

**Patient position:** Supine, with hands placed comfortably at the side.

**Therapist position, hand placement, and patient effort:** Stand at the head of the treatment table. Support the occiput with one hand and place the other hand across the forehead. Ask the patient to look upward gently as if nodding the head backwards and apply resistance against the patient's occiput, creating a gentle isometric contraction in the suboccipital muscles. When the patient relaxes, take up the slack by passively nodding the head through any new range.

**Alternate technique:** Sit on a stool at the head of patient with your forearms resting on the treatment table. One hand stabilizes the C2 vertebra by grasping the transverse processes between the proximal portions of the thumb and index finger; the other hand supports the occiput. Passively nod the patient's head with the hand under the occiput to take up the slack of the suboccipital muscles; then ask the patient to roll the eyes upward. This causes a gentle isometric contraction of the suboccipital muscles. The patient keeps looking upward for 3 to 5 seconds and then relaxes. After the patient relaxes, take up the slack by passively nodding the head through any new range. Repeat this procedure three to five times or until the desired outcome is achieved. Only motion between the occiput and C2 should occur. The contraction is gentle in order not to cause overflow into the multi-segmental erector spinae and upper trapezius muscles. This technique uses a gentle hold-relax, of the rectus capitis posterior minor muscle.

### Techniques to Increase Craniocervical Rotation (Fig. 16.12) VIDEO 16.2

**FIGURE 16.12** Muscle Energy: Craniocervical Rotation

**Patient position:** Supine, with hands placed comfortably at the side.

**Therapist position, hand placement, and patient effort:** Stand at the head of the patient. Wrap hands around the side of the patient's head with fingers under the occiput. Place the

patient's head in end-range cervical flexion. Next, rotate his or her head in the direction of the restriction (for example, with restricted rotation to the left, place head in end-range left rotation). Once the patient is at end-range, instruct the patient to look in the opposite direction (example, toward the right) while you resist this movement with gentle pressure against the side of the head. After a 3- to 5-second hold, have the patient relax and move the head into greater rotation. Repeat as needed.

## Mid and Lower Thoracic and Lumbar Regions: Stretching Techniques

### Techniques to Increase Lumbar Flexion

**PRECAUTION:** Do not perform if flexion causes a change in sensation or causes pain to radiate down the lower extremity.

#### Self-Stretching

- *Patient position and procedure:* Hook-lying. Have the patient first bring one knee and then the other toward the chest, clasp the hands around the thighs and pull them to the chest, elevating the sacrum off the mat (Fig. 16.13). The patient should not grasp around the tibia; it places stress on the knee joints as the stretch force is applied.

**FIGURE 16.13** Self-stretching the lumbar erector spinae muscles and tissues posterior to the spine. The patient grasps around the thighs to avoid compression of the knee joints.

- *Patient position and procedure:* Quadruped (on hands and knees). Have the patient perform a posterior pelvic tilt without rounding the thorax (concentrate on flexing the lumbar spine, not the thoracic spine), hold the position, then relax (Fig. 16.14 A). Repeat; this time bring the hips back to the feet, hold, and then return to the hands and knees position (Fig. 16.14 B). This also stretches the gluteus maximus, quadriceps femoris, and shoulder extensor muscles.

**FIGURE 16.14** Stretching of the lumbar spine. (A) The patient performs a posterior pelvic tilt without rounding the thorax. (B) The patient moves the buttocks back over the feet for a greater stretch.

### Techniques to Increase Lumbar Extension

**PRECAUTION:** Do not perform if extension causes a change in sensation or causes pain to radiate down the lower extremity.

#### Self-Stretching

- *Patient position and procedure:* Prone, with hands placed under the shoulders. Have the patient extend the elbows and push the thorax up off the mat but keep the pelvis down on the mat. This is a prone press-up (Fig. 16.15 A). To increase the stretch force, the pelvis can be strapped to the treatment table. This exercise also places the hip flexor muscles and soft tissue anterior to the hips in an elongated position, although it does not selectively stretch these tissues.
- *Patient position and procedure:* Standing, with the hands placed in the low back area. Instruct the patient to lean backward (Fig. 16.15 B).
- *Patient position and procedure:* Quadruped (hands and knees). Instruct the patient to allow the spine to sag, creating lumbar extension. Alternating between this motion and a posterior pelvic tilt (as in Fig. 16.14) can be used to teach the patient how to control pelvic motion.

### Techniques to Increase Lateral Flexibility of the Spine

Stretching techniques to increase lateral flexibility are used for intervention when there is asymmetrical flexibility in side bending as well as in the management of scoliosis. It is important to note that stretching has not been shown to correct or halt progression of structural scoliosis, although they may be beneficial in gaining some flexibility prior to surgical fusion of

**FIGURE 16.15** Self-stretching of the soft tissues anterior to the lumbar spine and hip joints with the patient (A) prone (using a press-up) and (B) standing.

the spine for correcting a scoliotic deformity. They may also be used to regain flexibility in the frontal plane when muscle or fascial tightness is present with postural dysfunction. All of the following exercises are designed to stretch hypomobile structures on the concave side of the lateral curvature.

When stretching the trunk, it is necessary to stabilize the spine either above or below the curve. If the patient has a double curve, one curve must be stabilized while the other is stretched.

- **Patient position and procedure:** Prone. Stabilize the patient (manually or with a belt) at the iliac crest on the side of the concavity. Have the patient reach toward the knee with the arm on the convex side of the curve while stretching the opposite arm up and overhead (Fig. 16.16). Instruct the patient to breathe in and expand the rib cage on the side being stretched.
- **Patient position and procedure:** Prone. Have the patient stabilize the upper trunk (thoracic curve) by holding onto the edge

**FIGURE 16.16** Stretching hypomobile structures on the concave side of the thoracic curve. Illustrated is a patient with a right thoracic left lumbar curve. The therapist stabilizes the pelvis and lumbar spine while the patient actively stretches the thoracic curve by reaching upward on side of concavity and downward on side of convexity.

of the mat table with the arms. Lift the hips and legs and laterally bend the trunk away from the concavity (Fig. 16.17).

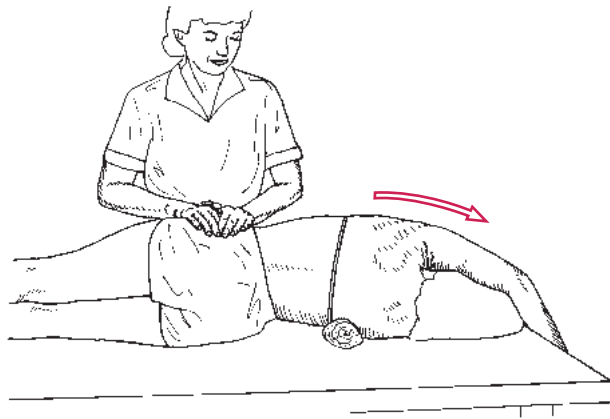

**FIGURE 16.17** Stretching hypomobile structures on the concave side of a left lumbar curve. The patient stabilizes the upper trunk and thoracic curve as the therapist passively stretches the lumbar curve.

- **Patient position and procedure:** Heel-sitting. Have the patient lean forward so the abdomen rests on the anterior thighs (Fig. 16.18 A); the arms are stretched overhead bilaterally; and the hands are flat on the floor. Then have the patient laterally bend the trunk away from the concavity by walking the hands to the convex side of the curve. Hold the position for a sustained stretch (Fig. 16.18 B).
- **Patient position and procedure:** Side-lying on the convex side of the curve. Place a rolled towel at the apex of the curve, and have the patient reach overhead with the top arm. Stabilize the patient at the iliac crest. Do not allow the patient to roll forward or backward during the stretch. Hold this position for a sustained period of time (Fig. 16.19).
- **Patient position and procedure:** Side-lying over the edge of a mat table with a rolled towel at the apex of the curve and the top arm stretched overhead. Stabilize the iliac crest. Hold this head-down position as long as possible (Fig. 16.20).

**FIGURE 16.18** (A) Heel-sitting to stabilize the lumbar spine. (B) Hypomobile structures on the concave side of a right thoracic curve are stretched by having the patient reach the arms overhead and then walk the hands toward the convex side.

**FIGURE 16.19** Stretching tight structures on the concave side of a right thoracic curve. The patient is positioned side-lying with a rolled towel at the apex of the convexity. The lumbar spine is stabilized by the therapist.

**FIGURE 16.20** Side-lying over the edge of a mat table to stretch hypomobile structures of a right thoracic scoliosis. The therapist stabilizes the pelvis.

### CLINICAL TIP

Hip muscles have a direct effect on spinal posture and function because of their attachment on the pelvis. It is important that they have adequate flexibility for proper pelvic and spinal alignment. In addition to manual stretching techniques described in

Chapter 4 (see Figs. 4.25 to 4.30), see Chapter 20 for specific self-stretching techniques in the hip. Of primary importance:

- Hip extension (see Figs. 20.10 and 20.11)
- Hip flexion (see Fig. 20.12, also knee to chest as in Fig. 20.10)
- Hip rotation (see Figs. 20.14 and 20.15)
- Hamstrings (See Figs. 20.17 and 20.18)
- Tensor fascia lata (See Figs. 20.19 to 20.21)

## Traction as a Stretching Technique

### Manual Traction: Lumbar Spine

Manual traction is not as easily applied in the lumbar region as in the cervical region. At least one-half of the patient's body weight must be moved, and the coefficient of friction of the part to be moved also must be overcome to cause vertebral distraction and stretching. It is helpful to place the patient on a split-traction table for ease in moving and stretching the spine.

**Patient position:** Supine or prone. Stabilize the thorax with a harness secured to the head end of the table or have an assistant stabilize the patient by standing at the head of the table and holding the patient's arms. Position the patient so there is maximal stretch on the hypomobile tissue.

- To stretch into extension, extend the hips.
- To stretch into flexion, flex the hips.
- To stretch into side bending, move the lower extremities to one side.

**Therapist position and procedures:** Position yourself so effective body mechanics and body weight can be used.

- If the lower extremities are extended to emphasize spinal extension, exert the pull at the ankles.
- If the lower extremities are flexed to emphasize spinal flexion, drape both of the legs over your shoulder that is closest to the mid-line of the table and exert the stretch force with your arms wrapped across the patient's thighs. As an alternative, place a pelvic belt with straps around the patient and manually pull on the straps.
- For unilateral impairments, pull on one extremity.

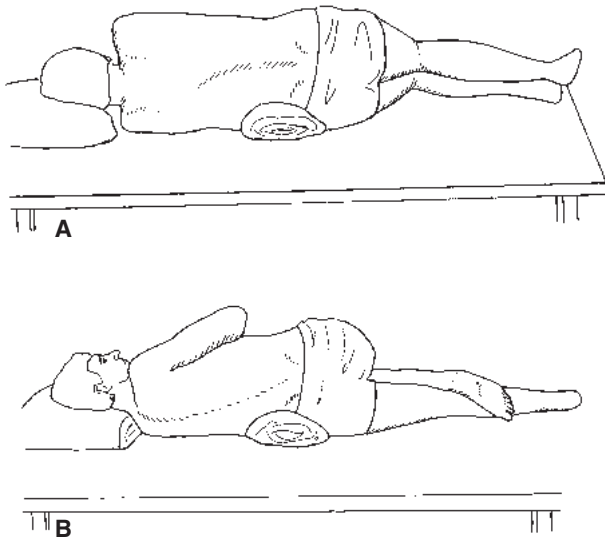

### Positional Traction: Lumbar Spine

The value of positional traction is that the primary traction force can be directed to the side on which symptoms occur, or it can be isolated to a specific facet, making it beneficial for selective stretching.

**Patient position:** Side-lying, with the side to be stretched uppermost. A rolled blanket or thick towel is placed under the spine at the level where the traction force is desired; this causes side bending away from the side to be treated and, therefore, an upward gliding of the facets (Fig. 16.21 A).

**Therapist position:** Standing, at the side of the treatment table facing the patient. Determine the segment that is to receive most of the traction force and palpate the spinous processes at that level and the level above.

**Procedure:** The patient relaxes in the side-bent position. Rotation is added to isolate a distraction force to the desired level. Rotate the upper trunk by gently pulling on the arm on which the patient is lying while simultaneously palpating the spinous processes with your other hand to determine when rotation has arrived at the level just above the joint to be distracted. Then flex the patient's uppermost thigh, again palpating the spinous processes until flexion of the lower portion of the spine occurs at the desired level. The segment at which these two opposing forces meet now has maximum positional distraction force (Fig. 16.21 B).

**FIGURE 16.21** Positional traction for the lumbar spine. (A) Side bending over a 6- to 8-inch roll causes longitudinal traction to the segments on the upward side. (B) Side-bending with rotation adds a distraction force to the facets on the upward side.

### CLINICAL TIP

Mechanical traction units can provide considerable stretch force to the tissues of the thoracic and lumbar spine. Positioning considerations are as described for manual traction. Instructions for use of the equipment are not part of this text.

## Thoracic and Lumbar Joint Manipulation and HVT Techniques

Joint manipulation and HVT techniques have been shown to have minimal risk to patients<sup>8,21</sup> and also to be an effective intervention for spinal pain.<sup>8,11,14,17,21</sup> Although HVT has been practiced in physical therapy since the 1920s,<sup>62</sup> these techniques should not be performed by physical therapist assistants or physical therapy aides.<sup>4,62</sup> The indications for joint manipulation and HVT are discussed in Chapter 5.

HVT techniques may be easier to perform if the application of the force is coordinated with the patient's breathing. Instruct the patient to breathe deeply several times, and on the final exhalation, a high-velocity, low-amplitude force is delivered. Use caution that the patient does not hyperventilate during these procedures.

### CLINICAL TIP

When applying spinal manipulation techniques:

- Modify the application force for pain modulation.
- Coordinate stretch manipulation and HVT techniques with patient breathing.
- HVT is a low-amplitude, high-velocity technique.
- HVT is applied with one repetition only.

### PRECAUTIONS:

- Do not perform if manipulation causes a change in sensation or pain to radiate down an extremity.
- Extreme caution should be used when performing these techniques if the patient is pregnant, reports a current history of corticosteroid use, or has excessive pain.

### CONTRAINDICATIONS:

- Unhealed fracture
- History of joint or ligamentous laxity caused by trauma or systemic diseases
- Spondylolisthesis
- Acute joint inflammation/irritation
- Cauda equine symptoms
- HVT is contraindicated in persons with a history of osteoporosis or osteopenia.

## Manipulation Technique to Increase Thoracic Spine Extension (Fig. 16.22)

### VIDEO 16.3

**Patient position:** Prone with arms resting comfortably at patient's side. Place a pillow under the thoracic region for increased patient comfort and to promote a neutral cervical-thoracic curve.

**Therapist position and hand placement:** Stand on one side of the patient with your body facing toward the head of the patient. Place the distal phalanx of your second and third fingers on the transverse processes of the superior vertebral segment to be manipulated (Fig. 16.22 A). This is also referred to as the "V-spread technique." Place the hypothenar eminence of your other hand on top of the two-finger contact (Fig. 16.22 B).

**Manipulation force:** Apply an anterior glide. The contact points on the transverse processes serve as a point of reference. Your other hand exerts a force through the hypothenar eminence in an anterior direction.

**FIGURE 16.22** Thoracic Spine Extension Manipulation or HVT—prone: (A) “V-spread” finger placement on transverse processes and (B) force application with hypothenar eminence.

## Manipulation Technique to Increase Thoracic Spine Flexion

**Patient position:** Prone with arms resting comfortably at patient’s side. Place a pillow under the thoracic region for increased patient comfort and to promote a neutral cervical-thoracic curve.

**Therapist position and hand placement:** Same as for thoracic extension except the V-spread contact is on the transverse processes of the inferior vertebral segment to be mobilized.

**Manipulation force:** Apply an anterior glide. The contact points on the transverse processes serve as a point of reference. The other hand exerts a force through the hypothenar eminence in an anterior direction. Modify your forces for pain modulation or to improve motion.

## Manipulation to Increase Thoracic Spine Rotation (Fig. 16.23)

**VIDEO 16.3** 🌐

**Patient position:** Prone with arms resting comfortably at patient’s side. Place a pillow under the thoracic region for increased patient comfort and to promote a neutral cervical-thoracic curve.

**Therapist position and hand placement:** Using the V-spread contact, place one finger on the superior transverse process and the second finger on the contralateral inferior transverse process

**FIGURE 16.23** Thoracic Spine Left Rotation Manipulation or HVT—prone.

to be mobilized. The finger placement follows the “Rule of the Lower Finger” (see Clinical Tip).

**Manipulation force:** Apply an anteriorly directed force against the transverse processes with the contralateral hand pressing through the contact fingers.

### CLINICAL TIP

#### Rule of the Lower Finger

When applying the V-spread contact on the contralateral transverse processes for thoracic rotation assessment or manipulation, rotation of a segment occurs in the direction of the finger on the inferior transverse process.

Example: Manipulation of the T6–7 segment into left rotation. The superior finger is on the right transverse process of T6, facilitating rotation to the left. Concurrently, the inferior finger on the left transverse process of T7 is facilitating a right rotation force (see Fig. 16.23). Since the lower finger is on the left transverse process, the “rule of the lower finger” makes it easy to remember this is a left rotation manipulation.

## Pistol Thrust to Increase Thoracic Spine Mobility (Fig. 16.24)

### VIDEO 16.4

**Patient position:** Supine with arms crossed.

**Therapist position and hand placement:** Stand at the patient’s side facing toward his or her head. Roll the patient toward you and reach across the patient’s body; contact the inferior vertebra of the three-joint complex to be manipulated using the “pistol grip” (Fig. 16.24 A and C). Once contact is achieved, passively return the patient to the supine position. To improve rotation, use the rule of the lower finger as described in the clinical tip above.

**FIGURE 16.24** Thoracic spine manipulation: (A) hand placement on thoracic spine using a “pistol grip” and (B) manipulation force against patient’s crossed arms. (C) Pistol grip on a spinal model, showing carpometacarpal joint of thumb on one transverse process and flexed middle phalanx on opposite transverse process.

**Manipulation force:** Place your trunk directly over the segment to be manipulated. A cephalad distraction force is initiated with the patient’s body weight at the segment to be manipulated; this is followed by a high-velocity, posterior force against the patient’s crossed arms toward the table (Fig. 16.24 B).

## Cross-Arm Thrust to Increase Thoracic Spine Mobility (Fig. 16.25)

**FIGURE 16.25** Thoracic spine manipulation using cross-arm thrust

**Patient position:** Prone with arms resting comfortably at patient's side. Place a pillow under the thoracic region for increased patient comfort and to promote a neutral cervical-thoracic curve.

**Therapist position and hand placement:** Stand beside the patient. Cross your arms and place the pisiform (hypothelar eminence) of one hand on a left and one on a right transverse process of the segment to be manipulated. Modify transverse process contact to promote flexion, extension, or rotation by placing the pisiform on the superior, inferior, or "rule of the lower finger" transverse processes as described in the preceding sections.

**Manipulation force:** An anterior force is applied simultaneously by the hypothelar eminences. This may be used as either a manipulation or HVT intervention.

## Fall Thrust to Increase Thoracic Spine Mobility (Fig. 16.26) VIDEO 16.5

**Patient position:** Standing with arms crossed.

**Therapist position and hand placement:** Stand behind the patient and wrap your arms around the patient. Place a mobilization wedge or folded towel at the desired spinal level to direct the force to a specific thoracic segment. Grasp patient's elbows (left hand grasps patient's right elbow and right hand grasps left elbow). If unable to grasp the elbows, interlock your fingers in front of the patient.

**Manipulation force:** Lean backwards on your heels while applying an extension force on the patient's spine, then quickly drop down so your feet are flat on the floor.

**FIGURE 16.26** Thoracic spine manipulation using a fall thrust

## Rib Manipulation for Expiratory Restriction (Fig. 16.27) VIDEO 16.6

**FIGURE 16.27** Expiratory restriction rib manipulation

**Patient position:** Prone with arms resting comfortably at the patient's side or overhead. Place a pillow under the thoracic region for increased patient comfort and to promote a neutral cervical-thoracic curve.

**Therapist position and hand placement:** Stand beside the patient. The hypothelar eminence of your caudal facing hand is placed on the rib angle at the level of the hypomobility, and

the rest of the hand relaxes on the patient's back. The other hand is placed on the opposite rib to stabilize the rib cage.

**Manipulation force:** During active patient expiration, exert a series of four to five progressive manipulations against the restricted rib in an anterior, caudal, and medial direction during the last half of the expiratory phase. Use caution that the patient does not hyperventilate.

## Rib Manipulation for Inspiratory Restriction (Fig. 16.28)

**FIGURE 16.28** Inspiratory restriction rib manipulation

**Patient position:** Prone with scapula protracted on the side of the rib restriction. This can be accomplished by having the patient dangle the arm off the side of the treatment table. Place a pillow under the thoracic region for increased patient comfort and to promote a neutral cervical-thoracic curve.

**Therapist position and hand placement:** Stand on the side opposite the restriction; reach across the thorax with your inferior extremity and contact the pisiform or hypothenar eminence of your hand on the inferio-medial aspect at the angle of the rib to be manipulated. Stabilize your upper body with the contralateral hand leaning on the table.

**Manipulation force:** During patient exhalation, apply the force to remove all the slack from the costovertebral joint; continue with four to five progressive oscillations approximately half-way through the inspiratory phase. Apply the force perpendicular to the rib angle (in an anterior, caudal, and medial direction). Use caution that the patient does not hyperventilate.

## Elevated First Rib Manipulation (Fig. 16.29) VIDEO 16.7

**Patient position:** Sitting in a firm chair with his or her back supported. The head and neck are laterally flexed towards and rotated away from the side of restriction to stabilize the facets in the closed-pack position and relax the scalene muscle.

**FIGURE 16.29** Elevated first rib manipulation

**Alternate head/neck position:** The head and cervical spine are rotated toward the side of restriction to bring the transverse process posterior and place the first costotransverse articulation at end-range stretched position.

**Therapist position and hand placement:** Stand behind the patient and stabilize the head against your thorax. Place the second MCP of your other hand on the first rib just lateral to the costotransverse joint.

**Manipulation force:** Exert the manipulation force or HVT through the rib in a caudal and medial direction during patient exhalation.

## Manipulation Techniques to Increase Lumbar Spine Extension (Fig. 16.30)

VIDEO 16.8

**FIGURE 16.30** Lumbar spine extension manipulation/HVT—prone

**Patient position:** Prone. Place a pillow under the abdominal region for patient comfort and to provide a neutral lumbosacral curve.

**Therapist position and hand placement:** Place your pisiform (hypothenar eminence) over the spinous process. Relax the rest of your hand on the patient's back.

**Anterior glide manipulation force:** Push with your hypothenar eminence in an anterior direction. Align your trunk directly over the segment, so the force is directed downward and not at an angle.

## Manipulation to Increase Lumbar Spine Rotation (Fig. 16.31)

VIDEO 16.8 

FIGURE 16.31 Lumbar spine left rotation manipulation/HVT—prone

**Patient position:** Prone. Place a pillow under the abdominal region for patient comfort and to provide a neutral lumbosacral curve.

**Therapist position and hand placement:** Place your pisiform (hypothenar eminence) over one transverse process on the side opposite of the direction of the motion you wish to facilitate (i.e., if wanting to promote left rotation, place your hypothenar eminence on the right transverse process). Relax the rest of your hand on the patient's back.

**Anterior glide manipulation force:** Push with your hypothenar eminence in an anterior and medial direction.

## Manipulation to Increase Lumbar Intervertebral Side Bending (Fig. 16.32) VIDEO 16.9

**Patient position:** Side-lying with the restricted side down. Position the patient as close to the edge of the bed as possible and flex the hips and knees to 90°.

**Therapist position and hand placement:** Stand facing the patient. Place the finger tip from your caudal hand on the superior spinous process to monitor motion. Passively rotate the patient's trunk backward to “take up the slack” until just

FIGURE 16.32 Lumbar spine side-bending manipulation—side-lying

before you feel the vertebral segment move. Now, place the finger tip of your cephalad hand on the superior spinous process to monitor motion. Flex both of the patient's legs (hips) until just before you feel the vertebral segment move. The patient's legs can then be supported either on the plinth or your thigh.

**Manipulation force:** Lift the patient's legs into hip rotation, causing the lumbar spine to side bend in the same direction as the lifted legs.

## HVT Lumbar Roll to Increase Lumbar Rotation (Fig. 16.33)

VIDEO 16.10 

**Patient position:** Side-lying with the restricted side up. Position the patient as close to the edge of the bed as possible and flex the hips and knees to 90°. Provide a pillow for the patient to hold that can act as a physical barrier.

**Therapist position and hand placement:** Stand facing the patient. Place the fingertips of your cephalad hand on the inferior spinous process to monitor motion. Move the patient's top leg into hip flexion until just before you feel the inferior vertebral segment move. Maintain the patient's hip flexion by stabilizing the leg between the therapist's body and the treatment table, and move your cephalad hand to the superior spinous process to monitor motion (Fig. 16.33 A).

Passively rotate the patient's trunk backward to “take up the slack” until just before you feel the superior vertebral segment move, and rest the forearm on the patient's torso. The therapist's torso should be directly over the segment to be manipulated (Fig. 16.33 B).

**Manipulation force:**

- Therapist exerts a downward rotational thrust toward the table with the cephalad forearm and hand while exerting a rotational force through the caudal forearm by pulling

**FIGURE 16.33** Lumbar roll HVT: **(A)** monitor motion at the spine as the hip is flexed then stabilized by the therapist's trunk; **(B)** rotate the patient's trunk backward to take up the slack, and apply a rotational force through the lower spine by moving the innominate forward; **(C)** rotational forces applied to the segment above and below, including the innominate, demonstrated on a spine model.

the patient's lower trunk toward your body (Fig. 16.33 B and C).

- Alternative method is to use the caudal forearm and apply a rotational force through the patient's innominate. This technique (patient contact) is particularly useful if attempting to increase rotation at L5–S1.

## SI Joint Manipulation Technique to Increase Sacral Nutation (Flexion) (Fig. 16.34) [VIDEO 16.11](#)

**FIGURE 16.34** SI Nutation (Flexion) Manipulation.

**Patient position:** Prone. Place a pillow under the abdominal region for patient comfort and to provide a neutral lumbosacral curve.

**Therapist position and hand placement:** Place your pisi-form (hypothener eminence) over the sacral base (S1) region. Relax the rest of your hand on the patient's back.

**Anterior glide manipulation force:** Push with your hypothener eminence in an anterior-inferior direction.

## SI Joint Manipulation Technique to Increase Sacral Counternutation (Extension) (Fig. 16.35) [VIDEO 16.11](#)

**FIGURE 16.35** SI Counternutation (Extension) Manipulation

**Patient position:** Prone. Place a pillow under the abdominal region for patient comfort and to provide a neutral lumbosacral curve.

**Therapist position and hand placement:** Place your pisiform (hypothenar eminence) over the apex of the sacrum (S5) region. Relax the rest of your hand on the patient's sacrum.

**Anterior glide manipulation force:** Push with your hypothenar eminence in an anterior-inferior direction.

## Posterior Rotation Manipulation to Innominate (Fig. 16.36)

VIDEO 16.11 

FIGURE 16.36 Posterior Rotation Innominate Manipulation

**Patient position:** Supine with arms crossed over chest. Move the patient's trunk and legs toward the side of the restriction to create side-bending in the lumbar spine.

**Therapist position and hand placement:** Stand on the side opposite the restriction. Contact the patient's opposite anterior superior iliac spine (ASIS) with your caudal hand. With the cephalad, roll the patient's trunk toward you.

**Manipulation force:** Exert a progressive oscillation or HVT force posterior through the hand contact at the innominate.

## Muscle Performance: Stabilization, Muscle Endurance, and Strength Training

**Goals.** To (1) activate and develop neuromuscular control of deep segmental and global spinal stabilizing muscles to support the spine against external loading; (2) develop endurance

and strength in the muscles of the axial skeleton for functional activities; and (3) develop control of balance in stable and unstable situations.

This section is divided into two main sections. The first section presents principles and techniques of stabilization exercises for the cervical and lumbar spinal regions with a subsection on motor control exercises for segmental muscle activation and a subsection on global muscle stabilization. The second section presents principles and techniques of general isometric, dynamic, and functional exercises for the neck and trunk.

## Stabilization Training: Fundamental Techniques and Progressions

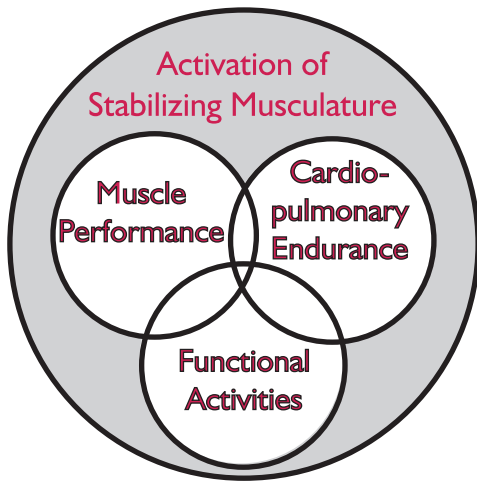

“Proximal stability for distal mobility,” a well-known phrase, is an underlying principle of intervention with therapeutic exercise. “Strengthening the core” has become a popular phrase in general exercise programs and classes, supporting the importance of focusing exercises on the trunk musculature to support the spine, even if not differentiating the specific functions of the various muscle groups. The primary functions of the muscles of the trunk are to provide stability so upright posture can be maintained against a variety of forces that disturb balance, to provide a stable base so the muscles of the extremities can execute their function efficiently and without undue stress to the spinal structures, and to move and control trunk motions during functional activities.

In Chapter 14, the two muscle systems that provide spinal stability and control are identified and described in detail: the deep segmental and superficial global (multi-segmental) musculature (see Figs. 14.10 to 14.15). Several studies have demonstrated altered or delayed neuromuscular recruitment patterns in the deep stabilizing muscles of the lumbar spine during active movement in individuals with LBP.<sup>31,34,35,55,61</sup> Results of other studies have shown improved ability to recruit these muscles with specific training<sup>9,60</sup> and improved outcomes compared with individuals not receiving the training.<sup>30,60,61</sup> Studies have also demonstrated improved outcomes in patients with cervical pain and cervicogenic headaches with recruitment of the deep stabilizing musculature in the cervical spine in conjunction with total trunk stabilization.<sup>40,46,50, 53</sup>

Therefore, one of the primary areas of emphasis for rehabilitation of individuals with spinal problems is teaching them how to recruit the segmental muscles and then how to use them to respond along with the global musculature to various forces and demands imposed on the spine to improve coordination of their overall function. Activation of the stabilizing musculature is then reinforced when progressing to muscular endurance and strengthening exercises, when performing aerobic exercises, and when practicing functional activities throughout the rehabilitative process with the anticipation

that muscle activation for stabilization will become automatic during all daily activities and functional challenges (Fig. 16.37).

**FIGURE 16.37** Exercises to improve muscle performance, cardiopulmonary endurance, and functional activities are integrated over a background of activating the deep segmental and global multi-segmental spinal stabilizing musculature.

Stabilization training follows the basic principles of learning motor control first by developing awareness of muscle contractions and spinal position, then by developing control in simple patterns and exercises, then progressing to complex exercises, and finally by demonstrating automatic maintenance of spinal stability and control in a progression of simple functional activities to complex and unplanned situations.<sup>75</sup> Many of the exercises can be used to accomplish more than one purpose; there is definite overlap with kinesthetic training, muscle performance, and functional training. The choice and progression of exercises described in each of the sections rely on clinical judgment of the patient's response and attainment of goals, not on a strict, time-based protocol or number of days from injury. The ability of the patient to control the spine in a neutral or non-stressful position is paramount for all the exercises.

#### CLINICAL TIP

*Stabilization training* follows basic principles of learning motor control.

1. Patient develops awareness of muscle contractions and spinal positions.
2. Patient develops control of spine when performing simple extremity patterns and exercises.
3. Patient demonstrates control of spine when progressing to complex exercises.
4. Patient demonstrates automatic maintenance of spinal stability and control in a progression of simple functional activities to complex and unplanned situations.

There is considerably more research on muscle function and its stabilization action in the lumbar spine than the cervical spine. The cervical spine requires more mobility to position the head, yet relies on the thoracic and lumbar spinal regions to provide a base for stability and postural control. Even though there are unique anatomical considerations in the cervical spine, there is overlap between stabilization training for cervical and lumbar problems.

## Guidelines for Stabilization Training

It is important to understand and use the principles and progression of stabilization training for effective instruction.<sup>7,56,69-71</sup> The following guidelines are summarized in Box 16.2.

1. *Kinesthetic training* for awareness of safe motion and positions must precede stabilization training. The functional range and functional position in which symptoms are minimal or absent are used for stabilization exercises.<sup>56</sup> When the condition is not acute, most people find the midrange (the neutral position) to be their functional position. It is important to recognize that this position or range is not static, nor is it the same for every person. In addition, it may change as the tissues heal, nociceptive stimuli decrease, and flexibility improves.<sup>56</sup>
2. *Activation* of the deep segmental muscles of the trunk, specifically the transversus abdominis (TrA) and multifidus (Mf), is often delayed or absent in patients with back pain.<sup>31,35,61</sup> In addition, ultrasound and MR imaging studies on individuals with unilateral LBP have shown decreased activation and atrophy of these deep muscles on the side of symptoms compared to the uninvolved side when performing voluntary contractions.<sup>22,79</sup>

### BOX 16.2 Guidelines for Stabilization Training: Principles and Progression

1. Begin training with awareness of safe spinal motions and the neutral spine position or bias.
2. Have patient learn to activate the deep stabilizing musculature while in the neutral position.
3. Add extremity motions to load the superficial global musculature while maintaining a stable neutral spine position (*dynamic stabilization*).
4. Increase repetitions to improve holding capacity (endurance) in the stabilizing musculature; increase load (change lever arm or add resistance) to improve strength while maintaining a stable neutral spine position.
5. Use alternating isometric contractions and rhythmic stabilization techniques to enhance stabilization and balance with fluctuating loads.
6. Progress to movement from one position to another in conjunction with extremity motions while maintaining a stable neutral spine (*transitional stabilization*).
7. Use unstable surfaces to improve the stabilizing response and improve balance.

Learning conscious activation of the deep segmental muscles without contracting the global trunk musculature is the first step in developing habitual activation for spinal stability in patients with pain related to poor spinal control and segmental instability. Once the individual learns correct activation of the segmental stabilizers using the “drawing-in” maneuver, this maneuver is used prior to all exercises and activities to develop the activation and stabilizing function and eventually automatic feedforward stabilization from the muscles.<sup>36</sup> A study involving 42 subjects demonstrated that it is possible to alter abdominal muscle activation consciously and automatically with specific exercises.<sup>60</sup>

In the cervical region, the deep cervical flexors, the longus colli and longus capitis, and the deep cervical and upper thoracic extensors are activated to stabilize the cervical spine in a neutral spinal position (axial extension with mild lordosis).

3. *Extremity motions* are added to the stabilization program to coordinate segmental muscle activity with the global stabilizing musculature. Loading via the extremities increases the stabilizing challenge to the musculature. The patient positions the spine in the neutral position (using pelvic tilt motions in the lumbar region and gentle head nodding in the cervical region), performs the drawing-in maneuver, and then begins moving one or several extremities while maintaining the neutral position. Extremity motions are performed within the tolerance of the trunk or neck muscles to control the neutral or functional position. This is called *dynamic stabilization*, because the stabilizing muscles in the spinal area must respond to the changing forces coming from the dynamic movement of the extremities. Exercises that require stabilization against transverse plane rotational forces on the pelvis more consistently activate the oblique abdominal and deep spinal stabilizers than sagittal plane resistive forces.<sup>68</sup>
4. *Increase muscular endurance and strength* once control of the spinal position is established and the patient can activate the stabilizing muscles. Repetitions of extremity motions are increased, and resistance is applied to the extremities. The intent is to challenge the trunk muscles to stabilize against these increased forces yet stay within their tolerance and ability to control the spinal position. Repetitions also help develop *habit*; therefore, it is important to use careful instructions and provide feedback. Fatigue is determined by the inability of the trunk or neck muscles to stabilize the spine in its functional position or by increased pain. For example:
  - Begin at a resistance force that the patient can repeat for 30 to 60 seconds and maintain the neutral position of the spine; progress the repetitions to 3 minutes.
  - Progress by adding resistance to or increasing the lever arm of the extremities; initially, reduce the time and again progress to doing the new activity for 1 to 3 minutes.
  - Another way to develop endurance in the trunk muscles is to begin exercising at the most difficult level for that
- patient, then shift to simpler levels of resistance as fatigue begins in order to keep moving. It is important that the patient does not lose control of the functional position or experience increased symptoms.
5. *Alternating isometric contractions* between antagonists and *rhythmic stabilization* of the trunk muscles against manual resistance also enhance stabilizing contractions. When performed while sitting and standing, the alternating contractions and co-contractions also develop control of balance.
6. *Transitional stabilization* develops as the patient moves from one position to another in conjunction with extremity motions. This requires graded contractions and adjustments between the trunk flexors and extensors and requires greater awareness and concentration.<sup>7,56</sup> For example, any motion of the arms or legs away from the trunk tends to cause the spine to extend. The abdominals (trunk flexors) must contract to maintain control of the functional spinal position. This occurs, for example, when lifting a load from the floor to overhead. Then, as the arms or legs move anteriorly toward the center of gravity, the spine tends to flex, which requires the extensors to contract to maintain the functional position (as would occur when lowering a weight to the floor). Greater concentration on maintaining the functional spinal position is necessary when doing more advanced functional activities.
7. *Perturbation (balance) training*, exercising against destabilizing forces or on unstable surfaces, develops neuromuscular responses to improve balance.

## Deep Segmental Muscle Activation and Training

The function of the deep musculature (TrA and Mf in the lumbar spine and longus colli and other deep musculature in the cervical spine) is described in Chapter 14, and the results of impaired function in these muscles are described in Chapter 15. Techniques for activation of the segmental musculature are described in this section.

### FOCUS ON EVIDENCE

Methods for testing and training activation of the deep segmental musculature have been developed and used in both research and clinical settings.<sup>48,65</sup> Placement of fine-wire electrodes with ultrasound guidance has provided valuable information regarding the muscle function and recovery in research settings,<sup>36,37,63</sup> and ultrasound imaging has provided a valuable tool for biofeedback in training.<sup>28,32,33,80</sup> Use of ultrasound biofeedback imaging has been prohibitively expensive to use clinically for training activation of the deep musculature. As an alternative device, a pressure biofeedback unit (Stabilizer™; © 2006 Encore Medical, L.P.) was developed and has been shown to have clinical usage in training activation and control of the stabilizing musculature of the trunk and neck.<sup>38,76</sup>

## Cervical Musculature

In the cervical region, the goal is to activate and control the muscles that control axial extension (cervical retraction). This requires capital flexion, slight flattening of the cervical lordosis, and flattening of the upper thoracic kyphosis (Fig. 16.38).

**FIGURE 16.38** Axial extension (cervical retraction) involves the motion of capital flexion and movement of the lower cervical and upper thoracic spine toward extension, resulting in slight flattening of the cervical lordosis and “lifting” of the head.

## Deep Neck Flexors: Activation and Training (Fig 16.39) VIDEO 16.12

**Patient position and procedure:** Supine. For craniocervical flexion and gentle axial extension, teach the patient to perform slow, controlled nodding motions of the head on the upper cervical spine (“yes” motion). If the patient has a significant forward head posture, place a folded towel under the

occipital area so extension of the head on the neck does not occur. Facilitate the motion with manual cues to ensure the longus colli is contracting, or the sternocleidomastoid is at a relative state of rest. Once the patient is able to activate the motion, the Stabilizer™ (or blood pressure cuff) may be used to monitor the amount of cervical flattening and measure the muscular endurance for holding the contraction (Fig. 16.39).

The protocol for use of the Stabilizer™ is summarized in Box 16.3.

## FOCUS ON EVIDENCE

Jull and associates<sup>41</sup> reported that the controlled performance of upper cervical flexion increases the pressure in the Stabilizer™ to 30 mm Hg and that the test-retest reliability of the craniocervical flexion test (conducted on 50 asymptomatic subjects 1 week between tests) was an ICC of 0.81 for the activation score and 0.93 for the performance index (see Box 16.3).

## Lower Cervical and Upper Thoracic Extensor Activation and Training

**Patient position and procedure:** Prone with forehead on the treatment table and arms at the sides. Have the patient lift the forehead off the treatment table, keeping the chin tucked and eyes focused on the table to maintain the neutral spinal position (reinforces the craniocervical flexion motion learned in the supine position). Lifting the head is a small motion (Fig. 16.40).

## Progression

Once the patient learns to activate the deep musculature and assume the neutral posture in the cervical spine, practice throughout the day is encouraged in order to develop good postural control. Stabilization training is initiated by

**FIGURE 16.39** (A) The Stabilizer™ pressure biofeedback unit (© 2006 Encore Medical, L.P.) is used to provide visual feedback to the patient while training for spinal stabilization; (B) Stabilizer folded into thirds under the cervical spine to test and train capital flexion with neutral spine axial extension.

### BOX 16.3 Testing and Training Deep Segmental Muscle Activation in the Cervical Spine

- Place blood pressure cuff or the folded Stabilizer™ pressure biofeedback unit (folded into thirds) under the upper cervical spine and inflate to 20 mm Hg.
- Instruct the patient to nod and increase pressure on the cuff to 22 mm Hg and hold the pressure steady for 10 seconds.
- If the patient is successful (i.e., can hold the position with minimal superficial muscle activity), have him or her relax and repeat the flexion, this time increasing pressure to 24 mm Hg. Repeat this incremental activation up to 30 mm Hg (total 10 mm Hg increase).
- The final pressure is the one at which the patient can hold steady for 10 seconds.
- Muscle endurance (holding or tonic capacity) of the deep neck flexors is measured by the number of 10-second holds (up to 10) at the final pressure.

A *performance index* can be used to document an objective measure. Multiply the pressure increase by the number of times the patient can repeat the 10-second holds—with 100 reflecting the holding of a 10 mm Hg increase for 10 repetitions.<sup>41</sup>

**FIGURE 16.40** Prone lying axial extension (cervical retraction) exercises.

coordinating control of the neutral spinal position with upper extremity loading. The extremity motions are used to stimulate muscular endurance as well as strengthen the stabilizing musculature in the spine. These exercises are described in the next section (Global Muscle Stabilization Exercises).

### Lumbar Musculature

Three techniques for abdominal muscle activation have been described and used in clinical practice: the drawing-in maneuver, abdominal bracing, and posterior pelvic tilt (Fig. 16.41). Each technique differs in the stabilization activity of the

**FIGURE 16.41** Three methods to activate the stabilizing musculature in the lumbar spine. **(A)** Drawing-in maneuver in which the patient hollows the abdominal region (“draws” the belly button toward the spine). **(B)** Abdominal bracing in which setting the abdominal muscles results in flaring laterally around the waist. **(C)** Posterior pelvic tilt in which the pelvis is actively tilted posteriorly and the lumbar spine flattens.

abdominal and Mf muscles.<sup>67</sup> Studies have demonstrated that the drawing-in maneuver is more selective in co-activating the TrA and Mf muscles than the abdominal bracing and posterior pelvic tilt techniques<sup>38,67</sup> and that the drawing-in maneuver leads to improvement in feedforward postural strategies.<sup>82</sup> The drawing-in maneuver also functions to increase intra-abdominal pressure by inwardly displacing the abdominal wall. Because of this, the drawing-in maneuver is recommended for stabilization training; the other two methods are also described, primarily so the reader can recognize the differences.

### Drawing-In Maneuver (Abdominal Hollowing Exercise) for TrA Activation VIDEO 16.13

**Patient positions:** Training may be easiest in the quadruped position in order to use the effects of gravity on the abdominal wall. Hook-lying (with knees 70° to 90° and feet resting on an exercise mat), prone-lying, or semi-reclined positions may be used if more comfortable for the patient. It is important to progress training to sitting and standing as soon as possible.<sup>51,54</sup>

**Procedure:** Teach the patient using demonstration, verbal cues, and tactile facilitation. Explain that the muscle encircles the trunk, and when activated, the waistline draws inward.

- Palpate the TrA muscle just distal to the ASIS and lateral to the rectus abdominis (RA) (Fig. 16.42). When the internal oblique (IO) contracts, a bulge of the muscle is felt; when the TrA contracts, flat tension is felt. The goal is to activate the TrA with minimal or no contraction of the IO. This is a gentle contraction.
- Have the patient assume a neutral spinal position and attempt to maintain it while gently drawing in and hollowing

**FIGURE 16.42** Palpation of the transversus abdominis (TrA) muscle just distal to the anterior superior iliac spine and lateral to the rectus abdominis muscle. The TrA feels like a tense sheet (a bulge is the internal oblique) when performing a gentle drawing-in maneuver.

the abdominal muscles.<sup>65</sup> Instruct the patient to breathe in, breath out, and then gently draw the belly button in toward the spine to hollow out the abdominal region. Once activated, have the patient maintain the contraction and resume breathing. When done properly, there are no substitute patterns; that is, there is minimal to no movement of the pelvis (posterior pelvic tilting), no flaring or depression of the lower ribs, no inspiration or lifting of the rib cage, no bulging out of the abdominal wall, and no increased pressure through the feet. Performing the drawing-in maneuver with the spine in a neutral position results in increased TrA response (measured as increased thickness in ultrasound imaging) compared to slouched sitting or slouched standing postures.<sup>64</sup>

If a patient has difficulty activating the TrA, the following two feedback techniques have been shown to assist with learning.<sup>25,66,67</sup>

- **Pressure biofeedback for clinical testing and visual feedback.** With the patient prone, the Stabilizer™ (or blood pressure cuff) is placed horizontally under the abdomen (centered under the navel). Inflate the Stabilizer™ to 70 mm Hg. Have the patient perform a drawing-in maneuver, as described above. A decrease of 6 to 10 mm Hg during the drawing-in maneuver (without substitutions) indicates proper activation of the deep abdominal muscles. The dial on the unit is large and easily read by the patient for immediate feedback.
- **Biofeedback with surface electrodes.** Surface electrodes placed over the RA and external obliques (EOs), near its attachment on the eighth rib, may be used in conjunction with the inflatable cuff. There should be minimal to no activation of these muscles if the drawing-in maneuver is done correctly.

As with the cervical spine, the Stabilizer™ can be used not only to train and reinforce activation of the TrA but also to measure control for a measured period of time as well as number of repetitions. The protocol is summarized in Box 16.4.

### BOX 16.4 Testing and Training Deep Segmental Muscle Activation (Transversus Abdominis) in the Lumbar Spine

- Patient is prone lying.
- Place a blood pressure cuff or the Stabilizer™ pressure biofeedback unit horizontally under the abdomen with the lower edge just below the anterior superior iliac spine (navel at center of unit).
- Inflate to 70 mm Hg and instruct the patient to perform the drawing-in maneuver.
- If done properly, the pressure drops 6 to 10 mm Hg.
- Have the patient maintain the gentle contraction while resuming relaxed breathing.
- See if the patient can maintain the pressure drop for up to 10 seconds.
- Muscle endurance (holding or tonic capacity) of the transversus abdominis is measured by the number of 10-second holds (up to 10).

Adapted from the instruction manual that accompanies the Stabilizer™ © 2006 Encore Medical, L.P., with permission.

### Abdominal Bracing

In contrast to the drawing-in maneuver, abdominal bracing occurs by setting the abdominals and actively flaring out laterally around the waist (see Fig. 16.41 B). There is no head or trunk flexion, no elevation of the lower ribs, no protrusion of the abdomen, and no pressure through the feet. The patient should be able to hold the braced position while breathing in a relaxed manner. This technique has been taught for a number of years as the method to stabilize the spine; it has been shown to activate the oblique abdominal muscles consistent with their global stabilization function.<sup>48,67</sup> In addition, abdominal bracing has been reported to activate a stronger contraction in the IOs than with sagittal plane exercises including various dynamic trunk flexion exercises.<sup>48</sup> Instructions to brace frequently during the day, whether combined with a strengthening or stretching exercise program, has been shown improved outcomes in managing LBP over a 10-year period.<sup>2</sup>

### Posterior pelvic tilt

Posterior pelvic tilt exercises (see Fig. 16.41 C) principally activate the RA muscle, which is used primarily for dynamic trunk flexion activity. It is a superficial muscle that does not have segmental attachments; therefore, it is not emphasized in the training for stabilization.<sup>67</sup> Pelvic tilt exercises are used to teach awareness of the movement of the pelvis and lumbar spine as the patient explores his or her lumbar ROM to find the functional spinal range and the neutral position.

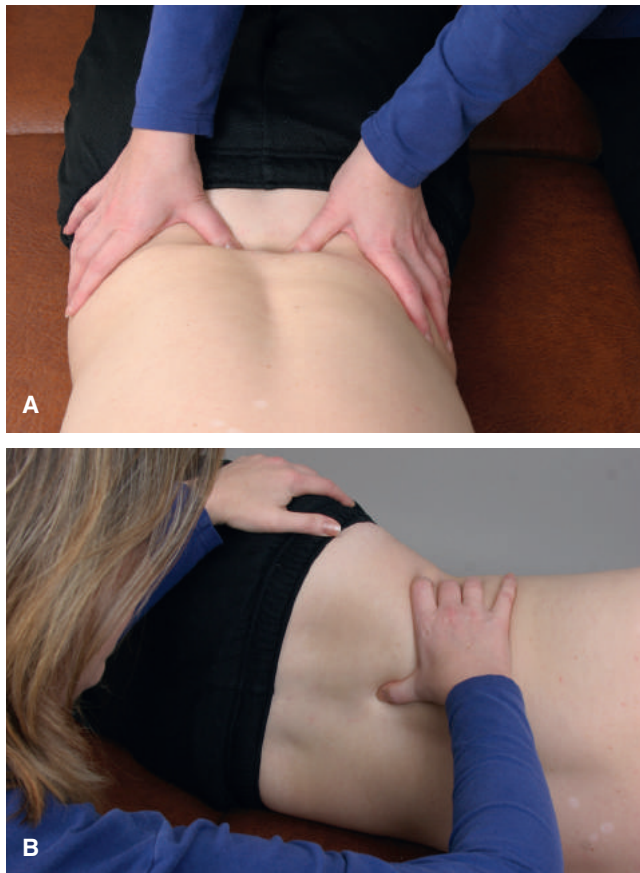

### Mf Activation and Training VIDEO 16.14

**Patient position and procedure:** Prone or side-lying. Place your palpating digits (thumbs or index fingers)

immediately lateral to the spinous processes of the lumbar spine (Fig. 16.43).

- Palpate each spinal level so comparisons in the activation of the Mf muscle can be made between each segment as well as from side-to-side.
- Instruct the patient to “swell the muscle” out against your digits. Palpate for consistency of muscle contraction at each level.
- Facilitation techniques include using the drawing in maneuver and gently contracting the pelvic floor muscles (as in Kegel exercises, described in Chapter 24).
- In the side-lying position, facilitate by gently applying manual resistance to the thorax or pelvis to activate the rotation function of the Mf.
- The patient may be taught to self-palpate a Mf contraction in the following manner. Sit and rock the pelvis to find the neutral position; with the fingers or thumbs placed along the lumbar spinous processes, lean forward a couple degrees. The Mf is thus activated. Differentiate a Mf contraction from tension in the aponeurosis of the global erector spinae.

**FIGURE 16.43** Palpation of the multifidus muscle lateral to the spinous processes in the lumbar spine, (A) bilaterally in the supine position and (B) unilaterally in the side-lying position.

### Progression

Once the patient learns to activate the deep segmental musculature, practice throughout the day is encouraged. Segmental muscle activation is then coordinated with stabilization training, using the global musculature and extremity loading. Extremity motions are added and used to stimulate muscle endurance as well as strengthen the trunk muscles. Global stabilization exercises are described in the next section.

## Global Muscle Stabilization Exercises

Even though this section is divided into cervical and lumbar regions, many of the same exercises may be used for impairments in either region because of the functional relationships of the entire axial skeleton.

### Stabilization Exercises for the Cervical Region

#### Stabilization With Progressive Limb Loading

In general, stabilization exercises begin in the recumbent position and progress to quadruped with the trunk supported on a large gym ball, sitting, sitting on a large gym ball, standing with the back supported against a wall, and finally standing without support. For advanced training, exercises are progressed to standing on an unstable surface.

- Begin all exercises with gentle craniocervical nods and axial extension to the neutral spinal position to activate the deep segmental muscles as described in the previous section. During the early phases of training, if the patient has difficulty maintaining a neutral spinal position, a small towel roll may be placed under the neck for passive support.
- Initially, the only resistance load comes from simple upper extremity movements. When the patient can perform multiple repetitions of the upper extremity motions without losing control of the spinal position or causing an increase in symptoms, resistance is added with handheld weights or elastic resistance.
- The principles of muscle endurance and strengthening described in Chapter 6 are used to challenge the spinal stabilizing musculature.
- Table 16.2 summarizes limb-loading exercises that emphasize the flexor muscles, and Figure 16.44 illustrates the basic exercise progression in the supine position.
- Table 16.3 summarizes limb-loading exercises that emphasize the lower cervical/upper thoracic extensor muscles, and Figure 16.45 illustrates a basic exercise progression in the prone position. It is important to note that these exercises do not isolate the flexors or extensors, but the designation is primarily for emphasis due to the effects of gravity.

### Variations and Progressions in the Stabilization Program

Remind the patient to find and maintain the neutral spinal position when doing these exercises.

**TABLE 16.2** Cervical Stabilization With Progressive Limb Loading—Emphasis on Cervical Flexors **VIDEO 16.15**

<i>Instructions:</i> Determine amount of support needed and amount of protection. Begin each exercise with axial extension to the neutral spinal position and maintain it while exercising; increase extremity repetitions, then increase resistance before progressing to a new challenge.		<b>Maximum Support</b> ←————→ <b>Minimum Support</b>			
		Supine	Sitting (sitting on ball for less stability)	Standing with wall support	Standing with no support (standing on unstable surface for less stability)

*Continued*

**FIGURE 16.45—cont'd (C)** shoulder elevation full range, **(D)** shoulders 90° with lateral rotation and elbow extended, horizontal abduction, and scapular adduction.

**Extremity loading.** During the early phases of training, limit shoulder flexion to 90° flexion and abduction. Once the patient can maintain stability and symptoms are not provoked, greater challenges occur with elevating the upper extremity full ROM. Unilateral and asymmetrical upper extremity motion require greater control than bilateral motion.

**External resistance.** Tables 16.2 and 16.3 summarize progressions based on position changes. In addition, use of resistance loads (free weights, elastic resistance, or manual resistance) to any of the exercises adds to the stabilizing challenge. Even though external resistance applied through the extremities has the benefit of increasing strength in the extremity musculature, the primary goal is to increase the stabilizing response of the cervical musculature. Therefore, any loss of the neutral spinal posture or increase in cervical symptoms signals the need to decrease the intensity of the resistance force.

**Unstable surfaces.** The application of external resistance while on an unstable surface, such as sitting on a large ball (Fig. 16.46 A), lying prone over a ball (Fig. 16.46 B), or standing supporting the ball between the head and the wall (Fig. 16.46 C), provides additional challenges to the muscles as they respond to perturbations. Many variations of these exercises can be used to challenge the stabilizing muscles so long as the patient is able to maintain control.

**Muscular endurance and strength.** Determine the maximum level of resistance tolerated by the cervical-stabilizing musculature that does not reproduce symptoms. Decrease the

intensity and have the patient exercise with multiple repetitions at that level (20 to 30 repetitions or for 1 minute). Resistance can then be added for strengthening (decrease the number of repetitions) at that level before progressing to endurance training at the next level.

### Integration of Stabilization Exercises and Posture Training

Good postural alignment of the neck begins with the pelvis and lumbar spine and moves up to the scapular and thoracic regions. The thorax must be lifted up from the pelvis and scapula retracted in a comfortable position for the cervical spine to assume an efficient position of axial extension (cervical retraction). Therefore, begin with lumbopelvic control if necessary and develop thoracic extension and scapular retraction. While the patient is performing the extremity motions to develop stability, reinforce good scapulohumeral alignment. It is important to remember that strengthening alone does not correct faulty posture and, therefore, to utilize the reinforcement techniques and environmental adaptations that are discussed in Chapter 14.

### Progression of Isometric and Dynamic Strengthening in Conjunction With Functional Activities

When the patient demonstrates good cervical stabilization and response to various upper extremity resistance changes, isometric and dynamic exercises are integrated into the program. These are described in the Isometric and Dynamic Exercise section following this section.

**FIGURE 16.46** Unstable surfaces provide increased challenges to the cervical stabilizing musculature, requiring greater control. Examples include performing upper extremity motions, such as diagonal patterns (A) while sitting on a gym ball, (B) while quadruped over a gym ball, and (C) while pressing a ball against the wall. Use of external resistance is also illustrated.

**Stabilization Exercises for the Lumbar Region**

Once the patient learns to activate the deep segmental muscles in the lumbar region, explain that prior to each exercise the patient is to find the neutral spinal position, perform the drawing-in maneuver, and then maintain control while applying an exercise load with extremity motions. The drawing-in maneuver develops the pattern of setting the deep abdominal and Mf muscles in a feedforward pattern and then trains their holding capacity in coordination with the global muscles.<sup>25</sup>

**Stabilization With Progressive Limb Loading**

Begin with the patient supine for greatest support, adding quadruped exercises when able. If the patient cannot control the position, pre-position him or her using pillows or supports (see Box 15.6 in Chapter 15).

- To improve the holding capacity of the stabilizing muscles, increase the amount of time the patient does the exercises. It is important that no exercise is continued if the patient cannot maintain the stable position. If the deep abdominals cannot stabilize, substitute patterns in the superficial muscles that override the deep muscle activation.
- The Stabilizer™ Pressure Biofeedback unit (or blood pressure cuff) may be used for feedback during this early training (see Box 16.5 for guidelines).
- Table 16.4 summarizes basic limb-loading exercises in the supine position that emphasize the abdominal muscles, and Figures 16.47 and 16.48 illustrate the exercise progression.
- Table 16.5 summarizes limb-loading exercises in the quadruped and prone positions that emphasize the extensor muscles, and Figure 16.49 illustrates a basic exercise progression.

**TABLE 16.4** Basic Lumbar Stabilization With Progressive Limb Loading—Emphasis on Abdominals

<p><i>Instructions:</i> Patient position hook lying (knees 90°). Place pressure cuff under lumbar spine and inflate to 40 mm Hg. Begin each exercise with drawing-in maneuver to activate deep segmental muscles. Determine level at which patient can maintain pressure constant (stable pelvis) while performing either A, B, or C limb load activity. For endurance, decrease load and perform repetitive motion for 1 minute or longer. For strength, progress load.</p>		<p><b>Progressive Limb Loading</b> <span style="font-size: 2em;">→</span></p>

**FIGURE 16.47** Bent-leg fall out. Level 2 limb loading for basic stabilization of the abdominal muscles in the supine position. This requires control to prevent pelvic rotation; stability is assisted by the opposite lower extremity while hook-lying. **VIDEO 16.17**

### BOX 16.5 Instructions for Use of Stabilizer™ for Stabilization Training With Leg Loading

*Patient position:* Supine, hook lying.

- Place the three-chamber pressure cell under the lumbar spine horizontally across low back area.
- Position the spine in neutral.
- Inflate the pressure cell to a baseline of 40 mm Hg.
- Draw in the abdominal wall without moving the spine or pelvis.
- Pressure should remain at 40 mm Hg ( $\pm 10$  mm Hg) while performing the lower extremity loading exercises.

Adapted from the instruction manual that accompanies the Stabilizer™ © 2006 Encore Medical, L.P., with permission.

**FIGURE 16.48** Limb loading for basic stabilization progression of the abdominal muscles in the supine position, levels 3 to 6: level 3, stability assisted by opposite extremity in hook-lying position; level 4, stability assisted by patient holding opposite leg at 90°; level 5, stability challenged by patient actively holding opposite leg at 90°; level 6, stability challenged with both lower extremities moving. **(A)** Bent leg lift to 90°. **(B)** Heel slide to extend knee. **(C)** Straight-leg lift to 45°. **VIDEO 16.18**

**TABLE 16.5** Basic Lumbar Stabilization With Progressive Limb Loading: Emphasis on Trunk Extensors

<p><i>Instructions:</i> Patient position quadruped or prone. Patient assumes neutral spine in lumbar and cervical regions (keeping eyes focused toward floor or exercise mat), performs drawing-in maneuver, and moves extremities. Motions are repeated or alternated from side to side.</p>	Lower intensity	Quadruped position	Flex one UE	
			Greater intensity and spinal compression	Extend one LE by sliding it along the exercise mat
				Extend one LE and lift 6–8 inches off exercise mat
		Flex one UE and extend contralateral LE		
		Extend one LE		
	Prone lying position—near end of range of motion, requiring greater control of neutral spine	Extend both LE		
		Lift head, arms, and LE		

**FIGURE 16.49** Limb loading for basic stabilization progression of the lumbar extensors. Begin in the quadruped position and progress the intensity by **(A)** flexing one UE; **(B)** extending one LE with a leg slide; **(C)** extending one LE by lifting it off the mat; **(D)** flexing one UE while extending contralateral LE and then alternate to opposite extremities. Progress to prone: **(E)** extending one LE; **(F)** extending both LE; and **(G)** lifting head, arms, and trunk. **VIDEO 16.19**

### CLINICAL TIP

Performance of extremity loading in the prone position places a greater compressive load on the lumbar spine<sup>5,52</sup> and is not possible if there are hip flexion contractures; therefore, initiate extension exercises in the quadruped position so the lumbar spine can be positioned more easily in neutral and the patient can learn control.

If the patient cannot bear weight on the extremities or maintain balance in the quadruped position, use a padded stool or large gym ball for additional support.

It is important to maintain the cervical spine in its neutral position during quadruped exercises. The patient should be able to align the head and focus the eyes on the floor. As the exercises progress, there is a greater challenge on co-activation of all of the stabilizing musculature.

**NOTE:** The exercise progressions described in Table 16.4 are adapted from several research studies that investigated the reliability, validity, and sensitivity to change one exercise level with abdominal muscle stabilizing ability using lower-limb loading.<sup>23,25,39</sup> The exercise progressions described in Table 16.5 are adapted from electromyography (EMG) studies that documented extensor activity with limb loading in the quadruped and prone-lying positions.<sup>6,52</sup>

### Variations and Progressions in the Stabilization Exercise Program

For all exercises, reinforce the importance of first finding the neutral spine (cervical and lumbar regions), performing the drawing-in maneuver, and then maintaining the neutral spine while superimposing any extremity motions. It is critical to instruct the patient to stop the exercises (or decrease the intensity) as soon as loss of control of the stable spinal position is sensed. In order to develop the desired muscle response it is important not to progress the patient beyond what he or she is able to control. The emphasis is first on improving the static holding capacity (endurance) of the trunk muscles followed by strengthening. Endurance training of the trunk extensor muscles is related to decreased pain and improving function during the early stages of recovery in patients with subacute LBP.<sup>13</sup>

**Emphasis on muscle endurance.** Determine a level of exercise that the patient can perform for several repetitions while maintaining a stable spine in the neutral position. Have the patient exercise at that level with the goal of increasing the number of repetitions or the time. Once the patient can perform repetitions for 1 minute, add weights, decrease the repetitions, and emphasize strength. Progress to the next level of difficulty for muscular endurance.

**Use of external props.** Use of the Stabilizer™ pressure biofeedback unit to help the patient learn control while doing the abdominal stabilization exercises was described earlier (see Box 16.5). For exercises in the quadruped position, if the

patient has difficulty controlling the trunk rotation, use a prop, such as a dowel rod, placed along the spine. Have the patient attempt to keep it balanced while performing the arm and leg exercises (Fig. 16.50). It may be helpful to cue the patient not to shift his or her weight as the extremity is moved—this is difficult to do but is effective in bringing in the stabilizing trunk muscles.

**Extremity loading.** Boxes 16.5 and 16.6 identify a progression of exercises in supine and quadruped/prone positions with extremity loading. Initially, have the patient do the motions repetitively; then progress to alternating the extremities or moving all four extremities simultaneously (Fig. 16.51).

**FIGURE 16.50** Balancing a rod on the back while doing quadruped exercises provides reinforcement that the trunk is not twisting. (A) Single leg slides. (B) Lifting the opposite arm and leg simultaneously, then alternating extremities.

**FIGURE 16.51** (A) Alternating LE motions with the "modified bicycle" or (B) reciprocal and alternating patterns using the UE and LE simultaneously require a strong controlling action in the abdominals.

This requires the stabilizing musculature to adjust to the shifting loads. Motions begin in the sagittal plane and then progress to the transverse plane and diagonal patterns (unilateral and bilateral), in which movement away from the midline adds a rotational component and increases the challenge to the stabilizing musculature.

**External resistance.** Use weights, elastic resistance, or pulleys for strengthening. Several suggestions are illustrated in Figures 16.52, 16.53, and 16.54. Even though the extremities benefit from the exercises, the primary purpose is to improve performance in the stabilizing muscles of the trunk; therefore, when signs of fatigue occur, such as poor control of spinal stability (seen as movement of the pelvis or lumbar spine), reduce the intensity or stop the exercise and allow recovery.

**Position changes.** Apply the extremity-loading exercises in the sitting (supported then unsupported), kneeling, and standing positions. Also, use modified bridging and plank exercises to challenge the stabilizing function of the trunk musculature.

**FIGURE 16.52** Developing the stabilizing action of the abdominal muscles by using pull-down activities against a resistive force from pulleys or elastic bands. This exercise can also be done sitting or standing to increase the challenge to the muscles in less stable positions.

**FIGURE 16.53** Using elastic resistance to train and strengthen the abdominal muscles in the upright position. The drawing-in maneuver to set the deep segmental stabilizing muscles precedes the movement of the arms forward against the resistance.

**FIGURE 16.54** Using elastic resistance to train and strengthen the back extensor muscles to stabilize in the upright position (A) diagonal patterns while sitting on an unstable surface and (B) while standing.

These exercises are described in the following Isometric and Dynamic Exercises section.

**Functional activities.** Exercises, such as wall slides and partial lunges and bridging with extremity motions, use the extremities and trunk during weight bearing and prepare the muscles for functional activities. These exercises are described in the final section under Functional Activities but also serve the purpose of challenging the stabilizing muscles.

**Unstable surfaces.** Use a large gym ball, foam roller, or wobble board to challenge the patient's balance and develop the stabilizing musculature. Scott et al<sup>73</sup> documented increased cross sectional area of the Mf when sitting on a large gym ball when compared with sitting on a firm surface. With the ball, a variety of positions can be used, such as sitting upright on the ball with the feet on the floor (Fig. 16.55), lying supine with

**FIGURE 16.55** Strength, balance, and coordination are required to maintain spinal stabilization while sitting on a gym ball and moving the extremities. This activity is progressed by adding weights to the extremities.

the trunk on the ball and feet on the floor (see Fig. 16.60 B), or with the feet on a low mat or wobble board. The foam roller can be used with the patient supine (Fig. 16.56), kneeling, quadruped (with hands on one roller and knees on another), or standing. Use handheld weights or elastic or pulley resistance secured at various heights (see Fig. 16.54) to increase the challenge. **VIDEOS 16.20 AND 16.21**

### Quadratus Lumborum: Stabilization Exercises

#### VIDEO 16.22

The quadratus lumborum has been identified as an important stabilizer of the spine in the frontal and transverse planes.<sup>52,63</sup> Strongest activation of this muscle occurs with the side propping (side plank) position. The EOs are also activated in this position.<sup>48,52</sup>

**Patient position and procedure:** Begin side-lying. Have the patient prop up on the elbow and then lift the pelvis off the mat, supporting the lower body with the lateral side of the knee on the downward side. The position can be maintained for an isometric hold or performed intermittently (Fig. 16.57 A). Progress by having the patient support the upper body with the hand (with the elbow extended) and lateral aspect of the foot on the downward side (Fig. 16.57 B). Arm and leg movements (without then with weights) are added to increase the challenge.

**FIGURE 16.57** Quadratus lumborum stabilization training using side-propping (side plank) (A) on the elbow and knee and (B) on the hand and foot.

**FIGURE 16.56** Activation of the stabilizing trunk muscles occurs to maintain balance on a foam roll while the extremities move in various planes: (A) shoulder horizontal abduction/adduction and (B) ipsilateral hip and shoulder flexion/extension are shown. Weights are added to increase the challenge.

### FOCUS ON EVIDENCE

Using ultrasound imaging, Teyhen and associates<sup>81</sup> demonstrated that the side support (side propping) exercise resulted in the greatest change in muscle thickness of the TrA and IO muscles with the least amount of lumbar loading compared to five other trunk exercises (abdominal crunch, drawing-in maneuver, quadruped opposite upper extremity and lower extremity lift, supine lower extremity extender, and abdominal sit back).

### Progression to Dynamic Exercises

When the patient has developed control, endurance, and strength in the stabilizing muscles in weight-bearing and nonweight-bearing positions, dynamic trunk strengthening exercises are initiated at a low intensity (see the following section). The emphasis is on control and safety.

As the patient returns to his or her instrumental activities of daily living (IADLs) and limited work activities, instruct him or her to incorporate the deep segmental activation and global stabilization techniques into the activities.

### FOCUS ON EVIDENCE

In a 10-year follow up study of individuals with recurring LBP, half of whom were taught to incorporate abdominal bracing in daily activities in addition to either a strengthening or flexibility exercise program, it was reported that regardless of exercise intervention, those who regularly used

abdominal bracing when doing functional activities had fewer recurrences of LBP, suggesting that abdominal bracing adds to the exercise effect and improves long-term prevention of recurrent LBP.<sup>2</sup>

## Isometric and Dynamic Exercises

Isometric exercises may be considered stabilizing exercises, as there is little or no movement of the spinal segments. They are included in this section with dynamic exercises, however, because of the method of application of the resistive force; that is, the resistive force is applied directly to the axial skeleton rather than through limb loading, as described in the spinal stabilization section. The decision to use the isometric exercises described in this section must be based on the goals of intervention. The exercises may be combined with the stabilization exercises in a home exercise program.

Dynamic exercises with spinal movement are introduced into the patient's exercise program when the patient demonstrates effective segmental and global stabilization techniques and has developed endurance in the stabilizing musculature. Dynamic exercises should not be a substitute for stabilization exercises. Because of the load imposed on the spine, they may exacerbate the patient's symptoms if introduced prior to effective stabilization and control. They are important in the total rehabilitation of the individual with neck, thoracic, or LBP, as dynamic muscle endurance and strength is required for many daily activities as well as manual labor and athletic performance.

### Exercises for the Cervical Region

**PRECAUTION:** Use of external weights via a cable or pulley system applied directly to the head are contraindicated for cervical strength training due to the compressive loading on the spine and the potential loss of control during the exercise.

#### Isometric Exercises: Self-Resistance

The intensity of the isometric exercises can range from low to high, depending on the patient's symptoms and tolerance.

**Patient position and procedure:** Sitting.

- **Flexion.** Have the patient place both hands on the forehead and press the forehead into the palms in a nodding fashion while not moving (Fig. 16.58 A).
- **Side bending.** Have the patient press one hand against the side of the head and attempt to side bend, as if trying to bring the ear toward the shoulder but not allowing motion.
- **Extension.** Have the patient press the back of the head into both hands, which are placed in the back, near the top of the head (Fig. 16.58B).

**FIGURE 16.58** Self-resistance for isometric (A) cervical flexion and (B) axial extension.

- **Rotation.** Have the patient press one hand against the region just superior and lateral to the eye and attempt to turn the head to look over the shoulder without allowing motion.

#### Isometric Resistance Activities

**Patient position and procedure:** Standing with a basketball-sized inflatable ball between the forehead and a wall. Have the patient keep the chin tucked and not go into a forward-head posture. The patient maintains the functional position while superimposing arm motions. Progress by adding weights to the arm motions (see Fig. 16.46 C).

#### Dynamic Cervical Flexion

**Patient position and procedure:** Supine. If the patient cannot tuck the chin and curl the neck to lift the head off the mat, begin with the patient on a slant board or large wedge-shaped bolster under the thorax and head to reduce the effects of gravity (Fig. 16.59). Have the patient practice tucking the chin and curling the head up. Use assistance until the correct pattern is learned. Progress by decreasing the angle of the board or wedge and then adding manual resistance if the patient does not substitute with the sternocleidomastoid (SCM) muscles.

**FIGURE 16.59** Training the short cervical flexors while de-emphasizing the sternocleidomastoid for cervical flexion to regain a balance in strength for anterior cervical stabilization.

### CLINICAL TIP

Often with faulty forward-head postures, the patient substitutes using the SCM muscles to lift the head when getting up from the supine position rather than the overstretched, weak, deep cervical flexors. To correct this muscle imbalance, begin training capital flexion as described in the stabilization section (deep segmental muscle activation). For home exercise and when rising from a bed, emphasize “curling” the head and neck, not lifting the head up.

### Manual Resistance: Cervical Muscles

**Patient position and procedures:** Supine. Stand at the head end of the treatment table, supporting the patient’s head for each exercise.

- Place one hand on the patient’s head to resist opposite the motion. Do not resist against the mandible lest force be transmitted to the temporomandibular joint. Resistance is given to isolated muscle actions or to general ROMs, whichever best gains muscle balance and function.
- Isometric resistance can be applied with the head in any desired position before applying resistance. Avoid jerking the neck when applying or releasing the resistance by gradually building up the intensity, telling the patient to match your resistance, holding, and then gradually releasing and asking the patient to relax.

### Intermediate and Advanced Training

As the patient progresses in the rehabilitation program, greater challenges to the musculature to stabilize and control motion are emphasized, especially for those individuals returning to work, sports, or recreational activities that place greater demands on the cervical structures.

### Transitional Stabilization for the Cervical and Upper Thoracic Regions

- **Patient position and procedure:** Standing with a basketball-sized inflatable ball between the head and the wall. Have the

- patient roll the ball along the wall, using the head. This requires the patient to turn the body as he or she walks along.
- **Patient position and procedure:** Sitting on a large gym ball. Have the patient walk the feet forward so the ball rolls up the back and the thorax is resting on the ball (Fig. 16.60 A and B). The head and neck are maintained in neutral position, and the cervical flexors are emphasized. Have the patient then walk the ball farther, so it is under the head. The extensors are now emphasized (Fig. 16.60 C). The patient walks the feet forward and backward, alternating stabilization between the flexors and extensors. Progress to advanced training by adding arm motions and then arm motions with weights in each of the positions.

**NOTE:** This activity requires considerable strength in the cervical extensors to support the body weight and should be performed only with advanced training with patients who have been properly progressed to tolerate the resistance.

### Functional Exercises

Design exercises that simulate patient-specific functional activities. Identify what activities stress that individual’s neck and have the patient practice modifications of those activities with the spine kept in neutral position. Include pushing, pulling, reaching, and lifting (see the Functional Training section later in this chapter). Challenge the patient with increased repetitions and weight and by using patterns that replicate functional demands.

## Exercises for the Thoracic and Lumbar Regions

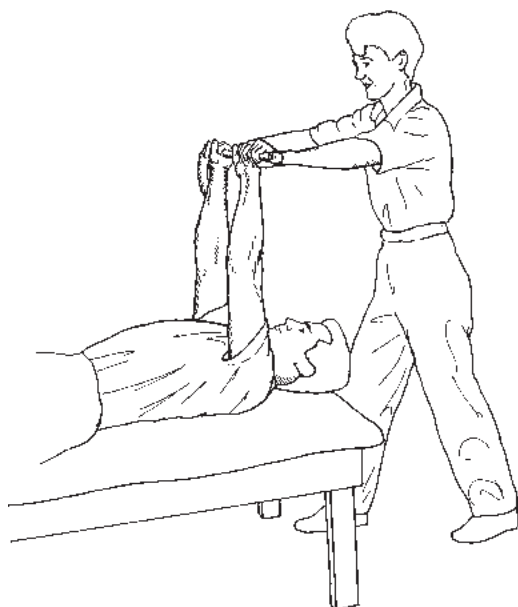

### Alternating Isometric Contractions and Rhythmic Stabilization VIDEO 16.23

**Patient positions and procedures:** Begin with the patient supine in the most stable position (Fig. 16.61). Progress to sitting kneeling, and then standing. Sitting, brings in the hip muscles, kneeling adds the knee muscles, and standing requires stabilizing action in the hip, knee, and ankle musculature

**FIGURE 16.60** Advanced exercises for strengthening the cervical and upper thoracic flexors and extensors as stabilizers. Begin by (A) sitting on a large gym ball, then (B) walking forward while rolling the ball up the back. With the ball behind the midthoracic area, the cervical flexors must stabilize. Continue walking forward until the ball is (C) under the head; the cervical extensors now must stabilize. Walk back and forth between the two positions (B and C) to alternate control between the flexors and extensors. Progress by adding arm motions or arm motions with weights to increase resistance.

**FIGURE 16.61** Alternating isometric resistance applied in the sagittal, frontal, and horizontal planes with the patient supine to stimulate the stabilizing function of the trunk musculature.

as well as the spinal muscles. Apply resistance directly against the patient's shoulders or pelvis, against a rod that is held by the patient (as in Fig. 16.61), or against the patient's outstretched arms.

- Have the patient find the neutral spine position and then activate the stabilizing muscles with the drawing-in maneuver prior to applying the resistive force. Then instruct the patient to “meet my resistance” while applying a force to stimulate isometric contractions. Apply the resistance in alternating directions at a controlled speed while the patient learns to maintain a steady position.
- Initially, provide verbal cues, such as “hold against my resistance, but do not overpower me. Feel your abdominal muscles contracting. Now, I’m pulling in the opposite direction. Match the resistance and feel your back muscles contracting.”
- Progress by shifting the directions of resistance without the verbal cues and then by increasing the speed and force.
- Begin with alternating resistance in the sagittal plane; progress to side-to-side and then transverse plane resistance. Isometric resistance to trunk rotation (transverse plane resistance) has been shown to be the most effective in stimulating the oblique abdominals, TrA, and deep spinal extensor muscles.<sup>68</sup>
- Increase the challenge by having the patient sit on a large gym ball while stabilizing against the alternating resistance.
- Alternating resistance to pelvic rotation can also be done by having the patient assume a modified bridge position. Apply resistance directly to the pelvis to stimulate rotation while the patient isometrically holds the pelvis and spine in a stable position.

## Isometric and Dynamic Strengthening: Abdominal Muscles

**NOTE:** Dynamic and high intensity isometric exercises of the trunk musculature are not initiated until late during the rehabilitation process and not until after the patient has learned to activate the drawing-in maneuver automatically for stabilization in all functional activities.

No one abdominal exercise equally challenges all of the abdominal muscles;<sup>52</sup> therefore, a variety of exercises should be included in the patient’s exercise program to include the entire region.

### FOCUS ON EVIDENCE

EMG studies have looked at abdominal muscle recruitment with various abdominal exercises.<sup>5,20,45,48,52,83</sup> Although there is some variation in outcomes, based on the study design and method of recording, in general the following can be summarized:

- Curl-ups (various types) recruit primarily the RA, with lower activity in the obliques, TrA, and psoas.
- Sit-ups (straight-leg and bent-knee) show high rectus and EO activity, high psoas activity, and high low back compression. Heel press sit-ups increase psoas activity.
- Hanging-leg raises show high EO and high spinal compression.
- Supine single-leg lifts show negligible global abdominal muscle activity (opposite lower extremity provides stability). Primarily, these exercises are used early in the stabilization exercise routines to train the deep stabilizing muscles under progressive extremity loading.
- Supine-bilateral leg lifts show increased activity in the RA, EO, and IO during the first part of the range of hip flexion and increased load on the spine.
- Curl-ups on a labile surface doubled the activity of the RA and increased the activity of the EOs four-fold compared with curl-ups on a stable surface.<sup>83</sup>
- V-sits show the greatest EMG muscle activity in the RA and EO.<sup>48</sup>
- Prone bridges (planks)<sup>15,43</sup> and pike with legs on a large gym ball show high activity in the RA, EO, and IO.<sup>20,43</sup>

*Rectus abdominis.* There is no clinically significant selective difference between the upper and lower RA function.<sup>45</sup> Both portions contract strongly in all trunk curl-type and leg lift exercises.<sup>45,52</sup> Strongest contraction occurs in V-sits, curl-ups, and sit-ups.<sup>48</sup>

*External obliques.* EOs contract strongest in sit-ups and diagonal sit-ups to the opposite side,<sup>50</sup> as well as v-sits.<sup>48</sup>

*Internal obliques.* IOs contract strongest in diagonal sit-ups to the same side and horizontal side propping (see Fig. 16.57),<sup>52</sup> as well as with abdominal bracing and hollowing.<sup>48</sup>

*Transversus abdominis.* Use of the drawing-in maneuver prior to the abdominal crunch, abdominal sit-back, and lateral side propping activates increased muscle thickness in the TrA (demonstrated with ultrasound imaging).<sup>81</sup>

### Trunk Flexion (Abdominals): Supine

**Patient position and procedures:** Supine or hook-lying with the lumbar spine neutral. McGill<sup>52</sup> suggested supporting the low back with the hands to maintain slight lordosis. The spine should not be allowed to go into an increased lordosis during the exercise—this indicates weakness of the abdominals and consequently lifting of the trunk occurs from hip flexor action only.<sup>42</sup> When training the abdominals, curl-up exercises should be performed at a slow, controlled rate to activate the stabilizing function of the abdominals.<sup>84</sup>

**PRECAUTIONS:** If a patient experiences pain or increased radicular symptoms with trunk flexion, these exercises should not be done. Use the stabilization exercises, as described in the previous section, with the spine maintained in a neutral position (slight lordosis).

**Curl-ups.** First, instruct the patient to perform the drawing-in maneuver to cause a stabilizing contraction of the abdominal muscles.<sup>81</sup> Progress by lifting the shoulders until the scapulae and thorax clear the mat, keeping the arms horizontal (Fig. 16.62). A full sit-up is not necessary, because once the thorax clears the mat, the rest of the motion is performed by the hip flexor muscles.

- Further progress the difficulty of the curl-up by having the patient change the arm position from horizontal to folded across the chest and then to behind the head, and then by holding a weight or medicine ball.

**Curl-downs.** If the patient is unable to perform the curl-up, begin with curl-downs by having the patient start in the hook-sitting or long-sitting position and lower the trunk only to the point at which he or she can maintain a flat low back and then return to the sitting position.

- Once the patient can curl-down full range, reverse and perform a curl-up.

**Diagonal curl-ups.** Have the patient reach one hand toward the outside of the opposite knee while curling up, then alternate. Reverse the muscle action by bringing one knee up toward the opposite shoulder, then repeat with the other knee. Diagonal exercises emphasize the oblique muscles.

**FIGURE 16.62** The curl-up exercise to strengthen the abdominal muscles. The thorax is flexed on the lumbar spine. The arms are shown in the position of least resistance. Progress by crossing the arms across the chest and then behind the head.

**Curl-ups on an unstable surface.** Progress the above curl-up exercises on an unstable surface, such as a large gym ball (Fig. 16.63), foam roller, or a biomechanical ankle platform system (BAPS) board.

**FIGURE 16.63** Curl-ups on an unstable surface. The unstable surface increases activity in the oblique and rectus abdominis muscles.

### FOCUS ON EVIDENCE

Both healthy adults<sup>24</sup> and patients with chronic LBP<sup>3,29</sup> have been shown to have impaired balance. Using unstable surfaces, such as a gym ball or a balance board, while doing abdominal curl-up exercises has been shown to increase activity in the IOs and EOs and the RA.<sup>83</sup> The presumption is that these muscles generate increased activity to maintain balance on the unstable surfaces.

**Double knee-to-chest.** To emphasize the lower RA and oblique muscles, have the patient set a posterior pelvic tilt, bring both knees to the chest, and return. Progress the difficulty by decreasing the angle of hip and knee flexion (Fig. 16.64).

**FIGURE 16.64** Strengthening the abdominal muscles by flexing the hip and pelvis on the lumbar spine. The legs are shown in the position for least resistance. Progress by decreasing the angle of hip flexion until the legs can be lifted with the knees extended, as in the pelvic lift.

**Pelvic lifts.** Have the patient begin with the hips at 90° and the knees extended; then lift the buttocks upward off the mat (small motion). The feet move upward toward the ceiling (Fig. 16.65). The patient should not push against the mat with the hands.

**FIGURE 16.65** Pelvic lifts. Elevating the legs upward toward the ceiling by raising the buttocks off the floor emphasizes strengthening the lower abdominal muscles.

**Bilateral straight-leg raising.** Have the patient begin with legs extended; then perform a posterior pelvic tilt followed by flexing both hips, keeping the knees extended. If the pelvis and spine cannot be kept stable, the knees should be flexed to a degree that allows control. If the hips are abducted before initiating this exercise, greater challenge is placed on the oblique abdominal muscles.

**Bilateral straight-leg lowering.** Bilateral straight-leg lowering can be performed if the bilateral straight-leg raising is difficult. Have the patient begin with the hips at 90° and knees extended; then, lower the extremities as far as possible while maintaining stability in the lumbar spine (should not increase the lordosis), followed by raising the legs back to 90°. See the Precaution under the bilateral SLR exercise.

#### PRECAUTIONS:

- The strong pull of the psoas major causes shear forces on the lumbar vertebrae. Also, the bilateral straight-leg raising and lowering exercises cause increased spinal compression loads.
- If there is any LBP or discomfort, especially with spinal hypermobility or instability, the bilateral straight-leg raising and lowering exercises should not be performed even if the abdominals are strong enough to maintain a posterior pelvic tilt.
- Be sure the patients avoid holding their breath (Valsalva maneuver) as they may try to use their diaphragm to provide the stabilization.

#### Trunk Flexion (Abdominals): Sitting or Standing

**Patient position and procedures:** Sitting or standing. Pulleys or elastic material are secured at shoulder level behind the patient. Progress the resistance as the patient's abdominal strength increases.

- Have the patient hold the handles or ends of the elastic material with each hand and then flex the trunk, with emphasis

on bringing the rib cage down toward the pubic bone and performing a posterior pelvic tilt (Fig. 16.66).

- Have the patient perform diagonal motions by bringing one arm down toward the opposite knee with emphasis on moving the rib cage down toward the opposite side of the pelvis. Repeat the diagonal motion in the opposite direction.

**FIGURE 16.66** Standing trunk flexion against elastic material to strengthen the abdominal muscles. The patient performs a posterior pelvic tilt and then approximates the ribs toward the pubis.

#### Trunk Flexion (Abdominals): Prone

**Patient position and procedures:** Prone lying and with variations using a large gym ball.

**Planks (prone bridging).** Have the patient support self on elbows and knees and elevate the pelvis off the floor while maintaining a neutral spinal position (Fig. 16.67A). If tolerated, progress to supporting self on elbows and toes, hands and knees, or hands and toes. If able, have the patient alternately lift

**FIGURE 16.67** Plank position (A) on elbows and knees, and (B) on elbows and toes; shown is a progression with alternating lower extremity extension while in the elbow-toe position.

one leg then the other (Fig. 16.67B), and then one arm with opposite leg. Planks with either arms on a large gym ball, or legs on the ball require high stabilization activity in the abdominal muscles.<sup>15,20</sup>

**Roll-out on gym ball.** Have the patient begin with knees on the floor and hands on the ball, and then have the patient roll the ball outward away from the knees until the forearms are on the ball, and then return upright while maintaining a neutral spinal position (Fig. 16.68 A and B).

**FIGURE 16.68** Beginning (A) and end positions (B) for roll-out on a large gym ball to strengthen the abdominal muscles.

**Pike on a gym ball.** Have the patient begin with legs supported on the gym ball and hands on the floor then roll the legs along the ball while elevating the pelvis upward in a pike position. This is a difficult exercise requiring high activity in the abdominal muscles.<sup>20</sup>

**Advanced planks with push-ups.** Advanced variations of prone exercises that challenge the abdominal muscles combined with upper extremity push-ups, are depicted in the Functional Activities section later in this chapter (see Fig. 16.74) and in Chapter 23 (see Figs. 23.23 and 23.24).

### Isometric and Dynamic Strengthening: Erector Spinae and Multifidus Muscles

Strengthening the extensor muscles and an improved extensor/flexor ratio of the trunk muscles have been found

to be important in decreasing symptoms in patients with chronic LBP.<sup>78</sup>

### FOCUS ON EVIDENCE

Lee and associates<sup>44</sup> determined that the trunk extensor/flexor ratio is a sensitive parameter for predicting LBP. After following 67 asymptomatic individuals for 5 years, they found an increased incidence of LBP in those who had lower extensor strength than flexor muscle strength. Danneels and colleagues<sup>16</sup> demonstrated that intensive lumbar resistance training (isometric or dynamic) is necessary to develop paravertebral muscle strength and bulk. The following is a summary of specific exercise outcomes studies:

- Dynamic prone extension (prone arch), isometric trunk extension, and isometric leg extensions: result in high activity in both the Mf and erector spinae,<sup>59</sup> trunk extensor muscles activated at a higher level with trunk extension than with leg extension exercises,<sup>18</sup> and stronger contractions in the extensors when both lower extremities are stabilized during trunk extension.<sup>19</sup>
- Quadruped and prone upper and lower extremity lifts: stronger contractions than bridging (including bridging with feet on gymnastic ball or shoulders on gymnastic ball).<sup>19</sup>
- Isolated training of Mf: requires a low-intensity focus, as described in the Stabilization section.<sup>65</sup>

### Extension Exercises in Prone or Quadruped Position

Resistance can be applied to any of the following recumbent exercises by having the patient hold weights in the hands or by strapping weights around the patient's legs.

**PRECAUTIONS:** Extension exercises in the prone position (prone arch) are performed at the end of the ROM in spinal extension and therefore may not be appropriate for individuals with symptoms from conditions, such as arthritis, spondylolisthesis, nerve root compression, or other flexion bias conditions, or patients who develop symptoms under loaded conditions (e.g., with disc lesions). Modify the positioning toward more neutral spinal positions by using the quadruped position and emphasize stabilization with isometric holds rather than moving into full extension (see Figs. 16.49 A through D, 16.50, and 16.54).

**Thoracic elevation.** Begin with the arms at the sides, progress to behind the head or reaching overhead as strength improves. Have the patient tuck in the chin and lift the head and thorax. The lower extremities must be stabilized (Fig. 16.69).

**Leg lifts.** Initially, have the patient lift only one leg, alternate with the other leg, and, finally, lift both legs and extend the spine (see Fig 16.49 E through G). Stabilize the thorax by having the patient hold onto the side of the treatment table.

**FIGURE 16.69** Strengthening the back extensors with the arms in position to provide maximal resistance. Additional resistance can be provided by holding weights in the hands.

**Variations.** Patient positioned prone on a large gym ball; combine spinal extension with upper extremity and/or lower extremity resistance, similar to exercises described in the stabilization exercise section (see Fig. 16.46 B).

### Extension Exercises Sitting or Standing

**Elastic resistance or weighted pulleys.** Secure pulleys or elastic resistance in front of the patient at shoulder level. Have the patient hold onto the ends of the material or handles and extend the spine (Fig. 16.70).

**FIGURE 16.70** Using elastic resistance for concentric eccentric back extension.

For trunk rotation, use a pulley or elastic resistance secured under the foot or to a stable object opposite the side being exercised. Have the patient pull against the resistance, extending and rotating the back. Change the angle of pull of the resistance to recreate functional patterns specific to the patient's needs (Fig. 16.71).

**FIGURE 16.71** Rotation with extension strengthens the back extensors in functional patterns.

### Trunk Side Bending (Lateral Abdominals, Erector Spinae, Quadratus Lumborum)

Trunk side-bending exercises are used for general strengthening of the muscles that side bend the trunk.

### FOCUS ON EVIDENCE

McGill<sup>52</sup> identified the quadratus lumborum as one of the most important stabilizers of the spine and documented the isometric horizontal side support (side plank) as an effective exercise to strengthen this muscle (see discussion in the Stabilization section and Fig. 16.57).

Side-bending exercises are also used if there is scoliosis, although exercise alone has not been shown to halt or change the progression of a structural scoliosis curve. Exercise in conjunction with other methods of correction, such as bracing, is often employed.<sup>10,57,58</sup> When there is a lateral curve, the muscles on the convex side are usually stretched and weakened. The following exercises are described for use as strengthening exercises on the side of the convexity, although they may be used bilaterally for symmetrical strengthening. Stabilization exercises for spinal control, as previously described, may be beneficial for strengthening and conditioning when there is scoliosis.

- **Patient position and procedure:** Standing. Place elastic resistance under the foot or have the patient hold a weight in the hand on the side of the concavity; then have him or her side bend the trunk in the opposite direction.
- **Patient position and procedure:** Side-lying on the concave side of the curve with the apex at the edge of the table or

mat so the thorax is lowered. If you have access to a split table with one end that can be lowered, begin with the apex of the curve at the bend of the table. Have the patient place the lower arm folded across the chest and upper arm along the side of the body and side bend the trunk up against gravity. Progress by having the patient clasp both hands behind the head (Fig. 16.72). Stabilization of the pelvis and lower extremities must be provided.

A

B

**FIGURE 16.72** Antigravity strengthening of the lateral trunk musculature. (A) There is less resistance if the top arm is at the side and the bottom arm is folded across the chest. (B) Increase resistance by positioning the arms behind the head.

## Cardiopulmonary Endurance

**Goal.** To develop cardiopulmonary fitness for overall endurance and well-being.

Aerobic conditioning exercises provide many benefits for the patient with spinal symptoms. The activity not only improves cardiopulmonary endurance, but also stimulates feelings of well-being and relief of symptoms. Chapter 7 describes cardiopulmonary conditioning principles and procedures. Specific precautions and suggestions for medical conditions are also explained. For patients recovering from spinal injuries, surgery, or postural dysfunction, aerobic exercises may be initiated once signs of inflammation no longer exist. Begin

with low to moderate intensity and work with the patient to choose activities that do not place added stress on the recovering spinal structures. If a particular spinal bias has been identified (see Chapter 15), choose aerobic exercises that emphasize that spinal bias. A brief summary of the principles is reviewed in Box 16.6. Guidelines for safe application of common conditioning exercises when there are spinal impairments are described in this section.

## Common Aerobic Exercises and Effects on the Spine

Some aerobic exercises place the spine in end-range positions. They are reviewed so the reader understands why some activities may be inappropriate for patients with specific conditions. If modifications are possible, they should be considered.

### BOX 16.6 Summary of Aerobic Conditioning Principles

1. Establish the target heart rate and maximum heart rate.
  - The maximum heart rate is generally 220 minus the individual's age or may be the symptom-limiting heart rate (the rate at which cardiovascular symptoms appear).
  - Target heart rate is between 60% and 80% of the maximum heart rate.
2. Perform warm-up exercises for 10 to 15 minutes, including active movements of the neck and trunk.
3. Individualize the program of exercise.
  - Select activities that emphasize the patient's spinal bias if necessary (see information in the text).
  - Not all people are at the same fitness level and therefore cannot perform the same exercises. Any one exercise has the potential to be detrimental if attempted by someone not able to execute it properly.
  - To avoid overuse syndromes to structures of the musculoskeletal system, appropriate equipment, such as correct footwear, should be used for biomechanical support with weight-bearing exercises.
4. Increase the pace of the activity to reach the target heart rate and maintain it for 20 to 30 minutes.
5. Cool down for 5 to 10 minutes with slow, total body, repetitive motions and stretching activities.
6. Frequency of aerobic exercise should be three to five times per week.
7. Always stay within the tolerance of the individual. Overuse commonly occurs when there is an increase in time or effort without adequate rest (recovery) time between sessions. Increase repetitions or time by no more than 10% per week.<sup>47</sup> If pain begins while exercising, heed the warning and reduce the stress.

## Cycling

Road bikes place the thoracolumbar spine in flexion and the upper cervical spine in hyperextension. Use this exercise for patients who have a flexion bias in the lumbar region so long as there are no upper cervical symptoms. Modifications include using a bike that positions the body in a more upright posture, such as a mountain bike or hybrid bike. Many stationary bikes also position the individual in upright postures and therefore are less likely to precipitate cervical problems.

## Walking and Running

The upright posture emphasizes normal spinal curves, and lumbar extension is emphasized with walking and running (terminal stance). Emphasize the importance of identifying the neutral spine, activating the drawing-in maneuver, and stabilizing the spine while walking or running. Because conscious control is not possible during the entire exercise time, coach the patient to check his or her posture and muscle control frequently, such as each time he or she crosses an intersection or passes another individual or if symptoms develop in the spinal region. Walking or running with the cervical spine in retraction (axial extension) and the scapulae comfortably adducted, along with a rhythmic arm swing, reinforces cervical stabilization. Easy access to treadmills, tracks, or roads and trails makes these activities popular. Running is a high-impact activity and may not be tolerated by individuals with intervertebral disc lesions or degenerative joint conditions.

## Stair Climbing

Commercial devices that replicate stepping with various grades of resistance are used for strengthening and aerobic conditioning. Regular steps can also be used for aerobic conditioning. This activity requires pelvic control of the reciprocating lower extremities, because lifting the leg on one side emphasizes spinal flexion while the contralateral lower extremity and spine are extending. Coach the patient to maintain the neutral spine with the stabilizing muscles against the rotational forces.

## Cross-Country Skiing and Ski Machines

Cross-country skiing, whether out in the cold or on a commercial machine, is a high-intensity aerobic activity. The kicking motion that accompanies the backward motion of the leg emphasizes spinal extension. It is important to coach the patient to maintain the neutral spine and contract the stabilizing abdominal muscles.

## Swimming

**Breast stroke.** The breaststroke emphasizes extension in the cervical and lumbar spinal regions when taking a breath. Coach the patient not to extend the neck full range but to keep

it neutral and lift the head out of the water as a “solid” unit with the thorax just enough to clear the mouth for breath.

**Freestyle.** The freestyle stroke may exacerbate cervical problems because of the repetitive cervical rotation while taking a breath; this stroke also emphasizes lumbar extension with the flutter kick. Teach the patient to breathe using a “log-roll” technique in which the whole body rolls toward one side while breathing and then rolls back to the face-down position for the stroke. This requires good spinal stabilization.

**Backstroke.** The backstroke emphasizes spinal extension via kicking the lower extremities and the arm motions.

**Butterfly stroke.** The butterfly stroke moves the spine through a full ROM; emphasis is placed on controlling the range with the stabilizing muscles.

## Upper Body Ergometers

Ergometry machines provide upper extremity resistance and can also be used for aerobic training. Forward motions emphasize spinal flexion and shoulder girdle protraction; backward motions emphasize spinal extension and shoulder girdle retraction. Coach the patient to assume the neutral spinal posture and use the stabilizing muscles prior to and during the use of the ergometer to enhance postural responses. If the machine can be used standing, progression to the standing position stimulates a total body response.

## Step Aerobics and Aerobic Dancing

Stepping is similar to using stairs or a stair machine except for the jumping and bouncing that is usually added to the more advanced step aerobics programs.

Dancing moves take on many forms, and classes are taught that address various fitness levels and age groups. If possible, review safe movement patterns and help the patient recognize the safe limits of his or her spinal range and abilities.

## Cross Fit

This high intensity and variable strength training program has become increasingly popular since the early part of the century. It yields the benefits of aerobic exercise combined with team building. Smith et al<sup>74</sup> followed 43 participants in a 10-week program. Pre and post  $VO_{2max}$  and body fat percentage both showed improvement. To determine if people are at increased risk for injury, Hak et al<sup>26</sup> distributed online questionnaires to international Cross Fit forums. One hundred thirty-two people responded, with 97 reporting an injury that was caused by training, 9 of which required surgery. This yielded an injury rate of 3.1 per 1,000 hours of Cross Fit training. This injury rate is similar to Olympic sports such as weight lifting and gymnastics. As with all exercise programs, it is important to provide proper instruction for safe use of equipment and application of each exercise related to specific abilities or limitations of each person.

## “Latest Popular Craze”

People like variety and may be attracted to charismatic and energetic figures who demonstrate “new” workout techniques and routines or new exercise machines. Patients may ask for advice as to the value of the activities and techniques. Knowledge and skill in analyzing the biomechanics of the activity and the forces that are imposed through the spine should be used to provide advice about exercise safety. End-of-range postures and high-velocity stresses (such as vigorous kicking and ballistic motions) may be damaging to vulnerable tissues in the spine and should not be attempted by patients recovering from spinal problems.

## Functional Activities

**Goal.** To progress to independence safely.

**NOTE:** Achieving the maximum level of independence underlies all the goals of therapeutic exercise. The patient develops segmental and global spinal stability; develops flexibility, muscle endurance, and strength; learns how exercise and posture correction relieve stress; and develops cardiopulmonary endurance—all to be able to function safely in daily activities, including work, recreation, and athletic pursuits.

## Early Functional Training: Fundamental Techniques

Early functional training consists of teaching basic maneuvers needed for ADL, such as safely rolling over, moving from lying down to sitting (and reverse), and going from sitting to standing (and reverse). These techniques follow the early kinesiologic training instruction in which the patient learns to find his or her neutral spine and experiences the effect that simple arm and leg motions have on the spine, as well as early muscle performance training in which the patient learns how to activate the core musculature for segmental stabilization. If the examination reveals problems with basic ADL activities, the following are included in the early training program.

**Rolling.** Rolling with a neutral spine requires that the patient first find the neutral spine, perform the drawing-in maneuver, and then roll the trunk as a unit.

- It may be helpful to suggest that the patient “imagine a solid rod connecting the shoulders and pelvis so as not to twist” or suggest that he or she “roll like a log.”
- Encourage the patient to use the arms and top leg to assist the roll.

**Supine to sit/sit to lying down.** Have the patient use the log roll maneuver (as described above) to roll from supine to side-lying while simultaneously flexing the hips and knees and pushing up with the arms.

- Help the patient focus on stabilizing the trunk with commands such as “push up your trunk as if it is a board; do not allow it to twist or bend.”

- The reverse is practiced by coaching the patient to lower to the side-lying position as a unit first onto the elbow and then shoulder. Once down, the patient can roll to supine or prone-lying using the log-roll technique.

**Sit to stand/stand to sit.** The patient’s level of function dictates how much assistance from the upper extremities is needed to accomplish “sit to stand” or “stand to sit.” If the hip and knee extensors are not strong enough to elevate the body, the patient requires a chair with armrests, so there is some leverage for pushing up; alternatively, a firm seat or elevated seat may be necessary.

- To use the stable spine technique, instruct the patient to find the neutral spine by rolling the pelvis forward and backward, activate the drawing-in maneuver, and then bend forward at the hips while maintaining the neutral spine position.
- Help the patient focus on the hip motion while keeping the spine “solid like a board.” The reverse is also practiced.

**In and out of a car.** Getting in and out of a car is often symptom-provoking for patients with low back or sacroiliac joint pain. Once sit to stand can be safely performed, have the patient practice the following:

- Approach the open car door and seat with the back toward the seat; stabilize the spine in its neutral position with the drawing-in maneuver; then bend at the hips and sit down.
- Once seated, flex both hips and knees and pivot the whole body around as a unit, maintaining a stable spine.
- When exiting a car, keep both knees together and pivot the legs and trunk outward as a unit. Once the feet are on the ground, bend at the hips and elevate the trunk as a unit.

**Walking.** For some patients, walking may provoke symptoms.

- Remind the patient to use the neutral spine and drawing-in maneuvers to stabilize the spine while walking.
- It is not possible to maintain conscious control for long, so remind the patient to check the spinal posture and reactivate the drawing-in maneuver whenever the symptoms recur.

## Preparation for Functional Activities: Basic Exercise Techniques

Once the patient has learned to manage his or her symptoms and the symptoms of inflammation diminish, exercises are initiated that prepare the extremities and trunk for functional activities, such as safely lifting, carrying, pushing, pulling, and reaching in various directions. In the subacute or controlled motion phase of rehabilitation, emphasis is placed on strengthening the extremities in functional patterns while maintaining a stable spine. The patient should be able to perform IADLs and limited work activities at this stage. Evaluate the patient’s performance and modify what he or she is doing to include safe spinal postures and correct stabilization. Use the activities in this section to prepare for or advance the patient’s function.

Many of the strengthening exercises described in the extremity chapters are appropriate to use in preparation for functional training. With postural problems and recovery from back or neck injuries, it is critical to emphasize the neutral (functional) spinal posture before and during total body exercises. Many of the stabilization and movement patterns described earlier in this chapter can also be progressed in intensity, repetition, speed, and coordination to prepare for return to functional activities.

## Weight-Bearing Exercises

### Modified Bridging Exercises

Modified bridging exercises require stabilization with the trunk flexor and extensor muscles in conjunction with strengthening the gluteus maximus and quadriceps muscles in preparation for lifting activities. The abdominals function with the gluteus maximus to control the pelvic tilt, and the lumbar extensors stabilize the spine against the pull of the gluteus maximus.

**Patient position and procedures:** Begin with the patient hook-lying. Have the patient concentrate on maintaining the neutral spinal position while raising and lowering the pelvis (flexing and extending at the hips) (see Fig. 20.28). Hold the bridge for isometric control.

- Alternate arm motions; progress by adding weights to the hands.
- Alternate lifting one foot and then the other by marching in place (Fig. 16.73 A); progress by extending the knee as each leg is lifted. When the patient tolerates greater

**FIGURE 16.73** Holding a modified bridge to develop trunk control and gluteus maximus strength while superimposing extremity motions by (A) marching in place and (B) extending the extremities. Adding weights to the arms or legs requires greater strength and control.

resistance, add ankle weights and coordinate with arm motions (Fig. 16.73 B).

- Abduct and adduct the thighs without letting the pelvis sag. Progress by placing the feet on a stool, chair, or large gym ball and repeating the bridging activities, or by placing the large gym ball under the shoulder/neck region with feet on the floor.

### Push-Ups With Trunk Stabilization

Push-ups use the body weight to strengthen the triceps and shoulder girdle musculature in preparation for pushing activities. The trunk musculature must stabilize against the pull of the shoulder girdle musculature as well as control the neutral spinal position as the body is raised and lowered.

**Patient positions and procedures:** Standing facing a wall or prone-lying with hands placed against the wall or floor in front of the shoulders. Remind the patient to find and maintain the neutral spinal position while performing the exercise.

- These exercises may begin as wall push-ups if the patient is not strong enough to push up from the floor.
- Prone-lying on the floor, the patient may push up with the pivot point being the knees or may perform full body push-ups with the pivot point being the feet.
- To challenge the patient on an unstable surface, he or she begins prone on a large gym ball. Have the patient walk forward with the hands on the floor until just the thighs are supported by the ball, maintain a stable spinal posture, and perform push-ups with the arms. To progress, walk out farther with the hands until just the legs are supported by the ball (Fig. 16.74). Additional advanced push up activities are described and illustrated in Chapter 23 (see Figs. 23.21 to 23.24).

**FIGURE 16.74** Push-up activities with the lower extremities balanced on a gym ball for strengthening the arms and developing trunk control.

### Wall Slides

Wall slides develop strength in the hip and knee extensor muscles to prepare the lower extremities for squatting activities and training in safe body mechanics.

**Patient position and procedure:** Standing with the back to a wall and the spine held in its neutral position. Place a towel behind the back, so it slides easier along the wall. The exercise is more challenging if a large gym ball is placed between the back and the wall (Fig. 16.75). Have the patient slide his or

**FIGURE 16.75** Wall slides/partial squats to develop LE strength and coordinate with trunk stability in preparation for training body mechanics. **(A)** The back sliding down a wall, with bilateral arm motion for added resistance. **(B)** Rolling a gym ball down the wall, with antagonistic arm motion to develop coordination.

her back down the wall into a partial squat and hold the position for isometric strengthening of the hip and knee extensors or move up and down for concentric/eccentric strengthening.

- Superimpose arm motions such as alternating or bilateral shoulder flexion/extension.
- Progress strengthening by incorporating single leg movements with marching steps or alternate knee extension.
- Use handheld weights to add resistance for upper and lower extremity strengthening.

### Partial Lunges, Partial Squats, and Steps

Partial lunges and squats are described in Chapters 20 and 21. They are beneficial for strengthening total body movement in preparation for learning body mechanics. If necessary, begin by having the patient balance by holding onto the side of a treatment table or other stable object and then progress to balancing with a cane (see Fig. 20.32). Once able to perform multiple repetitions without holding on, add weights to the upper extremities for resistance.

- Add arm motions that are synchronized with the leg motions, such as reaching forward and downward to develop coordination and control.
- Progress to lunging onto an unstable surface and return upright.
- Add step-up/step-down activities, beginning with a low step and progressing the height.

### Walking Against Resistance

Secure a weighted pulley or elastic resistance around the patient's pelvis with a belt, or the patient can hold the handles. Have the patient walk forward, backward, or diagonally against the resistive force. Emphasis is placed on spinal control (see Fig. 23.34).

Progress by having the patient push and pull weighted objects, such as a cart or a box on a table. Place emphasis on maintaining a stable spinal position while the extremities are loaded (see Figs. 17.58, 18.21 A, 23.18, and 23.36).

## Transitional Stabilization Exercises

Exercises that cause movement into spinal flexion and then extension (and vice versa) challenge the patient to control the neutral spine position. The patient learns to stabilize the spine against alternating trunk and extremity motions.

### Quadruped Forward/Backward Shifting

**Patient position and procedure:** Quadruped. Have the patient rock back to rest the buttocks on the heels; then shift the body forward onto the hands in the press-up position. The patient concentrates on controlling the pelvis in its neutral position rather than allowing full spinal flexion when shifting toward the heels or full spinal extension when shifting forward toward the press-up position.

### Squatting and Reaching

**Patient position and procedure:** Begin standing. Have the patient reach downward while partially squatting. The tendency is for the spine to flex, so have the patient concentrate on maintaining a neutral spinal position with the spinal extensors. The patient then stands up and reaches overhead. This causes the spine to extend, so have the patient concentrate on using the trunk flexors to stabilize in the neutral position. Progress by lifting and reaching with weights while controlling the neutral posture of the spine.

### Shifting Weight and Turning

Have the patient practice shifting weight forward/backward and side-to-side while maintaining the neutral spinal position and absorbing the forces with the hip and knee muscles. Practice turning using small steps and rotating at the hips rather than the back. Instruct the patient to imagine two rigid poles connecting each shoulder to each hip that do not allow the spine to twist. Even though some movement in the spine occurs, the activity helps the patient focus on a stable spine rather than rotating full range. Progress by using weights and having the patient lift, turn, and then place the weight at a new location.

## Body Mechanics and Environmental Adaptations

### Principles of Body Mechanics: Instruction and Training

When teaching safe body mechanics, it is advisable not to overwhelm the patient with too many instructions. Most people “know” they are to lift with their legs rather than their back, but they still have faulty techniques. Initiate training by

suggesting that the patient find his or her neutral spine, perform the drawing-in maneuver, and then lift. Observe the technique they use and suggest modifications if needed. Squatting is often taught as the preferred method, yet not all patients are able to squat if they have impairments, such as knee pain or weakness. Under some circumstances, an individual may be more stable lifting with a lunge technique rather than the squat technique.

### Lumbar Spine Position

The position of the lumbar spine, whether it is flexed, extended, or in midrange, raises several issues. Of the three postures, lifting with a neutral spinal posture provides greater stability of the spine<sup>77</sup> and uses both the ligamentous and muscular system for stabilization and control.<sup>77</sup> After a back injury, the preferred lifting posture may have to be adapted, depending on the type of injury and the response of the tissues when stressed.<sup>77</sup>

**Spinal flexion.** When lifting with a flexed lumbar spine (posterior pelvic tilt), support for the spine is primarily from inert structures (ligaments, lumbodorsal fasciae, posterior annulus fibrosus, and facets); there is little muscle activity.

- Flexion occurs when stooping to the floor. Some have suggested that it may also be the posture of choice for a patient who has injured the back muscles because the muscles are “quiet” when the spine is in flexion since the ligaments provide support.<sup>77</sup>
- Lifting with the lumbar spine in flexion may pose some problems. When lifting slowly with a flexed spine, the load is maintained on the ligaments, and creep of the inert tissues occurs; this increases the chance of injury if the tissue is already weakened. In addition, with the muscles lengthened and relaxed, they may be at an unfavorable length-tension relationship to respond quickly with appropriate force to resist a sudden change in load. There is greater chance of ligamentous strain when a person lifts with a flexed spine.<sup>77</sup>

**Spinal extension.** When lifting with an extended (lordotic) lumbar spine, the muscles supporting the spine are more active than when flexed, which increases the compressive forces on the disc. Also, the facets are approximated (close-pack position). This posture relieves stress on the ligaments, but for an individual whose back muscles are in poor condition and fatigue quickly, this posture may jeopardize the spine when repeated lifts are performed because the ligaments are not providing support.<sup>77</sup>

### Load Position

Reinforce the concept of lifting and carrying objects as close to the center of gravity as possible.

- Have the patient practice carrying objects close to his or her center of gravity and draw attention to the feel of balance and control as well as less stress on the neck and back compared to the feel when carrying objects in more stressful

positions. Point out that when lifting, the closer the object is held to the center of gravity, the less stress is placed on the supporting structures.

- Have the patient practice shifting the load from side-to-side and turning. Have the patient practice turning with hip rotation and minimal trunk rotation. The action should be directed by the legs while the spine is kept stable.
- Replicate the mechanics of the patient’s job setting and practice safe mechanics.
- Teach the “golfer’s lift” for picking up light objects, such as keys, pencils, and small toys. This is done by flexing the trunk forward over one hip while the other hip extends. It allows the patient to maintain a neutral spine and places the majority of the work on the lower extremities.

## Environmental Adaptations

Ergonomic assessment and modification of the home and working environments are necessary to correct stresses as well as prevent future recurrence of symptoms.

### Home, Work, and Driving Considerations

- Chairs and car seats should have lumbar support to maintain slight lordosis. Use a towel roll or lumbar pillow if necessary.
- Chair height should allow knees to flex to take tension off the hamstring muscles, support the thighs, and allow the feet to rest comfortably on the floor.
- Arm rests should be used if prolonged sitting is required in order to take the stress off shoulders and the cervical spine.
- Desk or table height should be adequate to keep the person from having to lean over the work.
- Work and driving habits should allow frequent changing of posture. If normally sedentary, the patient should get up and walk every hour.

### Sleeping Environment

- The mattress needs to provide firm support to prevent any extreme stresses. If it is too soft, the patient sags and stresses ligaments; if it is too firm, some patients cannot relax.
- Pillows should be of a comfortable height and density to promote relaxation but should not place joints in an extreme position. Foam rubber pillows tend to cause increased tension in muscles because of the constant resistance they provide.
- Whether the person should sleep prone, side-lying, or supine is something that must be analyzed for each individual patient. Ideally, a comfortable posture is one that is in the midrange and that does not place stress on any supporting structure. Pain that is experienced when waking up in the morning is often related to sleeping posture; if this is the case, listen carefully to the patient’s description of postures when sleeping and see if it relates to the pain. Then, attempt to modify the sleep position accordingly. Remind the patient that it takes several weeks to change habits.

## Intermediate to Advanced Exercise Techniques for Functional Training

As the patient learns spinal control while doing the exercises, repetitions are increased to develop muscular endurance, and resistance is added to develop strength. If coordination, agility, and balance are required, they are emphasized. By this stage, it is recognized that the individual already knows the basic spinal stabilization techniques and is habitually assuming the neutral spinal position and activating the drawing-in maneuver. Reinforce the importance of this when doing the following exercises. It is also recognized that the patient should be able to control greater spinal ROM without experiencing symptoms. Adapt the exercises to replicate return to work or sport-related activities. Some examples include the following.

### Repetitive Lifting

The ability to do repetitive lifting throughout the workday is necessary for many jobs and may result in symptom recurrence. To prepare for returning to work, progressively increase the repetitions of lifting activities the patient must do to improve muscle endurance. Marras and Granta<sup>49</sup> demonstrated that with repetitive lifting (over a 5-hour period) subjects had a significant change in their lifting pattern and in the muscle recruitment patterns, so there was a decrease in spine stabilization (decreased compression) and an increase in anterior/posterior shear in the lumbar spine. To reduce the risk of recurrence of low back disorders, a patient needs to learn to monitor these changes and be conscious of correcting faulty patterns. Help the patient modify and adapt the stable spine body mechanics that were initiated under basic techniques to replicate the type of lifting he or she will be doing at home or on the job. Include variations in the lifting tasks to prepare for unexpected situations.

### Repetitive Reaching

Repetitive reaching requires that the patient learn to assume a comfortable stride and then practice shifting his or her weight forward and backward on the lower extremities rather than bending forward and backward with the spine. Preparatory exercises should include partial lunging forward, sideways, and backward. During practice, have the patient use a weight comparable to that in the real-life situation and go through the action on a repetitive basis, concentrating on spinal control and resting only when control is no longer possible.

### Repetitive Pushing and Pulling

Repetitive pushing and pulling require strong upper extremities and a stable spine. Preparatory activities should include pushing and pulling against elastic resistance or pulley

resistance set at heights that replicate the work environment. Progress to pushing and pulling a weighted cart or a weighted box across a table. Reinforce the importance of activating the spinal stabilizers.

### Rotation or Turning

Turning with a load is a component of most work activity. A person may rotate the spine to reach around to place a load to the side or behind. Rotation may create an unstable situation or may be damaging to the spinal structures. Therefore, it is important to take the rotation out of turning. Have the patient practice a “stable spine turn,” which requires motion and control in the hips or taking steps into the direction of the turn rather than twisting and rotating the back.

### Transitional Movements

Most functional activities require transitional motions, such as reaching downward to pick up something (spinal flexion), then reaching overhead to place it on a high shelf (spinal extension). In sports activities, the activity may require moving quickly from a forward-bent position to an extended position with arms overhead (such as dribbling a basketball and then shooting). Set up drills that replicate the speed and movements of the desired outcome; have the patient practice moving through the patterns while attempting to maintain control of his or her functional spinal position and range.

### Transfer of Training

Ideally, each patient is progressed through rehabilitation to the level of being able to transfer skills learned to closely related but new situations. Provide variable learning opportunities from simple to complex and then help the patient analyze successful adaptations to each new experience. (See Fig. 1.8 and accompanying text in Chapter 1 for examples of how to vary tasks from simple to complex.)

## Patient Education for Prevention

Education occurs on a continual basis. Before discharge, review the following relationships of posture and pain with the patient.

- When experiencing pain or the recurrence of symptoms, check posture. Avoid any one posture for prolonged periods. Change positions before pain or discomfort is experienced.
- If sustained postures are necessary, take frequent breaks and perform appropriate ROM exercises at least every half hour. Finish all exercises by assuming a well-balanced posture.
- Avoid hyperextending the neck or being in a forward-head posture or forward-bent position for prolonged periods.

Find ways to modify a task so it can be accomplished at eye level or with proper lumbar support.

- If in a tension-producing situation, perform conscious relaxation exercises.
- Use common sense and follow good safety habits.
- Review the home exercise program and explain how to safely progress and vary the exercises to maintain interest.
  - Teach flexibility, muscle endurance, and strengthening exercises appropriate for the patient to maintain ROM, muscle endurance, and strength.

- Address any misconceptions the patient may have about exercise and management of the spine.
- Teach the patient to safely progress the aerobic exercise program. Reinforce the importance of maintaining cardiopulmonary endurance and its effect on managing symptoms.

## Independent Learning Activities

### Critical Thinking and Discussion

1. Observe a homemaker or worker doing an activity that requires pushing, pulling, reaching, lifting, or some other repetitive pattern. Analyze what component motions are part of the total pattern and decide if strength, range, endurance, balance, or coordination (or a combination) is necessary in the upper extremities, lower extremities, and trunk. Decide what is necessary to make the spine safe while doing this activity and design an exercise program that encompasses all the components.
2. Go to a health club or exercise class and observe how individuals are performing the exercises. Note the activities that cause stress to the spine or pelvis. How would you modify each exercise? Consider safe use of the equipment, safe biomechanics, and appropriate instruction for the audience. Can you tell the purpose of each exercise (strength, stretch, endurance, balance)? Are the directions appropriately given for the level of participants?
3. What is the law in your state as it pertains to physical therapists performing manipulation and HVT? What are some situations in which you would perform a manipulation rather than an HVT technique? What are some situations in which you would perform an HVT technique rather than a manipulation technique?

### Laboratory Practice

1. With a laboratory partner practice the kinesthetic training techniques and deep segmental muscle activation techniques for the cervical spine and the lumbar spine until you become proficient at performing them and recognizing when they are done correctly. Then practice teaching them to a family member or friend and see how well they understand what they are to do.
2. Practice the progression of spinal stabilization exercises described in the muscle performance section. Start at the easiest level and progress the leg and arm movements until you feel you are at your maximum resistance for stabilization.

After resting, time yourself for 1 minute, beginning at the most difficult level of movement. The idea is to keep the spine stable during the entire minute. If you begin to feel you are losing control, decrease the amount of extremity resistance (e.g., going from moving both lower extremities in a reciprocal pattern to moving just one extremity while the other is on the floor). This can also be done for 3 minutes. Were you able to meet the challenge yet keep the spine stable? Did you feel your stabilizing muscles “working”?

3. Practice doing wall slides, partial squats, and partial lunges with a stable spine. When you can do the squat comfortably with a stable spine, practice lifting a box from the floor to table height, then from the floor to shoulder height, then place it on a shelf at each height. Feel what is happening to your spine. Then repeat the maneuvers with a stable spine, and see if you can control the spinal position with the drawing-in maneuver. When you can do the lunge comfortably, practice lifting small objects from the floor with a lunging technique and stable spine. Finally, practice lifting objects from the floor and turning (using legs and hips to change direction, not spinal rotation) to place the objects on a table or shelf. Feel what is happening to the spine and repeat the activities with a stable spinal posture.
4. Review the indications and contraindications for spinal manipulation. Practice the cervical manipulations with your laboratory partner in both the supine and prone positions. In which position do you have better control (patient supine or prone)?
5. Several HVT techniques were discussed in this chapter. What are the contraindications for HVT in the spine? Practice three HVTs to improve thoracic flexion. How would you change the technique if your goal was to improve rotation to the left?

### Case Studies

Review the cases described in Chapters 14 and 15 and modify your answers based on the information presented in this chapter.

### Independent Learning Activities 616

The shoulder complex design enables great mobility of the upper extremity. As a result, the hand can be placed almost anywhere within a sphere of movement, its range limited primarily by the length of the arm and the space taken up by the body. The combined mechanics of the three synovial and two functional joints with the many muscles that comprise the

shoulder complex interact to provide and control the mobility. When establishing a therapeutic exercise program for impaired function of the shoulder region, as with any other body region, the unique anatomical and kinesiological features must be considered along with the state of pathology and functional limitations imposed by the impairments.

This chapter is divided into three main sections. The first section reviews the structure and function of the shoulder complex. The second section describes common shoulder disorders and provides guidelines for conservative and postsurgical management. The last section describes exercise techniques commonly used to meet the goals of treatment during the stages of tissue healing and phases of rehabilitation.

## Structure and Function of the Shoulder Girdle

The shoulder girdle has only one bony articulation with the axial skeleton (Fig. 17.1). The clavicle articulates with the sternum via the small sternoclavicular (SC) joint, and this reduced articular contact area is an important reason for the considerable mobility of the upper extremity. Stability, however, is hampered by this articular arrangement and relies on an intricate balance among the scapular and glenohumeral (GH) muscles and the soft tissue structures of the joints in the shoulder complex.

**FIGURE 17.1** Bones and joints of the shoulder girdle complex.

## Joints of the Shoulder Complex

Three synovial joints (GH, acromioclavicular [AC], and SC) and two functional articulations (scapulothoracic and suprahumeral) make up the shoulder complex.

### Synovial Joints

#### Glenohumeral Joint

The GH joint is an incongruous, ball-and-socket (spheroidal) triaxial joint with a lax joint capsule. It is supported by the tendons of the rotator cuff and the GH (superior, middle, inferior) and coracohumeral ligaments (Fig. 17.2). The concave

**FIGURE 17.2** Ligaments of the glenohumeral (GH) and acromioclavicular (AC) joints.

joint surface, the glenoid fossa, is located on the superior-lateral margin of the scapula. It faces primarily laterally, somewhat anteriorly, and slightly upward, providing minimal stability to the joint. A fibrocartilagenous lip, the glenoid labrum, deepens the fossa to increase joint congruity and stability and serves as the attachment site for the capsule. The convex joint surface is the hemispheric head of the humerus. Only a small portion of the head contacts the fossa at any time, allowing for considerable joint movement but also the potential for instability.<sup>155</sup>

#### Arthrokinematics

According to the convex-concave theory of joint motion (see Chapter 5), with motions of the humerus (physiological motions), the convex head rolls in the same direction and slides in the opposite direction on the glenoid fossa. The arthrokinematics of the GH joint are summarized in ONLINE Box 19.1 on the FA Davis website that supports this textbook.

#### Stability

Both static and dynamic restraints provide GH joint stability (Table 17.1).<sup>28,44,180,218,221</sup> The structural relationships among the joint morphology, ligaments, and glenoid labrum, along with adhesive and cohesive forces in the joint, provide static stability. The tendons of the rotator cuff blend with the ligaments and glenoid labrum at their sites of attachment, so muscle contractions provide dynamic stability by tightening the static restraints (Fig. 17.3). The coordinated response of the muscles of the cuff and tension in the ligaments provide varying degrees of support depending on the position and motion of the humerus.<sup>170,180,204</sup> In addition, the long head of the biceps and the long head of the triceps brachii reinforce the capsule with their attachments and provide superior and inferior shoulder joint support, respectively, when functioning with

**TABLE 17.1** Static and Dynamic Stabilizers of the Scapula and Glenohumeral Joint

Description	Static Stabilizers	Muscular Stabilizers
<b>Scapula</b>		
Weight of upper extremity creates downward rotation and protraction moment on the scapula	<ul style="list-style-type: none"> <li>■ Cohesive forces of subscapular bursa, SC, and AC joint ligaments</li> <li>■ Scapulothoracic fascia</li> </ul>	Scapulothoracic musculature, especially upper, middle, and lower trapezius, serratus anterior, levator scapula, and rhomboids
<b>Glenohumeral joint</b>		
In dependent position: if scapula is in normal alignment, weight of arm creates an inferior translation moment on the humerus	<ul style="list-style-type: none"> <li>■ Superior capsule, superior GH ligament, and coracohumeral ligament are taut</li> <li>■ Adhesive and cohesive forces of synovial fluid and negative joint pressure hold surfaces together</li> <li>■ Slight upward inclination of glenoid and labrum deepens fossa and improves congruency; acts as inferior barrier</li> </ul>	Rotator cuff, deltoid, long head of biceps brachii, pectoralis major, latissimus dorsi, and teres major
When the humerus is elevating and the scapula is rotating upward	<ul style="list-style-type: none"> <li>■ Tension placed on static restraints by the rotator cuff</li> <li>■ Glenohumeral ligaments limit excessive translations of humeral head</li> </ul>	<ul style="list-style-type: none"> <li>■ Rotator cuff and deltoid; elbow action brings in two-joint muscle support</li> <li>■ Long head of biceps stabilizes against humeral elevation</li> </ul>

**FIGURE 17.3** Lateral aspect of the glenoid fossa (interior view), showing attachments of the glenoid labrum, capsule, and ligaments as well as their relationship to the rotator cuff and long head of the biceps brachii musculature.

elbow motions.<sup>105</sup> The long head of the biceps, in particular, stabilizes against humeral elevation<sup>105</sup> and contributes to anterior stability of the GH joint by resisting torsional forces when the shoulder is abducted and externally rotated.<sup>9,170</sup> Neuromuscular control, including movement awareness and

motor response, underlies coordination of the dynamic restraints.<sup>218,221</sup>

### Acromioclavicular Joint

The AC joint is a plane, triaxial joint that may or may not have a disk. The weak capsule is reinforced by the superior and inferior AC ligaments (see Fig. 17.2). The convex articular surface is a facet on the lateral end of the clavicle and the concave articular surface is a facet on the acromion of the scapula.

### Arthrokinematics

With motions of the scapula, the concave acromial surface slides in the same direction in which the scapula moves. Motions affecting this joint include upward rotation (the scapula turns so the glenoid fossa rotates upward), downward rotation, winging of the vertebral border (also called internal/external rotation), and tilting of the inferior angle.

### Stability

The AC ligaments are supported by the strong coracoclavicular ligament. No muscles directly cross this joint for dynamic support.

### Sternoclavicular Joint

The SC joint is an incongruent, triaxial, saddle-shaped joint with a disk. The joint is supported by the anterior and posterior SC ligaments and the interclavicular and costoclavicular ligaments (Fig. 17.4). The medial end of the clavicle is convex superior to inferior and concave anterior to posterior. The joint disk attaches superiorly. The superior-lateral portion of

**FIGURE 17.4** Ligaments of the sternoclavicular (SC) joint.

the manubrium and first costal cartilage is concave superior to inferior and convex anterior to posterior.

### Arthrokinematics

The motions of the clavicle occur as a result of the scapular motions of elevation, depression, protraction (abduction), and retraction (adduction). Rotation of the clavicle occurs as an accessory motion when the humerus is elevated above the horizontal position and the scapula upwardly rotates; it cannot occur as an isolated voluntary motion. The arthrokinematics of the SC joint are summarized in ONLINE Box 17.2 on the FA Davis website that supports this textbook.

### Stability

The ligaments crossing the joint provide static stability. There are no muscles crossing the joint for dynamic stability.<sup>40</sup>

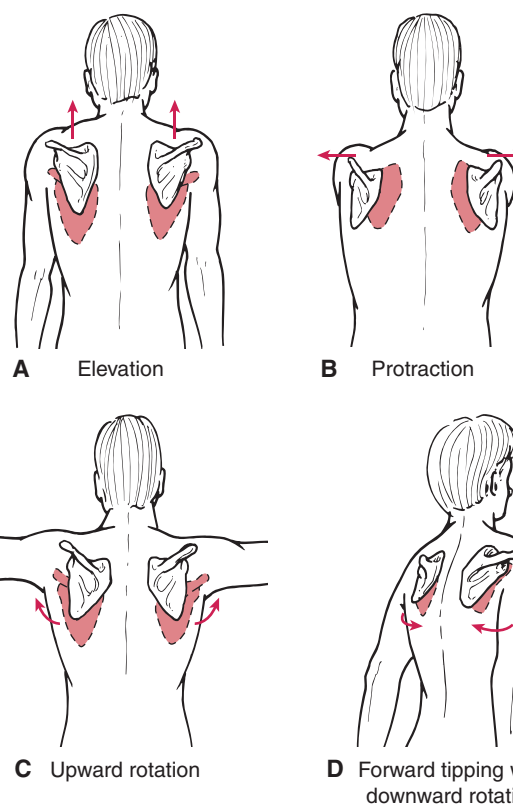

## Functional Articulations

### Scapulothoracic Articulation

Normally, there is considerable soft tissue flexibility, allowing the scapula to slide along the thorax and contribute to all upper extremity motions.

### Motions of the Scapula

- **Elevation, depression, protraction, and retraction:** These motions are seen with clavicular motions at the SC joint (Fig. 17.5 A and B). Elevation and depression occur in the frontal plane as the scapula moves upward and downward, respectively; protraction/retraction occur in the transverse plane as the scapula moves away from or toward the spinal column. They are also component motions when the humerus moves.
- **Upward and downward rotation:** These motions are seen with clavicular motions at the SC joint and rotation at the AC joint and occur concurrently in various planes with motions of the humerus (Fig. 17.5 C). Upward rotation along with posterior tilting and external rotation of the scapula are component motions that occur with full shoulder range of motion (ROM) of elevation (flexion, scapular plane abduction, and frontal-plane abduction of the humerus).<sup>60,131</sup>

**FIGURE 17.5** Scapular motions. (A) Elevation occurs with clavicular elevation at the SC joint when shrugging. (B) Protraction (abduction) occurs with clavicular abduction at the SC joint when reaching forward. (C) Upward rotation occurs with clavicular rotation at the SC and AC joints when flexing and abducting the shoulder. (D) Forward tilting (along with downward rotation) occurs at the AC joint when extending and internally rotating the shoulder.

- **Internal and external rotation and tilting:** These motions are seen with motion at the AC joint concurrently with motions of the humerus (Fig. 17.5 D). Internal and external rotations are transverse plane motions in which the medial border lifts away from (wings) or approximates the rib cage, respectively. Anterior tilting of the scapula occurs in conjunction with internal rotation and extension of the humerus when reaching the hand behind the back, while posterior tilting occurs during humeral elevation.<sup>64,133</sup>

## Scapular Stability

**Postural relationship.** In the dependent position, the scapula is stabilized primarily through a balance of forces. The weight of the arm creates a downward rotation, protraction, and forward tilting moment on the scapula. These moments are balanced by the support of the upper trapezius, serratus anterior, rhomboids, and middle trapezius<sup>116,181</sup> (see Table 17.1).

**Active arm motions.** With active arm motions, the muscles of the scapula function in synchrony to stabilize and control the position of the scapula, so the scapulohumeral muscles can maintain an effective length-tension relationship as they

function to stabilize and move the humerus. Without the positional control of the scapula, the efficiency of the humeral muscles decreases. The upper and lower trapezius along with the serratus anterior upwardly rotate the scapula whenever the arm elevates, and the serratus anterior protracts the scapula on the thorax to align the scapula during flexion or pushing activities. During arm extension or during pulling activities, the rhomboids function to downwardly rotate and retract the scapula in synchrony with the latissimus dorsi, teres major, and rotator cuff muscles. These stabilizing muscles also eccentrically control acceleration of upward rotation and protraction of the scapula.<sup>157</sup>

**Faulty posture.** A slouched posture significantly alters scapular kinematics. Specifically, sitting or standing with increased thoracic kyphosis decreases posterior tilting and external rotation of the scapula during elevation of the arm.<sup>60</sup> Furthermore, with faulty scapular alignment, muscle length and strength imbalances occur not only in the scapular muscles, but also in the humeral muscles, altering the mechanics of the GH joint. A forward tilt of the scapula (seen with a forward head posture and increased thoracic kyphosis) is associated with decreased flexibility in the pectoralis minor, levator scapulae, and scalenus muscles and weakness in the serratus anterior or trapezius muscles. This scapular posture also changes the posture of the humerus in the glenoid, which assumes a relatively abducted and internally rotated position with respect to the scapula (Fig. 17.6). The GH internal rotators may become less flexible, and external rotators may weaken, affecting the mechanics of the joint.

**FIGURE 17.6** Faulty forward head, thoracic kyphosis, and shoulder girdle posture result in a forward tilt and downward rotation of the scapula with relative abduction and internal rotation of the humerus when the arm is in a dependent position.

### FOCUS ON EVIDENCE

A study by Borstad and Ludewig,<sup>15</sup> which looked at the effect of pectoralis minor resting length on scapular kinematics in subjects without shoulder pain, documented that those

individuals with a shorter pectoralis minor ( $n = 25$ ) had greater scapular internal rotation (protraction) and less posterior tilting during arm elevation in flexion, abduction, and scapular plane than those with a longer pectoralis minor ( $n = 25$ ), thus providing evidence for altered pectoralis minor muscle length and altered scapular movement. In a related study by Borstad,<sup>16</sup> a correlation between the postural impairments of increased thoracic kyphosis, scapular internal rotation and forward tipping, and decreased pectoralis minor length was found to be significant, further supporting the relationship between muscle length and posture.

### Suprahumeral (Subacromial) Space

The coracoacromial arch, composed of the acromion and coracoacromial ligament, overlies the subacromial/subdeltoid bursa, the supraspinatus tendon, and a portion of the muscle (Fig. 17.7).<sup>116</sup> These structures allow for and participate in normal shoulder function. Compromise of this space from faulty muscle function, faulty postural relationships, faulty joint mechanics, injury to the soft tissue in this region, or structural anomalies of the acromion lead to impingement syndromes.<sup>15,101,109,114,130,233</sup> After a rotator cuff tear, the bursa may communicate with the GH joint cavity.<sup>44</sup>

**FIGURE 17.7** The supraspinatus and subacromial/subdeltoid bursa lie in the suprahumeral space.

## Shoulder Girdle Function

### Scapulohumeral Rhythm

Motion of the scapula, synchronous with motions of the humerus, allows for 150° to 180° of shoulder ROM into flexion or abduction with elevation. The ratio has considerable

variation among individuals but is commonly accepted to average 2:1 (2° of GH motion to 1° of scapular rotation) at the end of full arm elevation. During the setting phase (0° to 30° abduction, 0° to 60° flexion), motion is primarily at the GH joint, whereas the scapula seeks a stable position. During the midrange of humeral motion, the scapula has greater motion, approaching a 1:1 ratio with the humerus; later in the range, the GH joint again dominates the motion.<sup>38,116,187</sup>

- Early studies analyzed only upward rotation of the scapula. More recent three-dimensional research demonstrated component scapular motions to be upward rotation, posterior tilting, and scapular external rotation with full shoulder elevation (flexion, scapular plane abduction, and frontal-plane abduction of the humerus).<sup>101,131</sup>
- During humeral elevation, the synchronous motion of the scapula allows the muscles moving the humerus to maintain an effective length-tension relationship throughout the activity and helps maintain congruency between the humeral head and fossa while decreasing shear forces.<sup>38,116,187</sup>
- The upper and lower trapezius and the serratus anterior muscles create upward rotation of the scapula. Weakness or complete paralysis of these muscles results in the scapula rotating downward by the contracting deltoid and supraspinatus as abduction or flexion is attempted. These two muscles then reach active insufficiency, and functional elevation of the arm cannot be reached, even though there may be normal passive ROM and normal strength in the shoulder abductor and flexor muscles.<sup>187</sup>
- During elevation of the humerus, the pectoralis minor is lengthened as the scapula upwardly rotates, retracts, and tips posteriorly. Restricted scapular movement during humeral elevation from a shortened pectoralis minor results in patterns similar to those seen in patients with impingement symptoms and could be a risk factor for development of the syndrome.<sup>15</sup>

## Clavicular Elevation and Rotation With Humeral Motion

It is commonly accepted that the first 30° of upward rotation of the scapula occurs with elevation of the clavicle at the SC joint. Then, as the coracoclavicular ligament becomes taut, the clavicle rotates 38° to 55° about its longitudinal axis, which elevates its acromial end (because it is crank shaped). This motion allows the scapula to rotate an additional 30° at the AC joint.<sup>116</sup> Loss of any of these functional components decreases the amount of scapular rotation and thus the ROM of the upper extremity.

### FOCUS ON EVIDENCE

A three-dimensional study<sup>115</sup> of clavicular motion during humeral flexion, scapular plane elevation of the arm, and abduction to 115° using surface electromagnetic sensors on

30 asymptomatic subjects and 9 individuals with shoulder pathology documented 11° to 15° of clavicular elevation, 15° to 29° of retraction, and 15° to 31° of posterior long axis rotation, showing similar patterns but different ranges from previously reported studies. Ranges of clavicular motion above 115° were not reliable, owing to movement of the clavicle under the skin.

## External Rotation of the Humerus With Elevation

During elevation of the arm, the humerus externally rotates; this allows the greater tubercle of the humerus to clear the coracoacromial arch. Weak infraspinatus and teres minor muscles or inadequate external rotation may result in impingement of the soft tissues in the suprahumeral space, causing pain, inflammation, and eventually loss of function.

### FOCUS ON EVIDENCE

An *in vivo* study of elevation in flexion, in the plane of the scapula, and in abduction demonstrated approximately 55° external rotation in all planes.<sup>189</sup> During abduction, external rotation occurred up to 125° followed by some internal rotation; during forward flexion, external rotation occurred until 50° and then plateaued. Lastly, external rotation occurred again from 110° to 160°. During elevation in the scapular plane, external rotation occurred throughout.

## Deltoid–Short Rotator Cuff and Supraspinatus Mechanisms

Most of the force produced by the deltoid muscle causes upward translation of the humerus; if unopposed, it leads to impingement of the soft tissues in the suprahumeral space between the humeral head and the coracoacromial arch.

- The combined effect of the short rotator muscles (infraspinatus, teres minor, and subscapularis) produces stabilizing compression and downward translation of the humerus in the glenoid.
- The combined actions of the deltoid and short rotators result in a balance of forces that elevate the humerus and control the humeral head.
- The supraspinatus muscle has a significant stabilizing, compressive, and slight upward translation effect on the humerus during arm elevation. It functions with the deltoid in humeral elevation.
- Interruption of the coordinated function of these mechanisms may lead to tissue microtrauma and shoulder complex dysfunction.

## Referred Pain and Nerve Injury

For a detailed description of referred pain patterns, peripheral nerve injuries in the shoulder, thoracic outlet syndrome (TOS), and complex regional pain syndromes and their management, see Chapter 13.

### Common Sources of Referred Pain in the Shoulder Region

#### Cervical Spine

- Vertebral joints between C3 and C4 or between C4 and C5
- Nerve roots C4 or C5

#### Referred Pain From Related Tissues

- Dermatome C4 is over the trapezius to the tip of the shoulder.
- Dermatome C5 is over the deltoid region and lateral arm.
- Diaphragm: pain perceived in the upper trapezius region.
- Heart: pain perceived in the left axilla and pectoral region.
- Gallbladder: pain perceived at the tip of shoulder and scapular region.

### Nerve Disorders in the Shoulder Girdle Region

**Brachial plexus in the thoracic outlet.** Common sites for compression are the scalene triangle and the costoclavicular space and under the coracoid process and pectoralis minor muscle.<sup>104</sup>

**Suprascapular nerve in the suprascapular notch.** This injury occurs from either direct compression or from nerve stretch, such as when carrying a heavy book bag over the shoulder.

**Radial nerve in the axilla.** Compression occurs from continual pressure, such as when leaning on axillary crutches.

## Management of Shoulder Disorders and Surgeries

To make sound clinical decisions when managing patients with shoulder disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and to identify impairments, functional limitations, and possible disabilities. In this section, common pathologies and surgeries are presented, and the conservative and postoperative management of these conditions are described.

## Joint Hypomobility: Nonoperative Management

### Glenohumeral Joint

Restricted mobility of the GH joint may occur as a result of pathology, such as rheumatoid arthritis (RA) or osteoarthritis (OA); from prolonged immobilization; or from unknown causes (idiopathic frozen shoulder). Concurrent impairments in muscle performance and connective tissue mobility in the cervical and shoulder girdle region may also be present.

#### Related Pathologies and Etiology of Symptoms

**RA and OA (degenerative arthritis).** These disorders follow the clinical pictures described in Chapter 11.

**Traumatic arthritis.** This disorder occurs in response to a fall or high force blow to the shoulder.

**Postimmobilization arthritis or stiff shoulder.** This disorder occurs with lack of movement or as a secondary effect from conditions such as heart disease, stroke, or diabetes mellitus.

**Idiopathic frozen shoulder.** This disorder, which is also called *adhesive capsulitis* or *periarthritis*, is characterized by the development of dense adhesions, capsular thickening, and capsular restrictions, especially in the dependent folds of the capsule, rather than arthritic changes in the cartilage and bone, as seen with RA or OA. The onset is insidious and usually occurs between the ages of 40 and 65 years; there is no known cause (primary frozen shoulder), although problems already mentioned in which there is a period of pain and/or restricted motion, such as with RA, OA, trauma, or immobilization, may lead to a frozen shoulder (secondary frozen shoulder). With primary frozen shoulder, the pathogenesis may be a provoking chronic inflammation in musculotendinous or synovial tissue, such as the rotator cuff, biceps tendon, or joint capsule.<sup>40,70,100,145,148</sup> Patients with diabetes mellitus and thyroid disease are at increased risk for developing the disorder.<sup>97</sup>

#### Clinical Signs and Symptoms

**GH joint arthritis.** The following characteristics are typically associated with GH joint arthritis that leads to hypomobility.

- **Acute phase.** Pain and protective muscle guarding limit motion, usually external rotation and abduction. Pain frequently radiates distal to the elbow and may disturb sleep. Owing to the depth of the GH capsule, joint swelling is not detected, although tenderness can be elicited by palpating in the sulcus immediately below the edge of the acromion process between the attachments of the posterior and middle deltoid.
- **Subacute phase.** Capsular tightness, consistent with a capsular pattern (external rotation and abduction are most limited, and internal rotation and flexion are least limited), often begins to develop. The patient may feel pain as the

end of the limited range is reached. Passive accessory motion testing reveals limited joint play. If the patient can be treated as the acute condition begins to subside by gradually increasing shoulder motion and activity, the complication of joint and soft tissue contractures can usually be minimized.<sup>139,145</sup>

- **Chronic phase.** Progressive restriction of the GH joint capsule magnifies the signs of limited motion in a capsular pattern and decreased joint play. There is significant loss of function with an inability to reach overhead, outward, or behind the back. Pain is often localized to the deltoid region.

**Idiopathic frozen shoulder.** This clinical entity progresses through a series of four stages following a classic continuum.<sup>40,70,100,144,145,148</sup>

- **Stage 1.** Characterized by a gradual onset of pain that increases with movement and is present at night. Loss of external rotation motion with intact rotator cuff strength is common. The duration of this stage is usually less than 3 months.
- **Stage 2** (Often referred to as the “Freezing” Stage). Characterized by persistent and more intense pain even at rest. Motion is limited in all directions and cannot be fully restored with an intra-articular injection. This stage is typically between 3 and 9 months after onset.
- **Stage 3** (“Frozen” Stage). Characterized by pain only with movement, significant adhesions, and limited GH motions. Excessive scapulothoracic movement is a typical compensation. Atrophy of the deltoid, rotator cuff, biceps, and triceps brachii muscles may be noted. This stage occurs between 9 and 15 months after onset.
- **Stage 4** (“Thawing” Stage). Characterized by minimal pain and no synovitis but significant capsular restrictions from adhesions. Motion may gradually improve during this stage. This stage lasts from 15 to 24 months after onset, although some patients never regain normal ROM.

Some references indicate that spontaneous recovery occurs, on average, 2 years from onset,<sup>70</sup> although others report long-term limitations without spontaneous recovery.<sup>173</sup> Inappropriately aggressive therapy at the wrong time may prolong the symptoms.<sup>13</sup> Management guidelines are progressed based on the continuum of stages<sup>100</sup> and are the same as for acute (maximum protection during stages 1 and 2), subacute (controlled motion during stage 3), and chronic (return to function during stage 4) joint pathology described in this section.

### Common Impairments of Structure and Function

- Night pain and disturbed sleep during acute flares
- Pain on motion and often at rest during acute flares
- Mobility: decreased joint play and ROM, usually limiting external rotation and abduction with some limitation of internal rotation and flexion
- Posture: possible faulty postural compensations with protracted and anteriorly tilted scapula, rounded shoulders, or

guarding the painful shoulder in a position of scapula elevation and arm adduction

- Decreased arm swing during gait
- Muscle performance: general muscle weakness and poor endurance in the GH muscles with overuse of the scapular muscles leading to pain in the trapezius, levator scapulae, and posterior cervical muscles
- Increased scapulothoracic motion during arm movements to compensate for limited GH mobility

### Common Activity Limitations and Participation Restrictions

- Inability to reach overhead, behind head, out to the side, and behind back leading to difficulty dressing (putting on a jacket or coat or in the case of women, fastening undergarments behind their back), reaching hand into back pocket of pants (to retrieve wallet), reaching out a car window (to use an ATM machine), self-grooming (combing hair, brushing teeth, washing face), and bringing eating utensils to the mouth
- Difficulty lifting heavy objects above shoulder level
- Limited ability to sustain repetitive activities

### GH Joint Hypomobility: Management—Protection Phase

See General Guidelines for Management When Symptoms Are Acute in Chapter 10 and Box 10.1.

#### Educate the Patient

- Provide information about what to expect regarding the stages of healing.
- Instruct patient in safe motions and activity modifications that minimize joint stress.

#### Control Pain, Edema, and Muscle Guarding

- The joint may be immobilized in a sling to provide rest and minimize pain.
- Intermittent periods of passive or assisted motion within the pain free/protected ROM and gentle joint oscillation techniques to minimize further adhesions are initiated as soon as the patient tolerates movement.
- Gentle soft tissue mobilization of the cervical and periscapular muscles may improve patient comfort and minimize protective guarding, as may cervical ROM and/or cervical grade I or II passive intervertebral mobilizations.

#### Maintain Soft Tissue and Joint Integrity and Mobility

**PRECAUTION:** If there is increased pain or irritability in the joint after use of the following techniques, either the dosage was too strong or the techniques should be modified by decreasing the range of passive movement or delaying joint glides.

**CONTRAINDICATION:** If there are mechanical restrictions causing limited motion, appropriate tissue stretching should be initiated only *after* the inflammation subsides.

- *Passive ROM (PROM)* in all ranges of pain-free motion (see Chapter 3). As pain decreases, the patient is progressed

to active ROM with or without assistance, using activities such as rolling a small ball or sliding a rag on a smooth table top. Planar, multiplanar and circular motions can be given to move the shoulder to the end range of its available motions. Be sure the patient is taught proper mechanics and to avoid faulty patterns, such as scapular elevation or a slumped posture.

- *Passive joint distraction and glides, grade I and II* with the joint placed in a pain-free position (see Chapter 5).
- *Pendulum (Codman's) exercises* are techniques that use the effects of gravity to distract the humerus from the glenoid fossa.<sup>28,31</sup> They help relieve pain through gentle traction and oscillating movements (grade II) and provide early motion of joint structures and synovial fluid. No weight is used during this phase of treatment (see Fig. 17.22).

### CLINICAL TIP

Many patients perform pendulum exercises incorrectly by using the GH muscles to initiate shoulder motion and by performing large excursion of motion. The technique must be taught as small, gentle pendular motions initiated with body swaying while keeping the shoulder muscles relaxed.<sup>113</sup>

- *Gentle muscle setting* to all muscle groups of the shoulder and adjacent regions, including cervical and elbow muscles because of their close association with the shoulder complex. Instructions are given to the patient to gently contract a group of muscles while slight manual resistance is applied—just enough to stimulate a muscle contraction without provoking pain. The emphasis is on rhythmic contracting and relaxing of the muscles to stimulate blood flow and prevent circulatory stasis.

### Maintain Integrity and Function of Associated Regions

- Complex regional pain syndrome type I is a potential complication after shoulder injury or immobility. Therefore, additional exercises, such as having the patient repetitively squeeze a ball or other soft object, may be given for the hand.
- The patient is educated on the importance of keeping the joints distal to the shoulder complex as active and mobile as possible. The patient or family member is taught to perform ROM exercises of the elbow, forearm, wrist, and fingers several times each day while the shoulder is immobilized. If tolerated, active or gentle resistive ROM is preferred to passive ROM for a greater effect on circulation and muscle integrity.
- If edema is noted in the hand, instruct the patient to elevate the hand above the level of the heart whenever possible.
- Cervical ROM (active and/or passive), intervertebral joint mobilizations, and soft tissue mobilization should also be considered.

### CLINICAL TIP

For conditions in which there is potential for a prolonged acute/inflammatory stage, such as with RA and during stages I or II of idiopathic frozen shoulder, it is critical to teach the patient active-assistive exercises to maintain muscle and joint integrity and as much mobility as possible without exacerbating the symptoms.

### GH Joint Hypomobility: Management—Controlled Motion Phase

When symptoms are subacute, follow the guidelines as described in Chapter 10, Box 10.2, emphasizing joint mobility, neuromuscular control, and instructions to the patient for self-care.

#### Control Pain, Edema, and Joint Effusion

- *Functional activities.* It is important to carefully monitor activities. If the joint is immobilized, the amount of time the shoulder is free to move each day is progressively increased.
- *ROM.* GH and scapula motions are progressed up to the point of pain. The patient is instructed in the use of self-assistive ROM techniques, such as wand exercises or hand slides on a table.

**PRECAUTION:** With increased pain or decreased motion after these techniques, the activity may be too intense or the patient may be using faulty mechanics. Reassess the technique and modify it by restricting the joint to a safer ROM, correcting faulty movements, or altering the intensity, frequency, and/or duration of the technique.

#### Progressively Increase Joint and Soft Tissue Mobility

- *Passive joint mobilization techniques.* Grade III sustained or grade III and IV oscillations that focus on the restricted capsular tissue at the end of the available ROM are used to increase joint capsule mobility<sup>94,207</sup> (see Figs. 5.15 to 5.20 in Chapter 5 and ONLINE Box 17.1). End-of-range techniques include rotating the humerus and then applying either a grade III distraction or a grade III glide to stretch the restrictive capsular tissue or adhesions (see Figs. 5.17, 5.21, and 17.20).
  - Use a grade I distraction with all gliding techniques. If the joint is irritable and gliding in the direction of restriction is not tolerated, glide in the opposite direction. As pain and irritability decrease, begin to glide in the direction of restriction.<sup>94</sup>

### FOCUS ON EVIDENCE

Evidence supporting joint mobilization techniques is limited. A multiple-subject case study, using seven subjects with adhesive capsulitis of the GH joint (mean disease duration 8.4 months, range 3 to 12 months) treated with end-range mobilization

techniques twice a week for 3 months, showed increased active and passive range and increased capacity of the joint capsule at the end of treatment and at the 9-month follow-up. No control groups were used; therefore, the natural course of the disease could not be excluded as the explanation for improvement.<sup>207</sup>

A follow-up study by the same author randomly assigned 100 subjects with stage II adhesive capsulitis to a group receiving high-grade mobilization techniques (end-range stretching using Maitland grade III or IV) or a group receiving low-grade mobilization techniques (Maitland grade I or II). After 3 months of treatment, both groups exhibited clinically significant improvement, with the group receiving the high-grade mobilization techniques showing greater improvement than the low-grade mobilization group. Because there was no control group, natural progression could not be ruled out.<sup>208</sup>

A study exploring the effect of the direction of joint mobilization demonstrated that a posterior glide was more effective than an anterior glide to increase GH external rotation ROM. Patients with stage II to IV primary adhesive capsulitis received distraction plus grade III sustained mobilizations, held for at least 1 minute, with treatment duration of 15 minutes, for six treatment sessions. Anterior mobilizations were progressed by placing the humerus at end-range abduction and external rotation, while posterior mobilizations were progressed by placing the humerus at end-range flexion and external rotation. At the end of the sixth visit, subjects in the anterior mobilization group ( $n = 10$ ) increased external rotation ROM by  $3.0^\circ$ , while those in the posterior mobilization group ( $n = 8$ ) increased by  $31.3^\circ$ , a difference that was statistically significant.<sup>93</sup>

**PRECAUTION:** Carefully monitor the joint reaction to the mobilization stretches; if irritability increases, grade III or IV techniques should not be undertaken until the chronic stage of healing.

- **Self-mobilization techniques.** The following self-mobilization techniques may be used for a home program.
  - **CAUDAL GLIDE.** *Patient position and procedure:* Sitting on a firm surface and grasping the fingers under the edge. The patient then leans the trunk away from the stabilized arm (Fig. 17.8).
  - **ANTERIOR GLIDE.** *Patient position and procedure:* Sitting with both arms behind the body or lying supine supported on a solid surface. The patient then leans the body weight between the arms (Fig. 17.9).
  - **POSTERIOR GLIDE.** *Patient position and procedure:* Prone, propped up on both elbows. The body weight shifts downward between the arms (Fig. 17.10).
- **Manual stretching.** Manual stretching techniques are used to increase mobility in shortened muscles and related connective tissue.
- **Self-stretching exercises.** As the joint reaction becomes predictable and the patient begins to tolerate stretching, self-stretching techniques are taught (see Figs. 17.24 through 17.29 in the Exercise section).

**FIGURE 17.8** Self-mobilization. Caudal glide of the humerus occurs as the person leans away from the fixed arm.

**FIGURE 17.9** Self-mobilization. Anterior glide of the humerus occurs as the person leans between the fixed arms.

**FIGURE 17.10** Self-mobilization. Posterior glide of the humerus occurs as the person shifts his weight downward between the fixed arms.

### Inhibit Muscle Spasm and Correct Faulty Mechanics

Muscle spasm may lead to a faulty deltoid-rotator cuff mechanism and altered scapulohumeral rhythm when the patient attempts arm elevation (Fig. 17.11). Greater relative deltoid activation may result in superior humeral head translation and impingement of the greater tuberosity on the coracoacromial arch, making it difficult and/or painful to elevate the arm. In this case, repositioning the humeral head with a caudal glide is necessary before proceeding with any other form of shoulder exercise. The patient must also learn to recognize and avoid “hiking the shoulder” when at rest or when elevating the arm. The following techniques may address these problems. See also Mobilization with Movement Techniques in the next section.

- Gentle joint oscillation techniques (grade I or II) to help decrease the muscle spasm.
- Sustained caudal glide joint techniques to reposition the humeral head in the glenoid fossa.
- Protected weight bearing, such as leaning hands against a wall or on a table, to stimulate rotator cuff and scapula stabilizer co-contraction and improve synovial fluid movement through hyaline cartilage compression. Techniques are progressed by gentle rocking forward/backward and side to side, moving from bilateral to unilateral, increasing the angle of the joint, or adding perturbations.
- GH internal/external rotation strengthening to facilitate stabilization of the humeral head (see Fig. 17.52).
- Movement retraining to minimize the substitution pattern of scapular elevation can be initiated by providing the visual feedback of a mirror or the tactile feedback of the opposite hand placed on the ipsilateral upper trapezius.

**FIGURE 17.11** Poor mechanics with the patient hiking the shoulder while attempting to abduct the arm. This results in limited scapula upward rotation and increased superior humeral head translations.

### Improve Joint Tracking

Mobilization with movement (MWM) techniques may assist with retraining muscle function for proper tracking of the humeral head.<sup>136</sup>

- *Shoulder MWM for painful restriction of shoulder external rotation* (Fig. 17.12).
- *Patient position:* Supine lying with folded towel under the scapula; the elbow is near the side and flexed to 90°. A cane is held in both hands.

**FIGURE 17.12** Mobilization with movement (MWM) to improve GH joint external rotation. A posterolateral glide is applied to the humeral head while the patient pushes the arm into the end-range of external rotation with a cane.

- *Therapist position and procedure:* Stand on the opposite side of the bed facing the patient and reach across the patient's torso to cup the anteromedial aspect of the head of the humerus with reinforced hands. Apply a pain-free graded posterolateral glide of the humeral head on the glenoid. Instruct the patient to use the cane to push the affected arm into the previously restricted range of external rotation. Sustain the movement for 10 seconds and repeat in sets of 5 to 10. It is important to maintain the elbow near the side of the trunk and ensure that no pain is experienced during the procedure. Adjust the grade and direction of the glide as needed to achieve pain-free function.
- *Shoulder MWM for painful restriction of internal rotation and inability to reach the hand behind the back* (Fig. 17.13).
- *Patient position:* Standing with a towel draped over the unaffected upper trapezius and affected hand at current range of maximum pain-free position behind back. The patient's hand on the affected side grasps the towel behind the back.

**FIGURE 17.13** MWM to improve GH joint internal rotation. An inferior glide is applied to the humerus while the patient pulls the hand up the back with a towel.

- Therapist position and procedure:** Stand facing the patient's affected side. Place the hand closest to the patient's back high up in the axilla with the palm facing outward to stabilize the scapula with an upward and inward pressure. With the hand closest to the patient's abdomen, hook the thumb in the cubital fossa and grasp the lower humerus to provide an inferior glide. Your abdomen is in contact with the patient's elbow to provide an adduction force to the arm. Have the patient pull on the towel with the unaffected hand to draw the affected hand up the back while the mobilization force is being applied in an inferior direction. Ensure that no pain is experienced during the procedure. Adjust the grade and direction of glide as needed to achieve pain-free function. Maximal glide should be applied to achieve end-range loading.
- Shoulder MWM for painful arc or impingement signs.** If impingement signs are present in addition to the capsular restrictions, the MWM active elevation technique may be appropriate. (See Fig. 17.17 and description in the impingement section.)

### Improve Muscle Performance

- Faulty postures or shoulder girdle mechanics when moving the upper extremity, such as scapula elevation or protraction or excessive trunk movement, should first be identified and corrected. Manual techniques, stretches, and strengthening exercises are initiated to correct muscle length or strength imbalances, followed by an emphasis on developing active control of weak musculature. As the patient learns to activate the weak muscles, progress to strengthening in functional patterns.

- Because faulty postures or shoulder girdle mechanics may be impacted by impaired trunk strength or control, an emphasis on trunk stability should also be considered. Exercises to manage faulty spinal posture are described in Chapter 16, with active cervical retraction and thoracic extension especially important for shoulder function.
- After proper mechanics are restored, the patient should perform active ROM of all shoulder motions daily and return to functional activities to the extent tolerated.

### GH Joint Hypomobility: Management—Return to Function Phase

For joint impairments in the chronic stage, follow the guidelines described in Chapter 10, Box 10.4.

#### Progressively Increase Flexibility and Strength

- Stretching and strengthening exercises are progressed as the joint tissue tolerates. The patient should be actively involved in self-stretching and strengthening by this time, so emphasis during treatment is on maintaining correct mechanics, safe progressions, and exercise strategies for return to function. Progressions may include increasing resistance and repetitions, performing exercises through multiple planes, adding perturbations, and incorporating regional muscle groups (such as the trunk) into dynamic exercises.
- If capsular tissue is still restricting ROM, vigorous manual stretching and joint mobilization techniques are applied.

#### Prepare for Functional Demands

If the patient is involved in repetitive heavy lifting, pushing, pulling, carrying, or reaching, exercises are progressed to replicate these demands. See the last section of this chapter and Chapter 23 for suggestions.

### FOCUS ON EVIDENCE

The *Clinical Practice Guidelines (CPGs) for Shoulder Pain and Mobility Deficits from Adhesive Capsulitis* published by the Orthopaedic Section of the American Physical Therapy Association summarizes research and makes treatment recommendations supporting patient education (moderate evidence), GH joint mobilization (weak evidence), modalities (weak evidence), translational manipulation (weak evidence), and stretching exercises (moderate evidence) for treating this patient population.<sup>97</sup>

### GH Joint Management: Postmanipulation Under Anesthesia

Occasionally, no progress is made and the physician chooses to perform manipulation under anesthesia. Following this procedure there is an inflammatory reaction and the joint

is treated as an acute lesion. If possible, joint mobility and passive ROM techniques are initiated while the patient is still in the recovery room. Surgical intervention with incision of the dependent capsular fold may be used if the adhesions are not broken with the manipulation. Postoperative treatment is the same with the following considerations.<sup>148</sup>

- The arm is kept elevated overhead in abduction and external rotation during the inflammatory reaction stage; treatment principles progress as with any joint lesion.
- Therapeutic exercises are initiated the same day while the patient is still in the recovery room, with emphasis on internal and external rotation in the 90° (or higher) abducted position.
- Joint mobilization procedures are used, particularly a caudal glide, to prevent re-adherence of the inferior capsular fold.
- When sleeping, the patient may be required to position the arm in abduction for up to 3 weeks after manipulation.

## Acromioclavicular and Sternoclavicular Joints

### Related Pathologies and Etiology of Symptoms

**Overuse syndromes.** Overuse syndromes of the AC joint may result from repeated stressful joint movements with the arm at waist level, such as with grinding, packing assembly, and construction work,<sup>71</sup> or repeated diagonal extension, adduction, and internal rotation motions, as when spiking a volleyball or serving in tennis. The AC joint is susceptible to overuse syndromes in conjunction with arthritis or following a traumatic injury.

**Subluxation or dislocation.** Subluxation or dislocation of either the AC or SC joints is usually caused by falling on the shoulder or an outstretched arm. At the AC joint, the distal end of the clavicle often displaces posteriorly and superiorly on the acromion, and the ligaments supporting the AC joint may rupture.<sup>147</sup> After trauma and associated overstretching of the capsules and ligaments of either joint, hypermobility is usually permanent because there are almost no muscles that provide direct stability to these joints.

**Hypomobility.** Decreased clavicular mobility may occur with SC joint OA and may contribute to TOS by compromising the space available for the neuromuscular bundle as it courses between the clavicle and first rib (described in Chapter 13).

### Common Impairments of Structure and Function

- Pain localized to the involved joint or ligament.
- Painful arc toward the end-range of shoulder elevation.
- Pain with shoulder horizontal adduction or abduction.
- Hypermobility if trauma or overuse is involved.
- Hypomobility if sustained posture, arthritis, or immobility is involved.

### Common Activity Limitations and Participation Restrictions

- Limited ability to sustain repeated forceful movements of the arm, such as with grinding, packing, assembly, and construction work.<sup>71</sup>
- Inability to reach overhead or perform repetitive overhead activities without pain.

### Nonoperative Management of AC or SC Joint Strain or Hypermobility

- Minimize joint loading by supporting the weight of the arm with a sling.
- Cross-fiber massage to the capsule or ligaments.
- Maintain ROM of the GH joint and scapulothoracic articulation.
- Instruction in self-application of cross-fiber massage if joint symptoms occur after excessive activity.
- Increase strength of shoulder complex, trunk, and legs.
- Gradually return to functional activities.

### Nonoperative Management of AC or SC Joint Hypomobility

Joint mobilization techniques are used to increase joint mobility (see Figs. 5.22 through 5.24).

## Glenohumeral Joint Surgery and Postoperative Management

Severe deterioration of one or both surfaces of the GH joint or an acute or nonunion fracture of the proximal humerus often must be managed with surgical intervention. Underlying pathologies that cause advanced joint destruction include late-stage OA, RA, traumatic arthritis, cuff tear arthropathy, and osteonecrosis (avascular necrosis) of the head of the humerus.

The most common surgical procedure used to treat advanced shoulder joint pathology is *GH arthroplasty*, often simply referred to as *shoulder arthroplasty*.<sup>34</sup> In rare situations, *arthrodesis* (surgical ankylosis) of the GH joint may be necessary as an alternative to arthroplasty or as a salvage procedure.<sup>124</sup>

The goals of these surgical procedures and the postoperative rehabilitation program are to (1) relieve pain, (2) improve shoulder mobility or stability, and (3) restore or improve strength and functional use of the upper extremity. The extent to which these goals are achieved is predicated on the patient's participation in postoperative rehabilitation, the distinguishing features and severity of the underlying pathology; the prosthetic design and surgical techniques; the integrity of the rotator cuff mechanism and other soft tissues; and the age, overall health, and anticipated activity level of the patient.<sup>33,124,179,185</sup>

## Glenohumeral Arthroplasty

GH arthroplasty falls into several categories, the most common of which are *total shoulder arthroplasty (TSA)*,<sup>124,141,179,185</sup> in which both the glenoid and humeral surfaces are replaced (Fig. 17.14), and *hemireplacement arthroplasty (hemiarthroplasty)*, in which only the humeral head is replaced.<sup>59,124,143,179,234</sup> *Reverse total shoulder arthroplasty (rTSA)* is another type of arthroplasty, typically used when rotator cuff integrity is compromised.<sup>37,127,211</sup> Other categories of shoulder arthroplasty include interpositional and resurfacing arthroplasties, which involve less extensive removal of bone.<sup>124,179,185,202</sup>

**FIGURE 17.14** Postoperative anterior-posterior view of the shoulder showing a Neer II type of cemented humeral prosthesis and a nonmetal backed polyethylene glenoid. (From *Tovin, BJ, and Greenfield, BH: Evaluation and Treatment of the Shoulder—An Integration of the Guide to Physical Therapist Practice. Philadelphia: F.A. Davis, 2001, p 266, with permission.*)

### Indications for Surgery

The following structural and functional impairments associated with these pathologies are widely accepted indications for GH arthroplasty.<sup>33,49,123,124,141,143,179,185,194,215</sup>

- Persistent and incapacitating pain (at rest or with activity) secondary to GH joint destruction is the primary indication for GH arthroplasty.
- Secondary indications include loss of shoulder mobility or stability and/or loss of upper extremity strength with an inability to perform functional tasks.

## Procedures

### Background

**Implant design, materials, and fixation.** Since the pioneering work of Neer during the 1960s and 1970s<sup>141,143</sup> prosthetic designs and surgical techniques for replacing the shoulder joint have continued to evolve. The designs of contemporary TSA hardware, composed of a high-density polyethylene glenoid component (usually all plastic) and a modular inert metal humeral component, closely approximate the biomechanical characteristics of the human shoulder.<sup>227</sup> The exception to this is the rTSA, the design of which reverses the native shoulder ball and socket relationship. Specifically, the glenoid fossa is replaced with a convex, “glenospherical” component attached to a glenoid base and the humeral head is replaced with a stemmed concave cup.<sup>209</sup> Fixation of the prosthetic components is achieved with cement, bio-ingrowth, or a press fit. The type of fixation selected by the surgeon depends on the component, the underlying pathology, and the quality of the bone stock. Cement fixation is most often necessary in patients with osteoporosis.<sup>33,123,124,227</sup>

The designs of total shoulder replacements, ranging from *unconstrained* to *semiconstrained* to *constrained*, provide varying amounts of mobility and stability to the GH joint. Box 17.1 summarizes the characteristics of each of these designs.<sup>33,123,124,176,179,185,202</sup>

**Selection of procedure.** Controversy exists over the specific criteria for selection of TSA versus rTSA versus hemiarthroplasty, but in general it depends on the etiology and severity of joint deterioration and the condition of the periarticular soft tissues, particularly the rotator cuff mechanism.<sup>124,186</sup> Several examples that follow underscore the complexity of the clinical decision-making process involved in the choice of operative procedure and prosthetic design.

In patients with late-stage primary OA, the GH joint typically exhibits loss or thinning of the articular cartilage of the head of the humerus and the posterior portion of the glenoid fossa. The rotator cuff is intact in approximately 90% to 95% of these patients, making them good candidates for either TSA or hemiarthroplasty.<sup>33,123,176,179,185</sup> A recent meta-analysis found better functional outcomes in those receiving a TSA, but no differences in instability or revision rates between TSA and hemiarthroplasty.<sup>48</sup> Chronic synovitis associated with RA or other types of synovium-based arthritis tends to erode periarticular soft tissues in addition to joint articular surfaces. As a consequence, a full-thickness rotator cuff tendon tear (typically the supraspinatus) develops in 25% to 40% of these patients and a biceps tendon rupture in an even greater percentage.<sup>59,176,185,202</sup> If the soft tissues can be repaired and their functions improved, a semiconstrained TSA may be indicated. If an effective repair cannot be achieved, an rTSA is usually indicated. When there is insufficient bone stock for fixation of a glenoid implant, hemiarthroplasty is usually the procedure of choice.<sup>59,124,176,179,186,202</sup>

Hemiarthroplasty is often used when the articular surface and underlying bone of the humeral head have deteriorated,

### BOX 17.1 Designs of Prosthetic Implants for Total Shoulder Arthroplasty

#### Unconstrained

- Anatomical design with a small, shallow glenoid component combined with a stemmed humeral component
- The most frequently used prosthetic design
- Provides the greatest freedom of shoulder motion but no inherent stability
- Indicated when the rotator cuff mechanism is intact or can be repaired to provide dynamic stability to the GH joint

#### Semiconstrained

- A larger glenoid component that is hooded or cup-shaped
- Some degree of joint stability inherent in the design
- Indicated when erosion of the glenoid fossa can be compensated for by reaming the fossa in conjunction with a functional rotator cuff; although deficient preoperatively, fossa can be improved by repair

#### Reversed Ball and Socket

- Small humeral socket that slides on a larger ball-shaped glenoid component
- Combines moderate stability with mobility for rotator cuff-deficient shoulders that cannot be repaired
- Provides an alternative to standard, semiconstrained total shoulder arthroplasty (TSA) and hemiarthroplasty

#### Constrained

- Fixed fulcrum, ball-in-socket designs with congruency of the glenoid and humeral components
- Greatest amount of inherent joint stability but less mobility than other designs
- Once thought to be an alternative to hemiarthroplasty for the selected patient with a deficient rotator cuff, cuff tear arthropathy, or chronic/recurrent GH joint dislocation after a previous TSR
- Rarely used today owing to high rate of loosening or failure of the components

but the glenoid fossa is reasonably intact, as seen with osteonecrosis.<sup>33,124,185</sup> For the patient with severe, chronic pain and loss of function as the result of a massive, irreparable cuff tear and subsequent *cuff tear arthropathy*, rTSA is usually indicated. (First used by Neer, the term “cuff tear arthropathy” refers to deterioration and eventual collapse of the head of the humerus, an infrequent but debilitating long-term result of a primary, massive, and irreparable tear of the rotator cuff.<sup>124,176,215,234</sup>)

Chronic deficiency of the rotator cuff mechanism often leads to superior migration of the humeral head on the glenoid fossa. If a glenoid TSA component is inserted under these conditions, superior migration creates an incongruous articulation that can increase the risk of component loosening and premature wear of the glenoid implant.<sup>32,79,176</sup> The rTSA was developed to overcome this complication by minimizing translation between the glenosphere and humeral articular

surfaces. Other features of the rTSA include reduced forces on the glenoid component, inherent stability owing to the congruency of the components, and increased deltoid moment arms. One limitation of the rTSA design is decreased GH ROM.<sup>20,127,209</sup>

#### Operative Procedures

TSA, rTSA, and hemiarthroplasty are open surgical procedures performed with the patient in a semi-reclining position. These operative procedures involve the following components:<sup>33,59,124,179,185</sup> (1) anterior approach using a deltopectoral incision that extends from the AC joint to the deltoid insertion for adequate surgical exposure; (2) release (tenotomy) of the subscapularis tendon from its proximal attachment on the lesser tuberosity; (3) anterior capsulotomy; (4) exposure of the humeral head for a humeral osteotomy; and (5) preparation of the humeral canal for insertion of the prosthetic implant. The glenoid fossa is either débrided or contoured to accept the implant for a TSA. After component placement, the subscapularis is then reattached and may be lengthened (medial advancement or Z-plasty) if external rotation ROM is limited.

Reconstruction and balancing of soft tissues is critical for optimal function after TSA, rTSA, and hemiarthroplasty. “Balancing” refers to the intraoperative lengthening or tightening of soft tissues to restore as near-normal resting tension in the tissues as possible, particularly in the rotator cuff, biceps, and deltoid muscle-tendon units.

Concurrent procedures that may be necessary during shoulder arthroplasty include:

- Repair of a deficient rotator cuff if the quality of the cuff tissue is sufficient.
- Capsular plication and tightening for chronic GH joint subluxation or dislocation.
- Anterior acromioplasty for a history of impingement syndrome.
- Bone graft of the glenoid if bone stock is insufficient for fixation of the glenoid implant.

After implantation of the prosthetic component(s) and repair of soft tissues but before closure of the skin incision, the shoulder is passively moved through all planes of motion to visually evaluate the stability of the prosthetic joint and the integrity of the repaired soft tissues. This determines the anatomical ROM possible after surgery and the aggressiveness of the postoperative program.<sup>33,124</sup>

#### Complications

Although the incidence of intraoperative and postoperative complications after current-day arthroplasty is low, even a single complication can adversely affect functional outcomes. The incidence of complications after TSA tends to be higher in patients with a deficient rotator cuff mechanism, osteoporosis, or a history of chronic GH joint instability.<sup>78</sup> Aside from medical complications such as infection or a deep vein thrombosis, complications specific to shoulder arthroplasty are noted in Box 17.2.<sup>32,78</sup>

### BOX 17.2 Complications Specific to Glenohumeral Arthroplasty

#### Intraoperative Complications

- Insufficient lengthening of a tight subscapularis muscle-tendon unit
- Intraoperative damage to the axillary or suprascapular nerves, affecting the deltoid and supraspinatus/infraspinatus muscles, respectively
- Humerus fracture

#### Postoperative Complications Related to Soft Tissue

- Re-tearing a repaired rotator cuff mechanism
- Disruption or failure of the repaired subscapularis
- Chronic GH joint instability or dislocation
- Dislocation (higher after rTSA than TSA)
- Progressive erosion of the glenoid fossa articular surface (after hemiarthroplasty)

#### Postoperative Complications Related to the Implants

- After TSA mechanical (aseptic) loosening, premature wear, or fracture of the polyethylene glenoid implant
  - Most often seen in a rotator cuff-deficient shoulder
  - Due to excessive stresses at the bone-prosthesis interface
  - Low incidence with unconstrained designs but higher with early-generation constrained designs
- Loosening of the humeral prosthesis after hemiarthroplasty

### Postoperative Management

**NOTE:** Effective patient education and close communication among the therapist, surgeon, and patient are the basis of an effective and safe rehabilitation program. Postoperative management is individualized to address the specific surgical procedures used and to meet the unique needs of each patient.

#### Special Considerations

**Integrity of the rotator cuff.** Regardless of the underlying cause of late-stage GH arthritis, the goals, components, and rate of progression of a rehabilitation program after TSA or hemiarthroplasty are influenced by the preoperative and postoperative integrity of the rotator cuff mechanism. The rehabilitation program for the patient with an intact rotator cuff prior to shoulder arthroplasty can be progressed more rapidly than the program for a patient with rotator cuff deficiency that requires repair at the time of shoulder arthroplasty.

When the rotator cuff is intact prior to surgery, the emphasis of postoperative rehabilitation is to restore shoulder mobility and functional use of the arm as soon as possible while protecting soft tissues as they heal. In contrast, with a tenuous repair or preoperative history of recurrent GH dislocation, rehabilitation will emphasize improving or maintaining joint stability rather than mobility.<sup>42,49,54,99,124</sup>

**Intraoperative ROM.** Goals for safe, stable postoperative ROM are based on intraoperative ROM measurements taken prior to closing the surgical incision. For a patient with an

unconstrained TSA and sufficient postoperative shoulder stability, the goal at the conclusion of rehabilitation is to achieve active ROM equal to intraoperative ROM—ideally, 140° to 150° of shoulder elevation and 45° to 50° of external rotation.<sup>42,124</sup> For the patient with a more constrained TSA, a deficient rotator cuff mechanism, or GH laxity, intraoperative ROM is typically less, and postoperative goals focus more on dynamic stability and less on shoulder mobility. Following rTSA, ROM is limited to 0° to 20° external rotation and 90° to 120° elevation for 3 months.<sup>20,127</sup>

**Posture.** When increased thoracic kyphosis and scapular protraction are present,<sup>103</sup> it is important to emphasize an erect sitting or standing posture during elevation of the arm and to incorporate spinal extension and scapular retraction exercises into the postoperative program.

#### Immobilization and Postoperative Positioning

At the close of the surgical procedure, the operated arm is placed in some type of shoulder immobilizer, usually a sling or sometimes a splint, for comfort and to protect reattached and repaired soft tissues.<sup>33,124,176,185,204</sup> Early postoperative positioning that protects the operated shoulder is detailed in Box 17.3.

Initially, the immobilizer is removed only for exercise and bathing. A patient who did not require repair of the rotator cuff is weaned from the sling during the day as quickly as possible to prevent postoperative stiffness. However, a patient who has undergone a cuff repair or other soft tissue reconstruction may need to wear the sling while in crowded areas or during sleep for approximately 4 to 6 weeks to protect the repaired tissues until sufficient healing has occurred.<sup>21,23,33,42,49,50,99,124,194</sup>

### BOX 17.3 Positioning After Shoulder Arthroplasty: Early Postoperative (Maximum Protection) Phase

#### Supine

- Arm immobilized in sling that is worn continuously
  - Elbow flexed to 90°
  - Forearm and hand resting on abdomen
- Arm supported at the elbow on a folded blanket or pillow slightly away from the side and anterior to the midline of the trunk
  - Forward flexion (10° to 20°), slight abduction, and internal rotation of the shoulder
  - Head of bed elevated about 30°

#### Sitting

- Arm supported in sling or resting on a pillow in the patient's lap or on the armrest of a chair

#### With Tenuous Rotator Cuff Repair

- In some cases, if a sling does not provide adequate protection of a repaired cuff, an abduction splint must be worn

A patient who has undergone an rTSA wears a shoulder immobilizer (sling and swathe) continuously for 3 to 4 weeks following surgery except for daily personal hygiene and periodic PROM during the day.<sup>127</sup>

### Exercise Progression

The guidelines for progression of exercises during each phase of rehabilitation after TSA, rTSA, or hemiarthroplasty presented in this section are primarily drawn from the limited number of published protocols available, most of which are based on clinical experience rather than evidence from controlled studies and none of which has been shown to be more effective than another.<sup>21,23,34,42,49,98,99,103,124,194,215</sup> Although most of the protocols are time-based, a handful of more

recent criteria-based protocols are now available.<sup>20,34,49,209,215</sup> It is important to note that these criteria and suggested timelines for progression of exercises and functional activities must be adapted to each patient based on periodic evaluations of the patient's status and ongoing communication between the therapist and the surgeon.

**NOTE:** The exercise guidelines in this section are for patients *without* preoperative rotator cuff deficiency and who *did not* undergo a cuff repair during TSA or hemiarthroplasty. For patients with a poor quality rotator cuff mechanism or who underwent rTSA, modifications in guidelines are noted. A comparison of postoperative exercise guidelines and precautions following TSA versus rTSA is summarized in Table 17.2.

**TABLE 17.2** Comparison of Exercise Guidelines and Precautions Following Total Shoulder Arthroplasty and Reverse Total Shoulder Arthroplasty

	Total Shoulder Arthroplasty (Intact Rotator Cuff)	Reverse Total Shoulder Arthroplasty
Progression of rehab	Phase 1: postop weeks 0–4 Phase 2: postop weeks 4–12 Phase 3: postop weeks 12+	Phase 1: postop weeks 0–6 Phase 2: postop weeks 6–12 or 16 Phase 3: postop weeks 12+ or 16+
Immobilization	<ul style="list-style-type: none"> <li>■ No immobilizer unless rotator cuff repaired</li> <li>■ Sling worn for comfort when shoulder unsupported and when in crowded, public areas or during sleep for about 4 weeks</li> <li>■ Sling removed for exercise soon after surgery as directed by surgeon</li> </ul>	<ul style="list-style-type: none"> <li>■ Abduction splint (shoulder in scapular plane)</li> <li>■ Worn 24 hours/day for first 3–4 or up to 6 weeks</li> <li>■ Removed for pendulum exercises 3–4 times/day and personal hygiene</li> </ul>

A-AROM = active-assistive ROM; AROM = active ROM; ADL = activities of daily living; GH = glenohumeral; NWB = nonweight bearing; ST = scapulothoracic; UE = upper extremity

### CLINICAL TIP

Remember, regardless of implant design, pain relief is the primary goal of shoulder arthroplasty, with improvement in functional mobility a secondary goal. Although improvements in surgical techniques and implant technology allow more accelerated progression of postoperative rehabilitation than was possible several decades ago, it is still important to proceed judiciously during each phase of rehabilitation to

avoid damage to the healing soft tissues, implant loosening, or excessive muscle fatigue or irritation.

### Exercise: Maximum Protection Phase

The maximum protection phase of rehabilitation following TSA begins on the first postoperative day and extends for 4 to 6 weeks. The emphasis of this phase is patient education, pain

control, and initiation of ROM exercises to prevent tissue adhesions and restore shoulder mobility to the ranges achieved during surgery as early as possible. Early motion is permissible after uncemented and cemented fixation.

While the patient is hospitalized, patient education includes reviewing early postoperative precautions and teaching the initial exercises of the patient's home program. Precautions during the first 4 to 6 weeks after TSA, when protection of soft tissues is crucial, are summarized in Box 17.4. A patient's adherence to these precautions is critical during this phase of rehabilitation.

**Goals and interventions.** The maximum protection phase of rehabilitation includes the following:<sup>21,23,34,42,49,50,98,99,124,194</sup>

■ **Control pain and inflammation.**

- Use a sling or splint for comfort.
- Use prescribed analgesic and anti-inflammatory medication.
- Use cryotherapy, especially after exercise.

■ **Maintain mobility of adjacent joints.**

- Active movements of the spine and scapula (while wearing the shoulder sling and when it is removed for exercise) to maintain motion and minimize muscle guarding and spasm. Incorporate "shoulder rolls" by elevating, retracting, and then relaxing the scapulae to reinforce an erect posture of the trunk. Emphasize active scapular retraction and spinal extension.

- Active ROM of the hand, wrist, and elbow when the arm is removed from the sling.
- **Restore shoulder mobility.**
  - Passive or therapist-assisted shoulder motions *within the safe ROM limits determined during surgery*. With the patient lying supine and the arm slightly away from the side of the trunk on a folded towel and the elbow flexed, perform elevation of the arm in the plane of the scapula to tolerance, external rotation to no more than 30° to 45°, and internal rotation until the forearm rests on the chest.
  - Pendulum (Codman's) exercises. In addition, encourage the patient to periodically remove the sling and swing the arm gently during ambulation at home.
  - Later in this phase, progress to *supine self-assisted* shoulder ROM (elevation and rotation) by first assisting with the sound hand and later with a wand or dowel rod. Add horizontal abduction to neutral and adduction across the chest with the assistance of a wand.
  - Self-assisted shoulder ROM with a wand *in sitting or standing* position by performing "gear shift" exercises (see Fig. 17.23), by sliding the arm forward on a tabletop (see Fig. 17.25), or with an overhead rope pulley system. Remind the patient to maintain an erect trunk when performing assisted shoulder motions while seated or standing.
  - Self-assisted reaching movements (to the nose, forehead, or over the head as comfort allows) to simulate functional movements.

### BOX 17.4 Precautions for the Maximum Protection Phase of Rehabilitation Following Shoulder Arthroplasty

#### Exercise

- Short but frequent exercise sessions (four or five times per day).
- Low number of repetitions per exercise.
- Only *passive* or *assisted* shoulder ROM exercises and only within the "safe" limits of ranges noted during surgery. *Absolutely no end-range stretching.*
  - Passive external rotation to neutral after rTSA or to less than 30° after TSA to avoid excessive stress to the surgically repaired subscapularis muscle.
  - During passive or assisted shoulder rotation with the patient lying supine, position the humerus slightly anterior to the midline of the body (by placing the arm on a folded towel) to avoid excessive stress to the anterior capsule and suture line.
  - No hyperextension or horizontal abduction (beyond neutral) of the shoulder to avoid stress to the anterior capsule.
  - No combined extension, adduction, and internal rotation
  - If an overhead rope-pulley system is used for assisted elevation of the arm, initially *have the patient face the doorway and pulley apparatus*, so shoulder elevation occurs only within a limited range.
  - Maintain an erect trunk during passive or assisted elevation of the arm while sitting or standing to avoid subacromial impingement of soft tissues.

- In most instances, no active (unassisted), antigravity, dynamic shoulder exercises, particularly resisted internal rotation.
- No resistance (strengthening) exercises.
- In general, a more gradual progression of exercises following rTSA and for a patient with a severely damaged and repaired or irreparable rotator cuff mechanism who underwent TSA than for a patient with a preoperatively intact cuff.

#### Activities of Daily Living

- Limit activities to those that can be performed with the elbow at waist level, such as eating or writing.
- Avoid reaching behind the back to tuck in a shirt, reach into a back pocket, or following toileting.
- Avoid weight bearing on the operated extremity, such as pushing during transfers or when moving in bed, especially the first few weeks after surgery.
- Avoid lifting objects with the operated arm.
- Support the arm in a sling during extended periods of standing or walking.
- Wear the sling while sleeping or outside in crowded areas.
- No driving for 4 to 6 weeks.

- For some patients, transition to *active* (unassisted) shoulder ROM is often possible by 4 weeks.
- Functional activities with the elbow at waist level, such as hand to face and writing, are permissible.
- **Minimize muscle inhibition, guarding, and atrophy.**
  - Gentle muscle-setting of shoulder musculature (excluding the internal rotators) with the elbow flexed and the shoulder in the plane of the scapula or neutral. Teach these exercises prior to discharge from the hospital by having the patient practice isometric contractions of the muscles of the *sound* shoulder. Postpone setting exercises (light isometrics) of the operated shoulder until about 4 to 6 weeks after surgery.
  - Scapular stabilization exercises in nonweight-bearing positions. Target the serratus anterior and trapezius muscles.

**NOTE:** For a patient who underwent TSA with repair of a large rotator cuff tear, it may not be permissible to begin ROM exercises immediately after surgery. When the sling or splint can be removed for exercise, perform only passive or assisted ROM throughout the first phase of rehabilitation. The range of shoulder elevation and external rotation initially permitted may be less than for shoulders that did not require cuff repair. Postpone active (unassisted), antigravity ROM and light isometrics until the second phase (approximately 6 weeks postoperatively, when repaired soft tissues are reasonably well healed).

Following rTSA, patients have a lifting limit of 1 lb or less for 6 weeks, and external rotation and elevation ROM are limited to 0° to 20° and 90° to 120°, respectively, for 3 months.<sup>20,127</sup> In addition, hyperextension, lifting, and supporting of body weight with the involved shoulder are all precautions following rTSA.<sup>20</sup> (Refer to Table 17.2 for additional precautions after rTSA.)

**Criteria to progress.** Criteria to advance to the second phase of rehabilitation following TSA are:

- ROM: At least 90° of passive elevation, at least 45° degrees of external rotation, and 70° of internal rotation in the plane of the scapula with minimal pain<sup>215</sup> or *almost* full, passive shoulder motion based on intraoperative measurements with little to no pain.<sup>34,99</sup>
- No pain during resisted, isometric internal rotation of the subscapularis.<sup>34</sup>
- Ability to perform most waist-level activities of daily living (ADLs) without pain.<sup>99</sup>
- For rTSA, criteria include tolerance of assisted ROM and demonstration of the ability to isometrically activate the deltoid and periscapular musculature while the joint is positioned in the scapular plane.<sup>20</sup>

### Exercise: Moderate Protection/Controlled Motion Phase

Although suggested timelines vary from one resource to another, the moderate protection/controlled motion phase of rehabilitation, which typically begins at about 4 to 6 weeks postoperatively and extends to at least 12 to 16 weeks, focuses on gradually establishing active (unassisted) control, dynamic

stability, and strength of the shoulder while continuing to increase ROM.<sup>21,23,42,49,98,99,124,194,215</sup>

**PRECAUTIONS:** During this phase of rehabilitation, although it is safe to place increasing stresses (stretching or resistance) on periarticular soft tissues, it is important to do so gradually so as not to irritate tissues that are continuing to heal. Therefore, continue with short but frequent exercise sessions and avoid vigorous stretching or resistance exercises or overuse of the involved shoulder during functional activities.

**Goals and interventions.** The goals and exercises for this phase of rehabilitation are as follows.

- **Continue to increase ROM of the shoulder.**
  - Transition from passive or assisted ROM to *low-intensity, pain-free* stretching in all anatomical and diagonal planes of motion to achieve intraoperative ROM.
  - Gentle joint mobilization techniques for specific capsular restrictions.
  - In addition to therapist-assisted stretching, teach the patient how to perform gentle self-stretching exercises to increase elevation, internal/external rotation, extension, and horizontal adduction/abduction. Suggestions are pictured in the Exercise Techniques section of this chapter.
- **Develop active control and dynamic stability and improve muscle performance (strength and endurance) of the shoulder.**
  - Continue with or gradually transition to *active* shoulder ROM exercises, initiating antigravity abduction when the patient can perform the movement without substituting scapula elevation.
  - Scapular and GH joint stabilization exercises (alternating isometrics and rhythmic stabilization) can progress from nonweight-bearing to minimal weight-bearing positions.

**NOTE:** For patients who have had an rTSA, maintain nonweight-bearing precautions for up to 12 weeks postoperatively.<sup>20</sup>

- Pain-free, low-intensity (submaximal) resisted isometrics of shoulder muscles can be incorporated, including the subscapularis and any other repaired muscle-tendon units.
- Begin dynamic resistance exercises for the scapula and shoulder musculature (between 0° and 90° of shoulder elevation) using light weights or light-grade elastic resistance. Begin in the supine position to support and stabilize the scapula and progress to the sitting position.
- Begin upper extremity endurance training with a stationary ergometer or a portable reciprocal exerciser on a table. Progress by increasing repetitions or time to increase muscular and cardiopulmonary endurance.

**Criteria to progress.** To advance to the final phase of rehabilitation, a patient should meet the following criteria:

- Full, passive ROM of the shoulder (based on intraoperative ranges)<sup>34,99</sup> or pain-free, passive or assisted shoulder flexion of at least 130° to 140° and abduction of 120°.<sup>215</sup>
- In the plane of the scapula, at least 60° pain-free, passive external rotation and 70° internal rotation.<sup>215</sup>

- Active (unassisted), antigravity elevation of the arm to at least 100° to 120° in the plane of the scapula while maintaining joint stability and using appropriate shoulder mechanics, particularly no scapula elevation during arm elevation.<sup>215</sup>
- 4/5 strength of rotator cuff and deltoid muscles.<sup>49,99</sup>
- rTSA patients should have documented improvements in function and increasing strength of the deltoid and periscapular muscles prior to progressing to the next phase.<sup>20</sup>

### Exercise: Minimum Protection/Return to Function Phase

The minimum protection/return to functional activity phase usually begins around 12 to 16 weeks postoperatively (depending on rotator cuff tissue quality and function) and extends for several more months.<sup>49,99,215</sup> Pain-free strengthening of the shoulder muscles for dynamic stability and functional use of the upper extremity for progressively more demanding tasks are the primary focuses of this phase. For optimal results, the home exercise program may need to be continued for 6 months or longer, and functional and recreational activities may need to be modified.

**Goals and interventions.** Goals and activities for the final phase of rehabilitation include the following:<sup>21,23,34,49,50,98,99,215</sup>

- **Continue to improve or maintain shoulder mobility.**
  - End-range self-stretching.
  - Grade III joint mobilization and self-mobilization, if appropriate.<sup>21,23,34,99</sup>
- **Continue to improve neuromuscular control and muscle performance of the shoulder.**
  - Pain-free, low-load, high-repetition progressive resistive exercise (PRE) of shoulder musculature in anatomical and diagonal planes and in patterns of movement that replicate functional tasks throughout the available ROM. Position the patient in a variety of gravity-resisted positions.
  - Closed-chain, resisted shoulder exercises, gradually increasing the amount of weight bearing through the upper extremity.
  - Use of the involved upper extremity for lifting, carrying, pushing, or pulling activities against increasing loads.
- **Return to most functional activities.**
  - Use of the operated upper extremity for progressively more advanced functional activities.
  - Recreational activities, such as swimming and golf are possible.
  - Modification of high-demand, high-impact work-related or recreational activities to avoid imposing excessive forces on the GH joint that could lead to loosening or premature wear of prosthetic implants.

**NOTE:** For the patient whose rotator cuff was irreparable or continues to be significantly deficient because of a tenuous repair and who has limited but pain-free shoulder ROM, modification of the environment and use of assistive devices may be necessary for independence in functional activities.

### Outcomes

As patient selection criteria, implant design, and surgical techniques have been refined, outcomes after shoulder arthroplasty have improved. Outcomes after TSA, rTSA, or hemiarthroplasty are influenced by many factors, including the type and severity of the underlying pathology, the integrity of soft tissues, the type and quality of the surgical procedure(s) performed, and patient-related factors such as participation in a postoperative rehabilitation program.<sup>29,33,215</sup> The outcomes most often reported are pain relief, quality of life, passive and active shoulder ROM, and the ability to perform functional activities.

Despite an emphasis by numerous resources that a patient's participation in postoperative rehabilitation is crucial for successful outcomes, there are no studies to support this opinion, because all patients undergoing shoulder arthroplasty are given some form of postoperative exercise instruction. Furthermore, published protocols are routinely modified to meet the needs of individual patients making comparison of postoperative protocols difficult.<sup>215</sup>

**Pain relief.** A decrease in pain is the most consistent result of GH arthroplasty. Almost all patients—regardless of the underlying pathology, the type of arthroplasty, or the design of the implants—report complete or substantial relief of shoulder pain and improved functional use of the arm.<sup>33,123,124,139,141,143,152,156,188,211</sup>

The extent of pain relief has been shown to be associated with the underlying cause(s) of GH arthritis. Neer and associates;<sup>141</sup> Matsen;<sup>123</sup> and more recently, Norris and Iannotti<sup>152</sup> reported that 90% of patients with primary OA or osteonecrosis had complete or near-complete pain relief after TSA. Similar results are reported for patients with OA who underwent hemiarthroplasty.<sup>112,124,143</sup> Patients with RA or other synovium-based diseases also report substantial pain relief after TSA or hemiarthroplasty, although not quite to the extent reported by patients with OA or osteonecrosis.<sup>33,176,202</sup> However, in a sample of 191 patients after rTSA, Wall and colleagues report statistically significant improvements in pain as measured by the Constant score regardless of patient diagnosis.<sup>211</sup>

TSA and hemiarthroplasty have been compared to each other for pain relief effectiveness. In one prospective study of patients with OA, postoperative pain scores were similar for both groups, with patients receiving a TSA demonstrating more improvement than patients with hemiarthroplasty because of higher levels of preoperative pain.<sup>156</sup> In another study, patients with OA randomly assigned to either TSA or hemiarthroplasty groups were evaluated over a 24-month period and both groups reported significant pain relief and improvements in other quality-of-life parameters, with no significant differences between the groups.<sup>112</sup> Whether or not TSA versus hemiarthroplasty is more effective for pain relief in patients with RA has not been clearly established.<sup>124,202</sup>

**ROM and functional use of the upper extremity.** Despite the postsurgical emphasis on improving ROM and functional

use of the arm during rehabilitation, improvements in these outcomes are less predictable than pain relief, with functional status improving more consistently than ROM.<sup>59,124,152,156,179,188,215</sup> In general, patients with primary OA or osteonecrosis demonstrate greater improvement in active flexion and rotation ROM than patients with RA, likely because of the higher incidence of cuff deficiency associated with RA or the use of more constrained prosthetic designs.<sup>176,202,215</sup> For example, in patients with OA or osteonecrosis, the mean active flexion changed from 105° to 161°, while in patients with RA, means range from 75° to 105°.<sup>188,215</sup>

Significant improvement in functional status has been reported in patients with OA or osteonecrosis following arthroplasty. Although functional improvement after arthroplasty has also been reported in patients with RA, many studies used nonstandardized measurement tools, making it difficult to compare their results with those of other studies.<sup>215</sup> Following rTSA, patients with primary rotator cuff arthropathy, primary OA with rotator cuff tear, or a massive rotator cuff tear had better functional and clinical outcomes than patients with post-traumatic arthritis or revision arthroplasty.<sup>211</sup> Regardless of the underlying pathology, resources agree that a well-functioning rotator cuff mechanism is the basis for significant postoperative gains in active ROM and functional abilities.<sup>33,185,215</sup>

## Painful Shoulder Syndromes (Rotator Cuff Disease and Tendinopathies): Nonoperative Management

Most of the soft tissues in the suprahumeral space (see Fig. 17.7) can be a source of pain that limits movement and function and interferes with sleep. Referred to for decades as *impingement syndrome*, this common and multifactorial cause of pain was originally believed to be the result of mechanical compression and irritation of suprahumeral tissues.<sup>80,109,117</sup> Recent evidence suggests that noncompressive mechanisms such as tendon degenerative processes and entrapment also cause shoulder pain. For this reason, terminology such as tendinitis, tendinopathy, rotator cuff disease, and anterior shoulder pain are sometimes used instead of impingement syndrome. Various etiological factors for rotator cuff disease have been identified, leading to the classification systems summarized in Box 17.5.

### Related Pathologies and Etiology of Symptoms

The cause of rotator cuff disease is often multifactorial, involving both structural and mechanical factors. The term impingement syndrome and its recent variants has traditionally described a cluster of signs and symptoms that typically includes pain with overhead reaching, a painful arc in

### BOX 17.5 Categories of Painful Shoulder Syndromes

*Rotator cuff disease and other painful shoulder conditions have varying etiologic factors and therefore can be categorized in several ways.*

#### Based on Degree or Stage of Pathology of the Rotator Cuff (Neer's Classification of Rotator Cuff Disease)<sup>140</sup>

- *Stage I.* Edema, hemorrhage (patient usually <25 years of age)
- *Stage II.* Tendonitis/bursitis and fibrosis (patient usually 25 to 40 years of age)
- *Stage III.* Bone spurs and tendon rupture (patient usually >40 years of age)

#### Based on Impaired Tissue<sup>40</sup>

- Supraspinatus tendonitis
- Infraspinatus tendonitis
- Bicipital tendonitis
- Superior glenoid labrum and/or biceps tendon instability
- Subdeltoid (subacromial) bursitis
- Other musculotendinous strains (specific to type of injury or trauma)
  - Anterior—from overuse with racket sports (pectoralis minor, subscapularis, coracobrachialis, short head of biceps strain)
  - Inferior—from motor vehicle trauma (long head of triceps, serratus anterior strain)

#### Based on Mechanical Disruption and Direction of Instability or Subluxation

- Multidirectional instability from lax capsule with or without impingement
- Unidirectional instability (anterior, posterior, or inferior) with or without impingement
- Traumatic injury with tears of capsule and/or labrum
- Insidious (atraumatic) onset from repetitive microtrauma
- Inherent laxity

#### Based on Progressive Microtrauma (Jobe's Classification)<sup>92</sup>

- *Group 1.* Pure impingement (usually in an older recreational athlete with partial undersurface rotator cuff tear and subacromial bursitis)
- *Group 2.* Impingement associated with labral and/or capsular injury, instability, and secondary impingement
- *Group 3.* Hyperelastic soft tissues resulting in anterior or multidirectional instability and impingement (usually attenuated but intact labrum, undersurface rotator cuff tear)
- *Group 4.* Anterior instability without associated impingement (result of trauma; results in partial or complete dislocation)

#### Based on Degree and Frequency

- Instability → subluxation → dislocation
- Acute, recurrent, fixed

the mid-range of arm elevation, and positive provocation tests. Patients also often report waking at night with pain. Symptoms from cuff tendinopathy are usually brought on by excessive or repetitive overhead activities that place a high demand on the shoulder joint. Insight into the multifactorial nature of rotator cuff disease can be appreciated by a classification system that describes impingement as *intrinsic or extrinsic*, with extrinsic further classified as *primary, secondary, and internal*.

Additional types of musculotendinous strain in the shoulder region can occur from overuse, such as anterior pectoral region pain from playing racket sports, or from trauma such as a fall, traction on the arm, or an automobile accident.

### Intrinsic Impingement: Rotator Cuff Disease

Intrinsic factors are those that compromise the structural integrity of the musculotendinous structures and include vascular changes in the rotator cuff tendons, tissue tension overload, and collagen disorientation and degeneration.<sup>61,135</sup> Intrinsic conditions typically involve the deep articular side of the tendons and may progress to articular-side rotator cuff tears, seen most often in those older than 40 years of age.<sup>77</sup>

### Extrinsic Impingement: Mechanical Compression of Tissues

Extrinsic impingement is believed to occur as a result of mechanical compression of the rotator cuff against the anteroinferior one-third of the acromion in the suprahumeral space during arm elevation (Fig. 17.15). Tendon compression is believed to result from anatomical or biomechanical factors that decrease the physical dimensions of the suprahumeral space.

**FIGURE 17.15** Decrease in the suprahumeral space during repetitive elevation activities leads to symptoms of impingement.

**Primary extrinsic impingement.** Primary extrinsic impingement can result from anatomical or biomechanical factors. Anatomical factors include structural variations in the

acromion or humeral head, and hypertrophic degenerative changes of the AC joint and coracoacromial ligament. Neer<sup>142</sup> first suggested that the size and shape of the structures that make up the coracoacromial arch are related to rotator cuff impingement. In later studies, variations of the acromion were identified and classified into three shapes: type I (flat), type II (curved), and type III (hooked) (Fig. 17.16).<sup>12</sup> Rotator cuff pathology may be associated with types II and III—but not type I—acromial shapes.<sup>1,133,233</sup> Anatomical factors that decrease the suprahumeral space often have to be managed surgically.<sup>61,168,233</sup> Biomechanical factors include altered orientation of the clavicle or scapula during movement, or increased anterosuperior humeral head translations as may occur with a tight posterior GH capsule.<sup>74</sup>

**Secondary extrinsic impingement.** Secondary impingement describes mechanical compression of the suprahumeral tissues due to hypermobility or instability of the GH joint leading to increased translation of the humeral head. This instability may be multidirectional or unidirectional and can occur with compromised static (GH ligaments) and/or dynamic restraints (rotator cuff insufficiency).

- **Multidirectional instability.** Some individuals have physiologically increased connective tissue extensibility, causing excessive joint mobility. In the GH joint, this increased extensibility allows larger than normal humeral head translations in all directions.<sup>156,181</sup> Many individuals, particularly those involved in overhead activities, develop laxity of the capsule from continually subjecting the joint to tensile forces.<sup>61,92</sup> A hypermobile GH joint may be supported satisfactorily by strong rotator cuff muscles; but with muscle fatigue, poor humeral head stabilization may lead to faulty humeral mechanics, trauma, and inflammation of the suprahumeral tissues.<sup>92,132</sup> With multidirectional instability, the mechanical impingement of tissue in the suprahumeral space is, therefore, a secondary effect of the increased humeral head translations.<sup>61</sup>

- **Unidirectional instability with or without impingement.** Unidirectional instability (anterior, posterior, or inferior) may be the result of physiological laxity of the connective tissues, but is more often the result of trauma and usually involves rotator cuff tears. Often, there is damage to the glenoid labrum and tearing of some of the supporting ligaments associated with these traumas.

**Internal extrinsic impingement.** Internal impingement is a type of extrinsic impingement that occurs in a position of elevation, horizontal abduction, and maximum external rotation, primarily in throwing athletes. This position and a posterior-superior shift of the humeral head on the glenoid results in a mechanical entrapment of the posterior supraspinatus tendon between the humeral head and the labrum. Internal impingement is associated with a combination of posterior GH capsule tightness and scapula kinematic alterations.<sup>106,138</sup>

**FIGURE 17.16** Classifications of the acromion by shape: (A) type I (flat); (B) type II (curved); (C) type III (hooked).

### Tendonitis/Bursitis

Neer categorizes tendonitis/bursitis as a stage II impingement syndrome (see Box 17.5).<sup>140</sup> In contrast to tendinopathy, these conditions are associated with active inflammatory processes and may be localized to one or more specific tissues. The following sections describe specific pathological diagnoses and typical presenting signs and symptoms.

**Supraspinatus tendonitis.** With supraspinatus tendonitis, the lesion is usually near the musculotendinous junction, resulting in a painful arc with overhead reaching. There is also pain with provocation tests and pain on palpation of the tendon just inferior to the anterior aspect of the acromion when the patient's hand is placed behind the back. It is difficult to differentiate tendonitis from subdeltoid bursitis because of the anatomical proximity of these two structures.

**Infraspinatus tendonitis.** With infraspinatus tendonitis, the lesion is usually near the musculotendinous junction, resulting in a painful arc during overhead, forward, or cross body motions. It may present as a deceleration (eccentric) injury due to overload during repetitive or forceful throwing activities. Pain occurs with palpation of the tendon just inferior to the posterior corner of the acromion when the patient horizontally adducts and externally rotates the humerus.

**Bicipital tendonitis.** With bicipital tendonitis, the lesion involves the long tendon in the bicipital groove beneath or just distal to the transverse humeral ligament. Swelling in the bony groove is restrictive and compounds and perpetuates the problem. Pain occurs with Speed's test and on palpation of the bicipital groove.<sup>119</sup> Rupture or dislocation of the biceps tendon may compromise its role as a humeral depressor during arm elevation, promoting impingement of tissues in the suprahumeral space.<sup>140,149</sup>

**Bursitis (subdeltoid or subacromial).** When acute, the symptoms of bursitis are the same as those seen with supraspinatus tendonitis. Once the inflammation is reduced, there are no symptoms with resisted motions.

### Other Impaired Musculotendinous Tissues

The following are examples of other musculotendinous problems in the shoulder region:

- The pectoralis minor, short head of the biceps, and coracobrachialis are subject to microtrauma, particularly in racquet sports requiring a controlled backward, then a rapid forward swinging of the arm. The scapular stabilizers, particularly the retractors, are also susceptible to microtrauma as they function to control forward motion of the scapula.<sup>111</sup>
- The long head of the triceps and scapular stabilizers may be injured in motor vehicle accidents, as the driver holds firmly to the steering wheel on impact.
- Injury, overuse, or repetitive trauma can occur in any muscle being subjected to stress.<sup>151</sup> Pain occurs when the involved muscle is lengthened or when contracting against resistance. Palpating the site of the lesion causes the familiar pain.

### Insidious (Atraumatic) Onset

Neer has identified rotator cuff tears as a stage III impingement syndrome, a condition that typically occurs in persons over age 40 after repetitive microtrauma to the rotator cuff or long head of the biceps.<sup>140</sup> With aging, the distal portion of the supraspinatus tendon is particularly vulnerable to impingement or stress from overuse strain. With degenerative changes, calcification and eventual tendon rupture may occur.<sup>61,146,154</sup> Chronic ischemia caused from tension on the tendon and decreased healing in the elderly are possible explanations, although Neer stated that, in his experience, 95% of tears are initiated by impingement wear rather than by impaired circulation or trauma.<sup>140</sup>

### Common Impairments of Structure and Function

Various impairments are common in rotator cuff disease; however, it is not known if they are the cause or an effect of the pathology.<sup>28,114,117,157</sup> A thorough examination of the

cervical spine and shoulder complex is necessary to differentiate signs and symptoms related to primary and secondary impingements or other causes of shoulder pain.<sup>19,47,119</sup> Common impairments associated with rotator cuff disease and painful shoulder syndromes are summarized in Box 17.6.

### Impaired Posture and Muscle Imbalances

Increased thoracic kyphosis, forward head, and protracted and forward-tilted scapula are often identified as related to impingement syndrome. Faulty scapular alignment may be one factor in decreasing the suprahumeral space and leading to irritation of the rotator cuff tendons with overhead activities.<sup>114</sup> Faulty upper quadrant posture may also lead to an imbalance in the length and strength of the scapulothoracic and GH musculature, decreasing the effectiveness of the dynamic and passive stabilizing structures of the GH joint.<sup>221</sup>

With increased thoracic kyphosis, the scapula is often protracted and tilted forward and the GH joint is internally rotated. With this posture, the pectoralis minor, levator scapulae, and shoulder internal rotators may become tight, and the external rotators of the shoulder and upward rotators of the scapula may test weak and have poor muscular endurance. When reaching overhead, faulty scapular and humeral mechanics may result in alterations of scapular alignment and in the muscular control of the shoulder complex.

#### BOX 17.6 Summary of Common Impairments With Rotator Cuff Disease and Tendinopathies

All, some, or none of the following may be present:

- Pain at the musculotendinous junction of the involved muscle with palpation, with resisted muscle contraction, and when stretched
- Positive impingement sign (forced internal rotation at 90° of flexion) and painful arc near 90° arm elevation
- Impaired posture: thoracic kyphosis, forward head, and forward (anterior) tipped scapula with decreased thoracic mobility
- Muscle imbalances: hypomobile pectoralis major and minor, levator scapulae, and internal GH joint rotators; weak serratus anterior and external GH joint rotators
- Hypomobile posterior GH joint capsule
- Hypomobile cervical and/or thoracic spine mobility, especially with secondary impingement
- Faulty kinematics during humeral elevation: decreased posterior tipping of scapula related to weak serratus anterior; scapular elevation and overuse of upper trapezius; and altered scapulohumeral rhythm during elevation or lowering of arm
- With a complete rotator cuff tear, inability to abduct the humerus against gravity
- When acute, pain referred to the C5 and C6 reference zones

### FOCUS ON EVIDENCE

In a study comparing the kinematics of 26 subjects without shoulder impairment and 26 with shoulder impingement, Ludewig and Cook<sup>114</sup> documented delayed upward rotation of the scapula during the 31° to 60° range of humeral elevation, incomplete posterior tilting of the scapula, and excessive scapular elevation in the impingement group. These motion alterations may all contribute to decreasing the available subacromial space. Decreased activation of the lower serratus anterior and increased activation of the upper trapezius were also reported. Excessive scapula elevation and upper trapezius activation were suggested as possible compensations for the reduced posterior serratus anterior function.

A study using a three-dimensional technique to compare shoulder complex kinematics between 12 asymptomatic and 10 symptomatic subjects reported that at 30° and 60° of scapular plane abduction, the symptomatic subjects had 7° and 6° more GH elevation, respectively, with less scapulothoracic upward rotation. The authors suggest the altered mechanics in the symptomatic group reflect compensatory mechanisms in the shoulder complex demonstrating regional interdependence of the joints.<sup>107,108</sup>

### Decreased Thoracic ROM

Thoracic extension is a component motion that is needed for full overhead reaching. Incomplete thoracic extension may decrease the functional range of humeral elevation. Explanations for this regional interdependence include decreased thoracic spine mobility leading to faulty scapulothoracic mechanics and altered muscle activity.<sup>73</sup> Although increased thoracic kyphosis has been noted to decrease shoulder elevation,<sup>24,60,96,121</sup> direct evidence linking thoracic mobility to shoulder motion is not available and recent studies evaluating the effect of thoracic spine manipulation in those with rotator cuff disease have reported decreased pain without significant changes in scapula kinematics or shoulder elevation ROM.<sup>73,137</sup>

### CLINICAL TIP

Full overhead shoulder movement is more difficult when there is increased thoracic kyphosis and forward head posture. This relationship can be used as an educational tool with a patient to demonstrate the importance of spinal posture. First, have your patient reach overhead while in a slouched posture; then, have him assume “good posture” and reach overhead again and note the difference in ROM. Reinforce the importance of spinal posture in the management and prevention of shoulder problems.

### FOCUS ON EVIDENCE

A study comparing the effects of thoracic manipulation on scapular mechanics and pain in 47 asymptomatic and 50 symptomatic subjects with shoulder impingement symptoms

demonstrated an immediate decrease in pain and a small change in scapular mechanics in the symptomatic group relative to the asymptomatic group and those receiving a sham treatment.<sup>73</sup>

### Rotator Cuff Overuse and Fatigue

If the rotator cuff musculature or long head of the biceps fatigue from overuse, they no longer provide the dynamic stabilizing, compressive, and translational forces that support the joint and control healthy joint mechanics. Fatigue is thought to be a precipitating factor in secondary impingement syndromes when capsular laxity is present and increased muscular effort is necessary for stability.<sup>158</sup> Without this dynamic stability, the tissues in the subacromial space may become impinged as a result of faulty joint mechanics. There is also a relationship between muscle fatigue and joint position sense in the shoulder that may play a role in impaired performance in repetitive overhead activities.<sup>30</sup>

### Muscle Weakness Secondary to Neuropathy

Muscle weakness may be related to compromised nerve function. Long thoracic nerve palsy has been associated with faulty scapular mechanics due to serratus anterior muscle weakness, a movement dysfunction that may lead to rotator cuff impingement in the suprahumeral region.<sup>181</sup>

### Hypomobile Posterior GH Joint Capsule

Loss of extensibility in the posterior GH joint capsule may negatively alter humeral head translations. Increased superior translations during arm elevation are reported in studies that have experimentally tightened the posterior capsule, an effect that would decrease the available suprahumeral space.<sup>74</sup>

## Common Activity Limitations and Participation Restrictions

- In the acute stages, pain may interfere with sleep, particularly when rolling onto the involved shoulder.
- Pain with overhead reaching, pushing, or pulling.
- Difficulty lifting heavy loads.
- Inability to sustain repetitive shoulder activities (such as reaching, lifting, throwing, pushing, pulling, or swinging the arm).
- Difficulty with dressing, particularly putting a shirt on over the head.

## Management: Painful Shoulder Syndromes

**NOTE:** Even though symptoms may be “chronic” in terms of long standing or recurring, the initial treatment priority is to control inflammation if present.

## FOCUS ON EVIDENCE

A review of seven research articles that reported outcomes of conservative physical therapy interventions for full thickness rotator cuff tears found that the most successful treatment approaches were those that respected the stage of tissue healing and irritability of symptoms and progressed the program based on patient response (acute stage, subacute stage and reintegration to regular activities).<sup>88</sup>

## Management: Protection Phase

### Control Inflammation and Promote Healing

- Modalities and low-intensity cross-fiber massage are applied to the site of the lesion. While applying the modalities, position the extremity to maximally expose the involved region.<sup>41,45</sup>
- If necessary to rest the part, temporarily support the arm in a sling.

### Patient Education

The environment and habits that provoke the symptoms must be modified or avoided completely during this stage. The patient should be informed about the mechanics of the irritation and the anticipated recovery, and be given guidelines regarding safe exercises at this stage of healing.

### Maintain Integrity and Mobility of the Soft Tissues

- Passive, active-assistive, or self-assisted ROM is initiated in pain-free ranges.
- Multiple-angle muscle setting and protected stabilization exercises are initiated. When exercising the shoulder, it is particularly important to stimulate the stabilizing function of the rotator cuff, biceps brachii, and scapular muscles at an intensity tolerated by the patient.

**PRECAUTION:** Exercises during this stage must avoid the impingement positions. Often, the midrange of abduction, with internal rotation, or an end-range position when the involved muscle is on a stretch (such as putting the hand behind the back) provokes a painful response.

### Control Pain and Maintain Joint Integrity

Pendulum exercises without weights can be used to cause pain-inhibiting grade II joint distraction and oscillation motions (see Fig. 17.22 in the section on exercise).

### Develop Support in Related Regions

- Postural awareness and correction techniques are used. (See related information in the Interventions for Impaired Posture section in Chapter 14.)
- Supportive techniques, such as shoulder strapping or scapular taping, tactile cues, and mirrors, can be used for reinforcement. Repetitive reminders and practice of correct posture are necessary throughout the day.

### FOCUS ON EVIDENCE

In a randomized placebo-controlled, crossover study<sup>109</sup> of 120 subjects (60 with impingement and 60 asymptomatic), postural correction with tape resulted in a significant increase in pain-free shoulder flexion and scapular plane elevation for both groups of subjects. Thoracic and scapular taping for posture correction also resulted in less forward head posture, reduced thoracic kyphosis, less lateral scapular displacement, and a less elevated and forward scapula position in both groups when compared to the effects of placebo taping.

### Management: Controlled Motion Phase

After the acute symptoms are managed, the emphasis shifts to progressive movements within safe limits and using proper mechanics while the tissues heal. Individual components of desired functional movements are initiated in a controlled exercise program.<sup>44,45,190,217,218,223</sup> If there is functional laxity in the joint, the intervention is directed toward developing neuromuscular control and strength of both the scapula and GH joint stabilizers.<sup>95,180,201</sup> If there is restricted mobility that prevents normal mechanics or interferes with function, mobilization of the restricted tissue is initiated. Specific exercise techniques and progressions are described later in the chapter.

### Patient Education

Patient adherence to the program and protection of healing tissues are necessary in this stage. The home exercise program is progressed as the patient learns safe and effective execution of each exercise. Continue to reinforce proper postural habits.

### Develop Strong, Mobile Tissues

- Manual therapy techniques, such as cross-fiber or friction massage, can be used. The extremity is positioned so the tissue is on a stretch if it is a tendon or in the shortened position if it is in the muscle belly. The technique is applied using forces and durations that are to the tolerance of the patient.
- Following these manual techniques, the patient is instructed to perform an isometric contraction of the muscle in several positions of their available range. The intensity of contraction should not cause pain.
- The patient should be taught how to self-administer the massage and isometric techniques.

### Modify Joint Tracking and Mobility

MWM may be useful to modify joint tracking and reinforce full movement when there is restriction of shoulder elevation because of a painful arc or impingement.<sup>136</sup> (See Chapter 5 for a description of principles.)

- Posterolateral glide with active elevation** (Fig. 17.17 A)
  - Patient position:** Sitting with the arm by the side and head in neutral retraction.
  - Therapist position and procedure:** Stand on the side opposite the affected arm and reach across the patient's

torso to stabilize the scapula with the palm of one hand. The other hand is placed over the anteromedial aspect of the head of the humerus. Apply a graded posterolateral glide of the humeral head on the glenoid. Request that the patient perform the previously painful elevation. Maintain the posterolateral glide mobilization throughout both elevation and return to neutral. Ensure that no pain is experienced during the procedure. Adjust the grade and direction of the glide as needed to achieve pain-free function. Add resistance in the form of elastic resistance or a cuff weight to load the muscle.

- Self-Treatment.** A mobilization belt provides the posterolateral glide while the patient actively elevates the affected limb against progressive resistance to end-range (Fig. 17.17 B).

**FIGURE 17.17** MWM to modify GH joint tracking and improve active elevation. A posterolateral glide is applied to the humeral head (A) manually or (B) with a belt for self-treatment, while the patient actively elevates the humerus. A weight is used to strengthen the muscles through the pain-free range.

### Develop Balance in Length and Strength of Shoulder Girdle Muscles

It is important to design a program that specifically addresses the patient's impairments. Typical interventions in the shoulder girdle include but are not limited to:

- Stretch shortened muscles.** Shortened muscles typically include the pectoralis major, pectoralis minor, latissimus dorsi, teres major, subscapularis, and levator scapulae.
- Strengthen and train the scapulothoracic muscles.** Important scapular muscles typically include the serratus anterior and lower trapezius for posterior tilting and upward rotation of the scapula and the middle trapezius and rhomboids for scapular retraction. Because it is important that the patient avoid scapular elevation when raising the arm, emphasize maintaining scapular depression when abducting and flexing the humerus.
- Strengthen and train the rotator cuff muscles.** Place emphasis on the shoulder external rotators.

### Develop Muscular Stabilization and Endurance

- Alternating isometric resistance is applied to the scapular muscles in *open-chain positions* (side-lying, sitting, supine), including protraction/retraction, elevation/depression, and upward/downward rotation so the patient learns to stabilize the scapula against externally applied forces (see Fig. 17.37 in the exercise section).
- Scapular and GH patterns are combined using flexion, abduction, and rotation. Alternating isometric resistance is applied to the humerus while the patient holds against the changing directions of the external resistance force (see Figs. 17.38, 17.39, and 17.42 in the exercise section).
- *Closed-chain stabilization* is performed with the patient's hands fixated against a wall, a table, or the floor (quadruped position) while the therapist provides graded, alternating isometric resistance or rhythmic stabilization. If abnormal scapular winging occurs during the applied resistance, the scapular stabilizers are not strong enough for the demand and the position should be modified to reduce the challenge (see Fig. 17.43 in the exercise section). This can be accomplished by changing the patient's body position relative to gravity or modifying joint angles.
- *Muscular endurance* is progressed by increasing the amount of time the individual holds the pattern against the alternating resistance. The limit is reached when any one of the muscles in the pattern can no longer maintain the desired hold. The goal at this phase should be stabilization for approximately 3 minutes.

### Progress Shoulder Function

As the patient develops strength in the weakened muscles, it becomes important to develop a balance in strength of all shoulder and scapular muscles within the range and tolerance of each muscle. To increase coordination between scapular and arm motions, dynamically load the upper extremity with submaximal resistance as the patient maintains the synergy pattern. To improve muscular endurance, increase the length of time the patient controls the correct pattern up to 3 minutes.

### Management: Return to Function Phase

Specificity of training toward the desired functional outcomes begins as soon as the patient has developed control of posture and can perform the basic components of their desired activities without exacerbating the symptoms. While working with the patient, continue to teach him or her how to progress the program and prevent recurrences after discharged from therapy. Suggestions are summarized in Box 17.7.

### Increase Muscular Endurance

To increase muscular endurance, repetitive loading of the defined patterns is increased from 3 minutes to 5 minutes.

### Develop Quick Motor Responses to Imposed Stresses

- Apply the stabilization exercises with increased speed with shorter durations and faster transitions between the applied forces.

### BOX 17.7 Patient Instructions to Prevent Recurrences of Shoulder Pain

- Prior to exercise or work, massage the involved tendon or muscle; follow with isometric resistance and then with full ROM and stretching of the muscle.
- Take breaks from activities that are repetitive in nature. If possible, alternate the stressful, provoking activity with other activities or patterns of motion.
- Maintain good postural alignment; adapt seating or workstation to minimize stress. If sport related, seek coaching in proper techniques or adapt equipment for safe mechanics.
- Prior to initiating a new activity or returning to an activity for which not conditioned, begin a strengthening and training program.

- Plyometric training in both open-chain and closed-chain patterns is initiated if power is a desired outcome (refer to Chapter 23).

### Progress Functional Training

Specificity of training progresses to an emphasis on timing and sequencing of events.

- Eccentric training is progressed to maximum load.
- Desired functional activities are simulated—first under controlled conditions, then under progressively challenging conditions using acceleration/deceleration drills.
- The patient is involved in assessing performance in terms of safety, symptom provocation, postural control, and ease of execution and then practices adaptations to correct any identified problems.

## Painful Shoulder Syndromes: Surgery and Postoperative Management

Surgical intervention is an option for painful shoulder syndromes when conservative management does not resolve symptoms or improve function. For an individual with primary impingement as a result of structural variations in the acromion (see descriptions and Fig. 17.16 in the previous section), subacromial decompression may be performed. An individual with a partial- or full-thickness rotator cuff tear may require surgical repair of the tissue.

### Subacromial Decompression and Postoperative Management

When pain and loss of functional mobility associated with primary impingement/rotator cuff disease do not resolve sufficiently with nonoperative management, *subacromial*

*decompression* is often warranted. This procedure is designed to restore or increase the volume of the subacromial space and provide adequate gliding room for the cuff tendons. Subacromial decompression also is referred to as *anterior acromioplasty* or *decompression acromioplasty*. Acromioplasty, which alters the shape of the acromion, is typically, but not always, one component of subacromial decompression.<sup>126</sup>

### Indications for Surgery

The following are generally accepted indications for surgical management of impingement syndromes/rotator cuff disease.<sup>1,56,76,81,126,142,146,168,210</sup>

- Pain during overhead activities and loss of functional mobility of the shoulder as the result of primary impingement that persists (typically for 3 to 6 months or longer) despite a trial of nonoperative interventions.
- Stage II (Neer classification; see Box 17.5) impingement with nonreversible fibrosis or bony alterations of the subacromial compartment, calcific deposits in the cuff tendons, and symptomatic subacromial crepitus.
- Intact or minor tear of the rotator cuff.

**NOTE:** Patients who present with GH joint hypermobility or instability associated with a partial- or full-thickness tear of the rotator cuff are not candidates for surgical subacromial decompression alone. For these patients, subacromial decompression is combined with concomitant repair of the cuff tear; otherwise, the procedures inherent in subacromial decompression can worsen GH instability.<sup>76,126,210</sup>

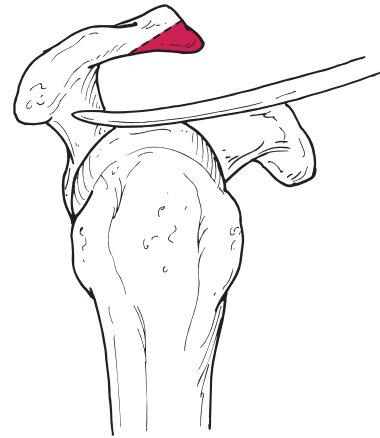

### Procedures

**Surgical approach.** Subacromial decompression is performed using an arthroscopic or open approach. Although an open approach has been used successfully for many years,<sup>81,139,142,168</sup> the preferred procedure today is an arthroscopic approach.<sup>56,210</sup> Unlike a traditional open approach, in which the proximal attachment of the deltoid must be detached and then repaired prior to closure,<sup>142</sup> the deltoid remains intact during an arthroscopic approach, which enables the patient to regain functional use of the upper extremity more rapidly after surgery. For the most part, the traditional open approach for subacromial decompression is now reserved for patients with a massive rotator cuff tear who are also undergoing an open repair. Another option preferred by some surgeons is a “mini-open” approach, which involves splitting the deltoid insertion vertically rather than detaching it.<sup>126</sup>

**Component procedures.** There are several surgical procedures that can be performed for subacromial decompression depending on the pathology observed during examination of the shoulder prior to or during surgery.<sup>1,56,71,76,126,153,210</sup>

- Removal of the subacromial bursa (*bursectomy*), which is typically thickened (enlarged) by chronic inflammation
- Release of the coracoacromial ligament, which is usually hypertrophied and may also be frayed, followed by complete or partial resection or recession

- Resection of the anterior acromial protuberance and contouring the undersurface of the remaining portion of the acromion (*acromioplasty*) to enlarge the subacromial space (Fig. 17.18)
- Removal of osteophytes at the AC joint and in some cases resection of the distal portion of the clavicle for advanced AC joint arthritis

**FIGURE 17.18** Arthroscopic acromioplasty showing the line of resection of the anterior acromion.

### Postoperative Management

The type of surgical approach used and the integrity of the rotator cuff significantly affect rehabilitation decisions after subacromial decompression. If the rotator cuff is intact preoperatively, rehabilitation after arthroscopic decompression progresses quite rapidly because the shoulder musculature is not damaged during the procedure. In contrast, if repair of a rotator cuff tear is required in addition to decompression, or a mini-open or open approach is used, rehabilitation progresses at a slower rate to allow the repaired shoulder musculature adequate time to heal.

**NOTE:** The guidelines outlined in this section are for postoperative rehabilitation after *arthroscopic* subacromial decompression for a patient with primary shoulder impingement who has an *intact rotator cuff*. If subacromial decompression is combined with repair of the rotator cuff, the guidelines presented in a later section of this chapter on rehabilitation after rotator cuff repair are appropriate.

#### Immobilization

Following surgery the shoulder is immobilized and supported in a sling with the arm positioned at the patient's side or in slight abduction and internal rotation, with the elbow flexed to 90°. The sling is worn for comfort for 1 to 2 weeks but is removed for exercise the day after surgery.<sup>126,210,219</sup>

#### Exercise Progression

Exercises after subacromial decompression focus on many of the impairments noted for rotator cuff impingement discussed previously in this chapter. This information merits

review to understand why specific exercises are included in the postoperative rehabilitation program. Because arthroscopic decompression is often performed on an outpatient basis, a patient may need to initially exercise at home with little supervision and then follow up with a series of outpatient therapy visits.

### Exercise: Maximum Protection Phase

The first phase of rehabilitation after arthroscopic decompression begins on the day after surgery and extends for 3 to 4 weeks. Emphasis is placed on pain control and immediate but comfortable assisted movement of the shoulder to prevent movement restrictions as soft tissues are healing. Attaining full or nearly full passive ROM of the involved shoulder is a reasonable goal by 4 to 6 weeks postoperatively.<sup>76</sup>

Patient education begins immediately and is directed toward helping the patient recognize and avoid postures that contribute to symptoms during exercise and ADL. Active (unassisted) shoulder ROM is permissible as soon as motions are pain-free and proper scapulothoracic and GH control can be maintained. This may be possible as early as 2 weeks postsurgery.

**Goals and interventions.** The following goals and exercises are indicated for the early stage of tissue healing:<sup>1,2,34,76,126,219</sup>

- **Control pain and inflammation.**
  - Use a sling when the arm is dependent.
  - Use cryotherapy and prescribed anti-inflammatory medication.
  - Shoulder relaxation exercises.
- **Prevent loss of mobility of adjacent regions.**
  - Active ROM of the cervical spine, elbow, wrist, and hand.
- **Develop postural awareness and control.**
  - Posture training, emphasizing cervical retraction, thoracic extension, scapula retraction, and a neutral lumbopelvic complex.
- **Restore pain-free shoulder mobility.**
  - Assisted shoulder ROM within pain tolerance, initially guiding the involved arm with the sound upper extremity and later with a cane or wand. Start in the supine position to stabilize the scapula against the thorax and place the upper arm on a folded towel in slight abduction and flexion. Shoulder motions include elevating the arm in the plane of the scapula, forward flexion, abduction, rotation, and horizontal abduction and adduction. Progress to performing exercises in a semi-reclining position and then in a seated or standing position while maintaining thoracic extension.
  - Assisted shoulder extension in a standing position with a wand held behind the back.
  - Stretching the posterior shoulder structures in pain-free range using a cross-chest stretch into horizontal adduction. Postpone until next phase if painful.
  - Active ROM (unassisted) of the shoulder and scapula within pain-free ranges, maintaining proper scapulothoracic and GH control; begin supine and progress to sitting. Active shoulder motions may be possible by 2 weeks postoperatively.

- **Prevent reflex inhibition and disuse atrophy of shoulder girdle musculature.**

- *Pain-free*, low-intensity, multiple-angle isometrics of GH musculature with the arm supported and emphasis on the rotator cuff against minimal resistance. Begin submaximal isometrics a week or so postoperatively. Lightly resist with the uninvolved upper extremity. Focus on increasing repetitions more than resistance.<sup>114,181</sup>
- Submaximal alternating isometric and rhythmic stabilization exercises for scapulothoracic muscles with the involved arm supported by the therapist. Target the scapular retractors and upward rotators.

**Criteria to progress.** Criteria to advance to the second phase include:<sup>34,76,98,126,219</sup>

- Minimal discomfort when the shoulder is unsupported; arm swing during ambulation is comparable to opposite arm.
- Almost full, pain-free, *passive* ROM of the shoulder (full mobility of the scapula; at least 150° of arm elevation; full internal/external rotation).
- In the supine position, pain-free *active* elevation of the arm well above the level of the shoulder.
- Pain-free, *active* external rotation of the shoulder to about 45°.
- At least fair (3/5) and preferably good (4/5) muscle testing grade of shoulder musculature.

### Exercise: Moderate Protection Phase

Exercises during the second phase of rehabilitation are focused on attaining full, pain-free shoulder ROM and improving neuromuscular control and muscle performance of the rotator cuff, scapular stabilizers, and prime movers. The patient may be ready to begin this phase of rehabilitation as early as 3 to 4 weeks postoperatively but more often by 4 to 6 weeks. This phase extends over a 4- to 6-week period or until the patient meets the criteria to progress to the next phase.

**Goals and interventions.** The goals, exercises, and activities during the second phase of rehabilitation are:<sup>34,76,98,219</sup>

- **Restore and maintain full, pain-free passive mobility of the shoulder girdle and upper trunk.**
  - Joint mobilization emphasizing posterior and caudal glides of the humerus and scapulothoracic mobility.
  - Low-intensity self-stretching of muscles that could restrict sufficient upward rotation of the scapula and rotation of the humerus, specifically the levator scapulae, rhomboids, subscapularis, latissimus dorsi, teres major, and pectoralis major and minor. Recall that tightness of these muscles may contribute to subacromial impingement during overhead movements of the arm.
  - Self-stretching of the posterior shoulder muscles and posterior capsule of the GH joint, as these structures may be tight in the presence of shoulder impingement.
  - Self-stretch the upper trunk and thoracic extension by lying supine on a rolled towel placed vertically between the scapulae.
  - Perform exercises and functional movement patterns into the acquired ROM.

- **Reinforce posture awareness and control.**
  - Continue to emphasize cervical, thoracic, and lumbo-pelvic alignment during exercises and function.
- **Develop dynamic stability, strength, endurance, and control of scapulothoracic and GH muscles.**
  - Stabilization exercises against increasing resistance and in weight-bearing positions. Emphasize isolated strengthening of the serratus anterior and trapezius muscles.
  - Upper extremity ergometry for muscular endurance. To avoid an impingement arc, initiate in a standing position rather than while seated.
  - Dynamic strengthening exercises of isolated shoulder muscles against low-loads (1- to 5-lb weight or light-grade elastic tubing), gradually increasing repetitions. Begin resisted elevation of the arm in the supine position to stabilize the scapula against the thorax; progress to sitting or standing.
  - Use the involved arm for functional activities that involve light resistance.

### CLINICAL TIP

Target the upward rotators of the scapulothoracic joint (serratus anterior, upper and lower trapezius) and the rotator cuff muscles<sup>184</sup> as well as the latissimus dorsi, teres major, and biceps brachii, which act as humeral head depressors and therefore oppose superior translation during active elevation of the arm. Initially, perform resisted motions of the humerus below the level of the shoulder; later, progress to overhead exercises if motions remain pain free.

**PRECAUTION:** Be certain the patient can perform active shoulder flexion and abduction against gravity without elevating the scapula before progressing to resisted exercises above shoulder level.

**Criteria to progress.** The criteria to progress to the final phase of rehabilitation are:<sup>34,98,219</sup>

- Negative provocation tests.
- Full, pain-free, active ROM of the shoulder without evidence of substitute motions.
- At least 75% strength of the shoulder musculature compared with the sound shoulder.<sup>219</sup>

### Exercise: Minimum Protection/Return to Function Phase

The final phase of rehabilitation usually begins 8 weeks postoperatively when soft tissues are reasonably well healed and require little to no protection. Exercises continue until about 12 to 16 weeks postoperatively or until the patient has returned to full activity. Exercises are directed toward improving strength and endurance of the shoulder girdle muscles using isolated movements and those that simulate functional activities. Patients often see continued improvement

in functional use of the operated upper extremity for 6 months postoperatively.<sup>2</sup>

The time necessary for full recovery and unrestricted activities depends largely on the level of demand of the patient's anticipated activities. A patient wishing to return to competitive sports requires a more demanding progression of advanced exercises (e.g., plyometric training and sport-specific drills) than a sedentary individual.<sup>34,219,222</sup>

**Goals and interventions.** The goals, exercises, and activities during the final phase of rehabilitation after subacromial decompression are similar to the final phase of nonoperative management of primary impingement syndrome. Refer to the information presented in the previous section of this chapter as well as other resources.<sup>34,45,217,219,222</sup>

### Outcomes

There appears to be no significant difference in the long-term results (pain-free ROM and return to desired functional activities) after either open or arthroscopic surgery for primary impingement syndrome with or without associated rotator cuff disease.<sup>56,126,210</sup> Based on the results of numerous outcome studies of open and arthroscopic procedures, 85% to 95% of patients report good to excellent results 1.0 to 2.5 years postoperatively.<sup>1,76,126,210</sup> In general, patients reporting the least satisfaction with their function after surgery are those who participate in high-demand athletic activities that involve overhead throwing and those with work-related injuries who are receiving workers' compensation.<sup>126</sup>

Several studies have documented advantages of an arthroscopic procedure rather than open surgical management of rotator cuff disease. Advantages include less postoperative pain, earlier restoration of full ROM and strength, earlier return to work (often as early as 1 week postoperatively), lower cost (shorter hospital stay or outpatient surgery), and a more favorable cosmetic result.<sup>1,76,126,210</sup>

Although exercises are routinely prescribed after subacromial decompression, the effectiveness of exercise has been the focus of very few studies. One prospective, randomized study compared the effectiveness of a 6-week therapist-supervised exercise program to a self-managed program after arthroscopic subacromial decompression.<sup>2</sup> Patients in the therapist-supervised group received exercise instruction while in the hospital and then for a 1-hour therapy session once a week for 6 weeks after discharge. Patients in the self-managed group received exercise instruction on one occasion prior to discharge from the hospital. Both groups received written instructions. At 6 weeks and at 3, 6, and 12 months, there were no significant differences in outcomes between the two groups with the exception of one variable. At 3 months postoperatively, the therapist-supervised group had a higher level of pain than the self-managed group. The authors concluded that initial, therapist-directed exercise instruction followed by a home-based, self-managed exercise program achieved rehabilitation goals as effectively as a therapist-supervised program.

## Rotator Cuff Repair and Postoperative Management

Rotator cuff tears are broadly categorized as either partial-thickness or full-thickness tears. Either type may require surgical management. A *partial-thickness tear* extends inferiorly or superiorly through only a portion of the tendon from either the acromial (bursal) or humeral (articular) surface of the tendon. A *full-thickness tear* is a complete tear, extending between the superior and inferior surfaces of the tendon.<sup>76,83,126</sup> Both types of tears can be oriented either parallel to or perpendicular to the primary orientation of the tendon fibers.

### Indications for Surgery

The primary indications for surgical management of a rotator cuff tear confirmed by imaging are pain and impaired function as the result of the following:<sup>5,76,83,126,159,210,231</sup>

- Partial-thickness or full-thickness tears of the rotator cuff tendons with irreversible, degenerative changes in soft tissues. Some patients with Neer stage II lesions and most with Neer stage III lesions who continue to be symptomatic and have functional limitations after a trial of nonoperative treatment are candidates for surgery.
- Acute, traumatic rupture of the rotator cuff tendons that may be combined with avulsion of the greater tuberosity, labral damage, or acute dislocation of the GH joint in individuals with no known history of prior cuff injury. Full-thickness, traumatic tears occur most often in young, active adults.

**NOTE:** Surgical repair is not indicated in patients who are asymptomatic despite the presence of a cuff tear confirmed by imaging.

### Procedures

There are several operative options for repairing a torn rotator cuff, including arthroscopic, open, and mini-open repairs.<sup>64,76,78,126,210</sup> The decision about which procedure to choose depends on the severity and location of the tear, the number of tendons involved, the extent of associated lesions, the type of onset (repetitive microtrauma or traumatic injury), the quality and mobility of the torn tissues, bone quality, patient-related considerations (age, health, activity level), and the surgeon's preference and training.

#### Type of Repair

The type of cuff repair is typically classified by the surgical approach and techniques used. There are three categories of repair:<sup>5,62,63,64,76,126,191,210,231</sup>

- **Arthroscopic approach.** The entire procedure is performed arthroscopically and requires only a few small skin incisions for inserting surgical instruments.
- **Mini-open (arthroscopically assisted) approach.** There are two variations of this type of procedure, both of which involve arthroscopic subacromial decompression and a *deltoid-splitting* approach. In one variation, only the subacromial

decompression is performed arthroscopically, whereas in the other variation a portion of the cuff repair itself is also performed arthroscopically.<sup>231</sup> In both cases, an anterolateral incision is made at the acromion and is extended distally (either 1.5 or 3.5 cm but no more than 4 cm to avoid the axillary nerve) along the fiber orientation of the deltoid. The deltoid is split longitudinally between its anterior and middle portions to allow visualization of the cuff tear without detaching the deltoid from its proximal insertion.<sup>58,64,126,159,199</sup>

- **Traditional open approach.** An anterolateral incision is made that extends obliquely from the middle one-third of the inferior aspect of the clavicle, across the coracoid process, and to the anterior aspect of the proximal humerus. The proximal insertion of the deltoid must be detached and reflected for exposure of the operative field during an open subacromial decompression and cuff repair. After the cuff repair is complete, the deltoid is reattached to the acromion.<sup>64,83,126</sup> As arthroscopic and arthroscopically assisted repair techniques have advanced, the use of this traditional open approach has decreased.

### Components of a Rotator Cuff Repair

Regardless of the approach, subacromial decompression is performed (particularly for cuff tears associated with chronic impingement) before repair of the cuff is undertaken. After the tear is visualized, the margins of the torn tendon are débrided and released from any adherent soft tissues. The cuff tendon is then mobilized for advancement and apposition to bone that has been prepared for sutures and attached by *tendon-to-bone* fixation. Depending on whether an arthroscopic or mini-open approach is used, fixation is accomplished by sutures and suture anchors, tacks, or staples.<sup>58,62,76,126,198,210</sup>

In addition to subacromial decompression, other concomitant procedures may be required during the procedure. For example, capsular tightening or labral reconstruction may be performed if unidirectional or multidirectional instability of the GH joint is present. Because degenerative changes in the tendon of the long head of the biceps brachii are often “associated with chronic rotator cuff disease, a repair of this tendon also may be necessary.

### Selection of Surgical Procedures

The surgeon weighs many factors when determining which type of procedure is most appropriate for each patient. One such consideration is the severity of the tear, including thickness (partial or full), size, and number of tendons torn. Although there is some variability in the literature, there are four generally accepted categories that describe the longitudinal size of rotator cuff tears: *small* (1 cm or less), *medium* (1 to 3 cm), *large* (3 to 5 cm), and *massive* (more than 5 cm or a full-thickness tear of more than one tendon).<sup>5,58,76,212</sup>

A small, *partial-thickness* cuff tear is usually managed surgically with a fully arthroscopic approach to débride the frayed margins of the torn tendon and includes a subacromial decompression. The torn portion of the tendon may or may not be repaired.<sup>5,76,126,191,198,210</sup>

Historically, small and medium *full-thickness* cuff tears only were managed with a fully arthroscopic approach.<sup>63,76,126</sup> With the advancement of arthroscopic techniques, however, an increasing percentage of large, full-thickness tears and some massive tears are now also managed with a fully arthroscopic approach.<sup>210,231</sup> Despite these surgical advances, variations of the mini-open (deltoid splitting) approach often remain the surgeon's choice for repair of medium and large tears.<sup>58,126,199</sup> Even some massive tears are managed with a deltoid-splitting approach.<sup>126,212</sup> The traditional open approach, requiring detachment and repair of the deltoid, is now primarily reserved for repairs of multiple tendon tears associated with extensive injury to the shoulder.<sup>58,126</sup>

The location of the cuff tear, amount of retraction and mobility of a full-thickness tear, and the quality of the remaining tendon and underlying bone also influence the surgeon's selection of the procedure expected to be most effective.<sup>76,126,198,210</sup>

Whereas small, medium, and large tears of the supraspinatus or infraspinatus are routinely managed with arthroscopic or mini-open approaches, tears of the subscapularis are often managed with a traditional open approach.<sup>58</sup> Also, with poor tissue quality or significant retraction and limited mobility of the torn tendon, many surgeons believe that a stronger repair can be achieved with an open procedure instead of an arthroscopic repair.<sup>76</sup>

### Postoperative Management

After surgical repair of a torn rotator cuff tendon, many factors influence decisions about the position and duration of immobilization, the selection and application of exercises, and the rate of progression of each patient's rehabilitation program. These factors and their potential impact are summarized in Table 17.3. These factors also will affect postoperative prognosis and outcomes.

**TABLE 17.3** Factors That Influence Progression of Rehabilitation After Repair of the Rotator Cuff

Factors	Potential Impact on Rehabilitation
■ Onset of injury	■ Chronic impingement and atraumatic cuff deficiency → slower progression than after acute traumatic injury
■ Size and location of the tear	■ Larger tears with more tendons involved → slower progression
■ Associated pathologies such as GH instability or fracture	■ More involved surgeries and potential for longer period of immobilization → slower progression of exercises or the need for additional precautions
■ Preoperative strength and mobility of the shoulder	■ Preexisting weakness and atrophy of the dynamic stabilizers or limited passive and active mobility of the shoulder → slower postoperative progression
■ Patient's general health	■ Patient in poor health; history of smoking; history of inflammatory disease → slower progression
■ History of steroid injections or previous, failed cuff surgery	■ Compromised bone and tendon tissue quality, which affects the security of the repair (fixation) → slower progression
■ Pre-injury level of activity or postoperative goals	■ Higher level activities increase risk of re-injury → a more extended and advanced postoperative training program
■ Age of patient	■ Older patient → slower progression more likely
■ Type of surgical approach	■ Traditional open approach (with deltoid detachment and repair) → slightly slower progression than after an arthroscopic or arthroscopically assisted (mini-open/deltoid splitting) repair
■ Type of repair	■ Tendon to tendon → slower progression than tendon to bone
■ Mobility (no excessive tension on the repaired tendon when arm at side) and integrity of the repair	■ If mobility is inadequate → longer duration of exercise within a protected ROM during early rehabilitation
■ Patient's compliance with the program	■ Lack of compliance (doing too much or too little) can affect outcome
■ Philosophy, skill, and training of the surgeon	■ All may have an impact that could → either slower or more accelerated progression

There is little consensus in the literature or in clinical practice as to how and to what extent each of these factors, singularly or collectively, impacts the decisions made by the surgeon and the therapist about a patient's postoperative rehabilitation program. Hence, predetermined guidelines and protocols for postoperative management after rotator cuff repair are diverse and sometimes contradictory.<sup>5,34,53,55,58,64,76,126,208</sup> For example, some authors suggest that if deltoid detachment and repair are components of the surgery deltoid strengthening exercises should be postponed for approximately 6 to 8 weeks postoperatively until the repaired deltoid has healed.<sup>34,55,126</sup> In contrast, another author suggests that rehabilitation should proceed similarly regardless of whether deltoid detachment was required so long as secure fixation of the deltoid was achieved.<sup>74</sup>

Given the diverse characteristics of patients undergoing rotator cuff repair and the variety of surgical options available, it is not surprising that no single postoperative program can be used for all patients or yields better outcomes than other programs. Therefore, to meet each patient's needs and goals, a therapist can use published protocols or those developed at individual clinical facilities as general guidelines for postoperative management. Modifications to protocols and guidelines should be made based on ongoing examination of the patient's response to interventions and through communication with the surgeon.

Despite variations among postoperative programs, they share three common elements: (1) immediate or early postoperative motion of the GH joint; (2) control of the rotator cuff for dynamic stability; and (3) gradual restoration of strength and muscular endurance. This section will present *general* exercise guidelines that incorporate these elements into the phases of rehabilitation after arthroscopic or mini-open repair of a *full-thickness* cuff tear. Potential modifications and precautions due to a traditional open procedure or on factors such as size, location of the tear, and the quality of the repair will be noted.

**NOTE:** The goals, exercise interventions, and progression of rehabilitation after débridement rather than repair of a *partial-thickness* tear are comparable to postoperative management after subacromial decompression for cuff impingement presented in the previous section of this chapter.

### Immobilization

The position and duration of immobilization of the operated shoulder after rotator cuff repair depends on many factors, including the size, severity, and location of the tear and the type and quality of the repair. The size of the cuff tear partially determines whether the patient's operated arm is supported in a sling (shoulder adducted, internally rotated, and elbow flexed to 90°) or in an abduction orthosis or splint (shoulder elevated in the plane of the scapula approximately 45°, shoulder internally rotated, and elbow flexed). Patients supported in an abduction splint may require assistance from a family member to support the operated arm in the 45° shoulder position when the splint is removed for exercise, dressing, or bathing.

Table 17.4 summarizes the immobilization recommendations for fully arthroscopic and mini-open/deltoid-splitting approaches. Immobilization after a traditional open procedure that involves deltoid detachment and repair is not included in Table 17.4 because of the variations in guidelines reported in the literature.<sup>34,76,126,212</sup>

The rationale for initially immobilizing the shoulder in abduction is based on two principles. In the abducted position, the shoulder is in a more relaxed, neutral position, reducing the possibility of reflexive muscle contractions that could disrupt the repairs. In addition, supporting the arm in abduction reduces tension on the repaired tendons and may also improve blood flow to the repair site.

### Exercise Progression

Regardless of whether a patient undergoes a rotator cuff repair on an inpatient or outpatient basis, contact with a therapist for exercise instruction after surgery is usually limited to a few visits. Therefore, the emphasis of a therapist's interaction with a patient must be placed on patient education for an effective and safe home-based exercise program.

Goals and interventions for each phase of rehabilitation after arthroscopic or mini-open cuff repair follow. General guidelines for exercise and precautions after rotator cuff repair are summarized in Box 17.8. Precautions specific to a particular type of cuff tear or surgical procedure are also noted. The suggested timelines for each phase are general and must be adjusted based on factors already noted (see Table 17.3).

**TABLE 17.4** Relationships between the Size of the Rotator Cuff Tear With the Type and Duration of Immobilization After Arthroscopic and Mini-Open Repair\*

Size of Tear	Type and Duration of Immobilization
Small ( $\leq 1$ cm)	Sling for 1–2 weeks; removal for exercise the day of surgery or 1 day postop
Medium to large (1 cm to 5 cm)	Sling or abduction orthosis/pillow for 3–6 weeks; removal for exercise 1–2 days postop
Massive ( $> 5$ cm)†	Sling or abduction orthosis/pillow for 4–8 weeks; removal for exercise 1–3 days postop

\*Fully arthroscopic and mini-open (arthroscopically assisted/deltoid splitting) approaches.

†A fully arthroscopic approach is not often used to repair massive cuff tears.

### BOX 17.8 General Exercise Guidelines and Precautions Following Repair of a Full-Thickness Rotator Cuff Tear

#### Early Shoulder Motion

- Perform passive or assisted shoulder ROM within *safe and pain-free ranges* based on the surgeon's intraoperative observation of the mobility and strength of the repair, a prescribed postsurgical protocol, and the patient's comfort level during exercise.
- Only passive ROM for 6 to 8 weeks after repair of a massive cuff tear or after a traditional open approach to prevent avulsion of the repaired deltoid.
- Initially perform passive and assisted shoulder ROM in the supine position to maintain stability of the scapula on the thorax.
- Minimize anterior and superior translations of the humeral head and the potential for impingement. Position the humerus slightly anterior to the frontal plane of the body and in slight abduction.
- While at rest in the supine position, support the distal humerus on a folded towel.
- When initiating passive or assisted shoulder rotation while lying supine, position the shoulder in slight flexion and approximately 45° of abduction.
- When initiating assisted shoulder extension, perform the exercise in prone position (arm over the edge of the bed) from 90° to just short of neutral. Later progress to exercises behind the back.
- When performing assisted or active exercises in the upright position (sitting or standing), be certain that the patient maintains an erect trunk posture to minimize the possibility of impingement.
- To ensure adequate humeral depression and avoid superior translation of the head of the humerus when beginning *active* elevation of the arm, restore strength in the rotator cuff, especially the supraspinatus and infraspinatus muscles, before dynamically strengthening the shoulder flexors and abductors.
- Do not allow *active* shoulder flexion or abduction until the patient can lift the arm without hiking the shoulder.

#### Strengthening Exercises

- When beginning isometric resistance to scapulothoracic musculature, be sure to support the operated arm to avoid excessive tension in repaired GH musculature.

- Use low exercise loads; resisted motions should not cause pain.
- No weight-bearing (closed-chain) exercises or activities for 6 weeks.
- Delay dynamic strengthening (progressive resistive exercise) for a *minimum* of 8 weeks postoperatively for small, strong repair and for at least 3 months for larger tears.
- If the supraspinatus or infraspinatus was repaired, proceed cautiously when resisting GH joint external rotation.
- If the subscapularis was repaired, proceed cautiously with resisted GH joint internal rotation.
- After an open repair, postpone isometric resistance exercises to the repaired deltoid and cuff musculature for *at least* 6 to 8 weeks unless advised otherwise.

#### Stretching Exercises

- Avoid vigorous stretching, the use of contract-relax procedures, or grade III joint mobilizations for at least 6 weeks and often for 12 weeks postoperatively to give time for the repaired tendon(s) to heal and become strong.
- If the supraspinatus or infraspinatus was repaired, initially avoid end-range stretching into GH joint internal rotation.
- If the subscapularis was repaired, initially avoid end-range stretching into GH joint external rotation.
- If the deltoid was detached and repaired, initially avoid end-range shoulder extension, adduction, and horizontal adduction.

#### Activities of Daily Living

- Wait until about 6 weeks after a mini-open or arthroscopic repair and 12 weeks after a traditional open repair before using the operated arm for light functional activities.
- After repair of a large or massive cuff tear, avoid use of operated arm for functional activities that involve heavy resistance (pushing, pulling, lifting, carrying heavy loads) for 6 to 12 *months* postoperatively.

#### Exercise: Maximum Protection Phase

The priorities during the initial phase of rehabilitation are to protect the repaired tendon, which is at its weakest approximately 3 weeks after repair,<sup>198</sup> and to prevent the potential adverse effects of immobilization. For almost all patients, the immobilization device is removed for brief sessions of passive or assisted ROM within protected and comfortable ranges during the first few days after surgery (see Table 17.4).

The maximum protection phase extends for 3 to 4 weeks after a fully arthroscopic or mini-open repair of small or medium tears to as long as 6 to 8 weeks after repair of large

or massive tears. After an arthroscopic repair of a small or medium tear, every effort is made to attain nearly full passive shoulder ROM, particularly elevation and external rotation, by 6 to 8 weeks postoperatively.<sup>58,126,210</sup>

**Goals and interventions.** The following goals and selected interventions are initiated during the maximum protection phase.<sup>5,34,53,55,64,76,126,210,212</sup>

- **Control pain and inflammation.**
  - Periodic cryotherapy.
  - Arm support for comfort.

- Shoulder relaxation exercises.
- Grade I oscillations of the GH joint.
- Use of medically prescribed medications.
- **Prevent loss of mobility of adjacent regions.**
  - Assisted ROM of the elbow.
  - Active ROM of the cervical spine, wrist, and hand.
  - Active scapulothoracic elevation/depression and protraction/retraction.
- **Prevent shoulder stiffness/restore shoulder mobility.**
  - Pendulum exercises typically the first postoperative day or when the immobilizer may be removed for exercise. Emphasize using the correct technique and keeping the shoulder muscles relaxed.
  - Passive ROM of the shoulder within safe and pain-free ranges. Initially perform exercises in the supine position; begin both arm elevation and external rotation in the plane of the scapula.
  - Self-assisted ROM using the opposite hand or a wand by 1 to 2 weeks for patients with repairs of small to medium tears and about 2 weeks later for patients with repair of large tears.
  - Active control of the shoulder with assistance as needed from the therapist or family members. With the patient lying supine, place the arm in 90° of shoulder flexion if pain free. In this position, the effect of gravity on the shoulder musculature is minimal. This position has been called the “balance point position” of the shoulder.<sup>53</sup> Help the patient control the shoulder while moving to and from the balance point position, making small arcs and circles with the arm.
  - Active shoulder ROM by the latter part of this phase for small tears and as symptoms permit, initially supine with the elbow flexed, progressing to a semi-reclining position with the elbow less flexed.

**PRECAUTION:** Use only passive, non-assisted ROM for 6 to 8 weeks for a repair of a massive cuff tear or after a traditional open repair with deltoid detachment.<sup>34,212</sup>

- **Prevent or correct postural deviations.**
  - Posture training and exercises to facilitate proper spinal alignment and shoulder retraction (see Chapters 14 and 16).
- **Develop control of scapulothoracic stabilizers.**
  - Active movements of the scapula.
  - Submaximal isometrics to isolated scapular muscles.<sup>114</sup> To avoid excessive tension in repaired GH musculature, see that the operated arm is supported but not bearing weight.
  - Side-lying scapular protraction/retraction to facilitate serratus anterior function.
- **Prevent inhibition and atrophy of GH musculature.**
  - Low-intensity, muscle-setting exercises against minimal resistance. Setting exercises should not provoke pain in a healing cuff tendon. Begin as early as 1 to 3 weeks postoperatively depending on the size of the tear and quality of the repair.<sup>34,53,55</sup>

**PRECAUTION:** Recommendations for the safest position of the shoulder in which to begin isometric training of the GH musculature after cuff repair are inconsistent. Perhaps the safest suggestion is to start in a position that creates minimal tension on the repaired cuff tendons (shoulder internally rotated and elevated in the scapular plane to about 45°, elbow flexed).<sup>55</sup> As the strength of the cuff muscles improves during the later phases of rehabilitation, exercises and activities can be performed with the arm positioned in more challenging and functional positions.

**Criteria to progress.** Criteria to advance to the second phase include:

- A well healed incision.
- Minimal pain with assisted shoulder motions.
- Progressive improvement in ROM.

### Exercise: Moderate Protection Phase

The focus of the second phase of rehabilitation is to develop neuromuscular control, strength, and endurance of the shoulder while continuing to attain full or nearly full, pain-free shoulder motion. Emphasis is placed on developing control of the scapulothoracic and rotator cuff muscles.

For the patient with repair of a small or medium tear, this phase begins around 4 to 6 weeks postoperatively and extends an additional 6 weeks. For most patients, strengthening exercises typically begin around 8 weeks postoperatively. This phase may begin as late as 12 weeks for the patient with repair of a large or massive tear.

### FOCUS ON EVIDENCE

Thomson et al<sup>193</sup> performed a systematic review of eleven RCT's comparing the effectiveness of postoperative rehabilitation protocols following rotator cuff repair. Six studies evaluated the effect of early ROM exercises and found some evidence for improved outcomes early in recovery with no detrimental long-term outcomes. With small to moderate tears and good fixation, passive ROM can begin one day following surgery, with active ROM started several days later. Patients with larger tears and additional factors such as poor tissue quality, systemic disease, or sedentary lifestyle should delay passive ROM for 4 to 6 weeks and wait to being active ROM until 6 to 8 weeks following surgery. CPM use is safe following surgery and may facilitate short-term pain relief and reduce postoperative stiffness, but does not offer any long-term benefit on outcomes.

**Goals and interventions.** The following goals and interventions are appropriate during this phase of rehabilitation.<sup>5,34,53,55,58,126</sup>

- **Restore nearly complete or full, pain-free, passive mobility of the shoulder.**
  - Self-assisted ROM with an end-range hold by means of wand or pulley exercises, in single planes and combined

(diagonal) patterns. Add shoulder internal rotation, extension beyond neutral, and horizontal adduction.

- Mobilization of the incision site if well healed to prevent adherence of the scar.

**PRECAUTION:** The use of passive stretching and grade III joint mobilizations, if initiated during this phase of rehabilitation, must be done *very cautiously*. Vigorous stretching is not considered safe for 3 to 4 months, the time needed for the repaired tendons to have healed and become reasonably strong.<sup>126</sup>

■ **Increase strength and endurance and re-establish dynamic stability of the shoulder musculature.**

- Active ROM of the shoulder through gradually increasing the pain-free ranges. Continue to have the patient perform active elevation of the arm in the supine position until the motion can be initiated without first elevating the scapula. When transitioning to upright positions (sitting or standing), reinforce the importance of maintaining an erect trunk during exercises.
- Isometric and dynamic strengthening to scapulothoracic muscles. First, use alternating isometrics in non-weight-bearing positions; then progress to rhythmic stabilization during light upper extremity weight-bearing activities.
- Submaximal multiple-angle isometrics of the rotator cuff and other GH musculature against gradually increasing resistance.
- Dynamic strengthening and endurance training of the GH musculature within pain-free ranges against light resistance, such as light-grade elastic tubing or a 1- to 2-lb weight. Perform exercises below the level of the shoulder if pain is provoked with active movements above shoulder height.
- Upper extremity ergometry at or just below shoulder height against light resistance to increase muscular endurance.
- Use of the involved upper extremity for *light* (no-load or low-load) functional activities.

### CLINICAL TIP

Because weakness and atrophy of the rotator cuff often are present prior to injury, strengthen and increase endurance of the cuff muscles before dynamically strengthening the shoulder abductors and flexors.

**Criteria to progress.** Criteria to transition to the final phase of rehabilitation and gradually return to unrestricted activities include:

- Full, pain-free passive ROM.
- Progressive improvement of shoulder strength and muscular endurance.
- A stable GH joint.

### Exercise: Minimum Protection/Return to Function Phase

This final phase usually begins no earlier than 12 to 16 weeks postoperatively for patients with strong repairs or at 16 weeks or later for a more tenuous repair. This phase may continue 6 months or more depending on the patient's expected activities.

**Goals and interventions.** The goals and interventions during this final phase of rehabilitation are consistent with those previously discussed for late-stage nonoperative management of cuff disorders and for the final phase of rehabilitation after subacromial decompression. However, the progression of activities after a cuff repair is more gradual, and the time frame for adhering to precautions is extended.

If full ROM still has not been restored by the beginning of this phase, include passive stretching of the GH musculature and joint mobilization. Incorporate activities that move the arm into the increased ROMs, such as gently swinging a golf club or tennis racket if the motions are pain free. Advanced, task-specific strengthening activities dominate this phase of rehabilitation.

Patients are generally not allowed to return to high-demand activities for 6 months to 1 year postoperatively, depending on the patient's level of comfort, strength, and flexibility as well as the demands of the desired activities.

### Outcomes

A considerable number of outcome studies of operative management of rotator cuff tears have been reported in the literature with follow-up ranging from less than 6 months to 5 years or more. Outcomes commonly measured include pain, shoulder ROM and strength, overall function, and patient satisfaction.

Long-term outcomes after fully arthroscopic, mini-open, and traditional open repairs are comparable.<sup>76</sup> For example, after fully arthroscopic repair of full-thickness tears (mostly small or medium but some large or massive tears), overall outcomes of several studies were reported as good to excellent in 84%<sup>62,63</sup> and 92%<sup>191</sup> of patients followed for 2 to 3 years. These results are comparable to results reported for open repairs.<sup>76,126</sup> However, it has been shown that regardless of the type of operative repair performed, the size of the cuff tear influences postoperative outcomes. For example, comparably favorable long-term functional outcomes and pain relief have been reported after mini-open and traditional open repairs of small to medium-sized, full-thickness tears,<sup>7,76,126</sup> while outcomes are less favorable after repairs of large or massive tears.<sup>126,212</sup>

Other factors, such as the acuity or chronicity of the tear and the patient's age also affect outcomes. Repairs of acute tears in young patients are more successful than repairs of similar size tears associated with chronic cuff impingement and insufficiency in elderly patients (>65 years).<sup>71</sup> The presence of fewer associated pathologies, such as a biceps tendon tear or cuff tear arthropathy, also are associated with better postoperative outcomes.<sup>126</sup>

**Pain relief.** Although the results of individual studies vary, a systematic review of the literature indicated that an average of

85% of patients who have operative repair of the rotator cuff report satisfactory relief of pain. Pain relief after arthroscopic and mini-open repairs ranges between 80% and 92%.<sup>174</sup> This is comparable to results of previous studies of traditional open repairs, in which satisfactory pain relief was reported by 85% to 95% of patients.<sup>75,83</sup> The preoperative size of the tear has an impact on pain relief with patients having small and medium tears reporting a higher percentage of satisfaction with pain relief than patients with large or massive tears.<sup>75,126,174</sup>

**Shoulder ROM.** In a prospective descriptive study of patients undergoing rotator cuff repair, the preoperative factor that most closely correlated with long-term limitation of shoulder ROM after surgery was the inability to place the hand behind the back.<sup>203</sup> Postoperative shoulder ROM is also associated with the size of the tear, with one study demonstrating that patients who had repairs of small to medium tears had more active flexion and abduction than patients with large tears.<sup>83</sup>

**Strength.** The rate of recovery of shoulder muscle strength also appears to be associated with the size of the tear, with faster recovery occurring with repair of small and medium tears than with repair of large or massive tears. Near-complete restoration of shoulder muscle strength occurs gradually and may take a year after repair of small and medium tears, while recovery of strength after repair of large or massive tears is inconsistent.<sup>126,174</sup> Although recovery of shoulder muscle strength occurs gradually throughout the first postoperative year, the most substantial gains are seen during the first 6 months.<sup>126</sup> In most cases, patients achieve 80% strength in the operated shoulder (compared to the noninvolved shoulder) by 6 months and 90% strength by 1 year.<sup>171</sup>

**Functional abilities.** It appears that long-term functional outcomes correlate with the size of the tear, type of repair, tissue quality, and the integrity of the repair.<sup>126</sup> For example, patients who have undergone a mini-open repair return to functional activities about a month earlier than those who have had an open repair.<sup>7</sup> However, this outcome may be skewed by the fact that mini-open repairs are performed more often in younger patients with less severe tears.

Lastly, in those patients who present with recurrence of a rotator cuff tear after repair, 80% had good to excellent short-term objective functional outcomes. This suggests that the evidence supporting a direct relationship between the integrity of the repair and functional outcomes is inconsistent.<sup>75</sup>

## Shoulder Instabilities: Nonoperative Management

### Related Pathologies and Mechanisms of Injury

GH joint hypermobility can be atraumatic or traumatic. *Atraumatic hypermobility*, often referred to as instability, can be due to generalized connective tissue laxity or from

microtrauma related to repetitive activities. *Traumatic instability* is caused by a single event or a sequence of high force events that compromise the integrity of the stabilizing structures, often dislocating the GH joint. With traumatic dislocation, there is complete separation of the articular surfaces of the GH joint from direct or indirect forces applied to the shoulder.<sup>155</sup> Atraumatic instability may be a predisposing factor to traumatic dislocation, especially with repetitive stressful overhead activities.<sup>85</sup> GH joint hypermobility, regardless of whether atraumatic or traumatic, is often categorized as unidirectional or multidirectional. A secondary effect of hypermobility is a painful shoulder syndrome (described in an earlier section).

### Atraumatic Hypermobility

**Unidirectional instability.** Unidirectional instability can be anterior, posterior, or inferior and is named for the direction in which the joint mobility is increased. It may be the result of physiological laxity of the connective tissues or repetitive non-uniform loading of the joint. With the compromise of stabilizing structures, the humeral head may continue to dislocate or sublux in the direction of the instability. This can lead to progressive degeneration and eventually tears in the supporting structures.

- *Anterior instability* usually occurs with posteriorly-directed forces applied to the arm when it is in an abducted and externally rotated position, resulting in anterior humeral head translations. If these forces occur with enough frequency and force to compromise anterior GH joint structures, instability results. Often these forces are self-generated, as in throwing athletes who repetitively position the arm such that the anterior capsule is overloaded. Positive clinical signs include apprehension, load and shift, and anterior drawer tests.<sup>119,220</sup>
- *Posterior instability* is much less common but can occur from repetitive posterior-directed forces applied against a forward-flexed humerus that translate the humeral head posteriorly. There is a positive posterior drawer sign with posterior instability.<sup>119,220</sup>
- *Inferior instability* is typically the result of rotator cuff weakness/paralysis and is frequently seen in patients with hemiplegia.<sup>68</sup> It is also prevalent in patients who repetitively reach overhead (workers or swimmers, for example) and those with multidirectional instability. This instability is evident with a positive sulcus sign.<sup>119,220</sup>

**Multidirectional instability.** The GH joint is considered to have multidirectional instability when stability is compromised in more than one direction. Some individuals have physiologically increased extensibility of connective tissue, causing excessive joint mobility. In the GH joint, this increased extensibility allows larger than normal humeral head translations in all directions.<sup>155,178</sup> Many individuals, particularly those involved in overhead activities, develop laxity of the capsule from continually subjecting the tissue to tensile forces.<sup>61,92</sup> Multidirectional instability is confirmed by a combination of the positive tests noted previously for unidirectional instability.

### Common Impairments of Structure and Function

With atraumatic instability, symptoms are often chronic, intermittent, and activity dependent. Acute symptoms are infrequent but may occur if there is a significantly increased demand placed on the joint. Decreased endurance of the rotator cuff muscles may be a precipitating factor of repetitive trauma of the joint.

### Common Activity Limitations and Participation Restrictions

- Possibility of recurrence when replicating the dislocating position or with forces applied to the arm in the dislocating position
- With anterior instability, restricted ability in sports activities such as throwing, swimming, serving, and spiking
- With posterior dislocation, restricted ability in sports activities, such as follow-through in throwing and golf; restricted ability in pushing activities, such as pushing open a heavy door or pushing one's self up out of a chair
- Discomfort or pain when sleeping on the involved side
- Inability to maintain arm positions or complete tasks requiring prolonged effort, especially overhead tasks

### Traumatic Hypermobility

**Traumatic anterior shoulder dislocation.** Anterior dislocation most frequently occurs when there is a posteriorly directed force to the arm while the humerus is in a position of elevation, external rotation, and horizontal abduction. In that position, stability is provided by the subscapularis, GH ligaments (particularly the anterior band of the inferior ligament), and long head of the biceps.<sup>105,170,204</sup> A significant force to the arm may damage these structures, along with the attachment of the anterior capsule and glenoid labrum (Bankart lesion is depicted in Fig. 17.19).<sup>43</sup>

**FIGURE 17.19** Lesions associated with traumatic anterior dislocation of the GH joint. A Bankart lesion is a fracture of the anterior rim of the glenoid with the attached labrum. The labrum is pulled away from the anterior glenoid along with a small piece of glenoid. A Hill-Sachs lesion, a compression fracture of the posterolateral humeral head, also may occur. (Adapted from Tovin, BJ, and Greenfield, BH: Evaluation and Treatment of the Shoulder—An Integration of the Guide to Physical Therapist Practice. Philadelphia: F.A. Davis, 2001, p 295, with permission.)

Traumatic anterior dislocation can be associated with complete rupture of the rotator cuff,<sup>6,165</sup> with the incidence increasing in those over 40 years of age.<sup>43</sup> There may also be a compression fracture (Hill-Sachs lesion, Fig. 17.19) at the posterolateral margin of the humeral head.<sup>43</sup> Neurological or vascular injuries may also occur during dislocations.<sup>72</sup> The axillary nerve is most commonly injured, but the brachial plexus or one of the peripheral nerves could be stretched or compressed.

**Traumatic posterior shoulder dislocation.** Traumatic posterior shoulder dislocation is less common. The mechanism of injury is usually a force applied to the arm when the humerus is positioned in flexion, adduction, and internal rotation, such as falling on an outstretched arm.<sup>161</sup> The injured person complains of symptoms when doing activities such as push-ups, a bench press, or follow-through on a golf swing.<sup>72</sup>

### Recurrent Dislocations

With significant ligamentous and capsular laxity, recurrent subluxations or dislocations may occur with any movement that reproduces the humerus positions and forces that caused the original instability. These episodes result in significant pain and functional limitations. Some individuals can voluntarily dislocate the shoulder anteriorly or posteriorly without apprehension and with minimal discomfort.<sup>155,182</sup> The rate of recurrence after the first traumatic dislocation is highest in the younger population (< 30 years). Because they are more active and place greater demands on the shoulder, longer immobilization (> 3 weeks) is advocated after dislocation in patient's less than 30-years old. A shorter immobilization (1 to 2 weeks) is recommended for older patients.<sup>125,128</sup>

### Common Impairments of Structure and Function

- After an acute traumatic injury, symptoms resulting from tissue damage include pain and muscle guarding due to bleeding and inflammation.
- When a dislocation is associated with a complete rotator cuff tear, there is an inability to abduct the humerus against gravity.
- Asymmetrical joint restriction/hypermobility. With anterior instability, the posterior capsule may become tight; with posterior instability, the anterior capsule may become tight. After healing from a traumatic event, there may be capsular adhesions.
- With recurrent dislocations, the individual can dislocate the shoulder at will, or the shoulder may dislocate during specific activities.

### Common Activity Limitations and Participation Restrictions

- With rotator cuff rupture, inability to perform all activities requiring humeral elevation.
- Possibility of recurrence when replicating the dislocating position or with forces applied to the arm in the dislocating position.

- With anterior dislocation, restricted ability in sports activities, such as throwing, swimming, overhead serving, and spiking.
  - Restricted ability with dressing, such as putting on a shirt or jacket, and with self-grooming, such as combing the back of the hair.
  - Discomfort or pain when sleeping on the involved side.
- With posterior dislocation, restricted ability in sports activities, such as follow-through in pitching and golf; restricted ability in pushing activities, such as pushing open a heavy door or pushing one's self up from a chair.

## Closed Reduction of Anterior Dislocation

**NOTE:** Several techniques are described in the literature utilizing either leverage or traction on the humerus to reduce an anterior dislocation.<sup>43</sup> Because of the risk of humeral fracture or injury to the brachial plexus or axillary blood vessels during reduction, the authors of this text recommend that these techniques should be undertaken only by someone specially trained to deal with these potential complications.

### Management: Protection Phase

#### Protect the Healing Tissue

- Activity restriction is recommended for 6 to 8 weeks in a young patient. If a sling is used, the arm is removed from the sling only for controlled exercise. During the first week, the patient's arm may be continuously immobilized because of pain and muscle guarding.
- An older, less active patient (> 40 years of age) may require immobilization for only 2 weeks.
- The position of dislocation must be avoided when exercising, dressing, or doing other daily activities.

### FOCUS ON EVIDENCE

Traditionally after acute anterior shoulder dislocation, immobilization has been instituted. However, a clinical commentary that evaluated outcomes from various studies found that the literature does not support the use of a traditional sling for immobilizing the shoulder following primary anterior shoulder dislocation.<sup>85</sup> It was also noted that there were significantly fewer redislocations when activity is restricted for 6 to 8 weeks in those less than 30 years of age compared to activity restriction of less than 6 weeks. The commentary also supported positioning the humerus in adduction and external rotation (rather than internal rotation) during immobilization for better approximation between the detached glenoid labrum (Bankart lesion) and the glenoid neck.

#### Promote Tissue Health

Protected ROM, intermittent muscle setting of the rotator cuff, deltoid, and biceps brachii muscles, and grade II joint mobilization techniques in safe directions (with the humerus

at the side or in the resting position) are initiated as soon as the patient tolerates them.

**PRECAUTIONS:** In order not to disrupt healing of the capsule and other damaged tissues after anterior dislocation, ROM into external rotation is performed with the elbow at the patient's side, with the shoulder flexed in the sagittal plane, and with the shoulder in the resting position (in the plane of the scapula, abducted 55° and 30° to 45° anterior to the frontal plane) but not in the 90° abducted position. The forearm is moved from maximal internal rotation to 0° or possibly 10° to 15° external rotation.

**CONTRAINDICATION:** Extension beyond 0° is contraindicated.

### Management: Controlled Motion Phase

#### Provide Protection

The patient continues to protect the joint and delay full return to unrestricted activity. If a sling is being used, the patient increases the time the sling is off. The sling is used when the shoulder is tired or if protection from external forces is needed.

#### Increase Shoulder Mobility

- Mobilization techniques are initiated using all appropriate glides except the anterior glide. The anterior glide is *contraindicated* even though external rotation is necessary for functional elevation of the humerus. For a safe stretch to increase external rotation, place the shoulder in the resting position (abducted 55° and horizontally adducted 30°); then externally rotate the humerus to the limit of its range and apply a grade III distraction force perpendicular to the treatment plane in the glenoid fossa (Fig. 17.20).
- The posterior joint structures are passively stretched with horizontal adduction self-stretching techniques.

**FIGURE 17.20** Mobilizing to increase GH joint external rotation when an anterior glide is contraindicated. Place the shoulder in resting position, externally rotate it, then apply a grade III distraction force.

### Increase Stability and Strength of Rotator Cuff and Scapular Muscles

Both the internal and external rotators need to be strengthened as healing occurs.<sup>22</sup> The internal rotators and adductors must be strong to support the anterior capsule. The external rotators must be strong to stabilize the humeral head against anterior translating forces and to participate in the deltoid-rotator cuff force couple when abducting and laterally rotating the humerus. Scapulothoracic muscle strength is important for normal shoulder function and to maintain the scapula in normal alignment. The following exercises are initiated:

- *Isometric resistance* exercises with the joint positioned at the side and progressed to various pain-free positions within the available ranges.
- Partial weight-bearing and stabilization exercises.
- *Dynamic resistance*, limiting external rotation to 50° and avoiding the position of dislocation.
- At 3 weeks, supervised *isokinetic resistance* for internal rotation and adduction at speeds of 180° per second or higher may be used.<sup>7</sup> Position the patient standing with the arm at the side or in slight flexion and elbow flexed 90°. The patient performs internal rotation beginning at the zero position with the hand pointing anteriorly and moving across the front of the body.
- Progress to positioning the shoulder at 90° flexion. Have the patient perform the exercise from zero to full internal rotation. Do not position in 90° abduction.
- By 5 weeks, all shoulder motions are incorporated into exercises on isokinetic or other mechanical equipment except for the position of 90° abduction with external rotation.

### Management: Return to Function Phase

#### Restore Functional Control

The following are emphasized:

- A balance in strength of all shoulder and scapular muscles
- Coordinated scapulothoracic and arm motions
- Endurance for each previously described shoulder stability exercise
- As stability improves, progress to:
  - Eccentric training to maximum load.
  - Increasing speed and control of combined motions.
  - Simulating desired functional patterns for activity.

#### Return to Full Activity

- The patient can return to normal activities when there is no muscle strength imbalance, good coordination is present during skilled movements, and the apprehension test is negative. Full rehabilitation takes 2.5 to 4 months.<sup>4</sup>
- It is important that the patient learns to recognize signs of fatigue and impingement and is educated about how to reduce the exercise load when these signs are noticed.

### Closed Reduction of Posterior Dislocation

The management approach is the same as for anterior dislocation with the exception of avoiding the position of humeral flexion with adduction and internal rotation during the acute and healing phases.

#### CLINICAL TIP

Use of a sling following a posterior dislocation may be uncomfortable because of the adducted and internally rotated position of the humerus, particularly if the sling elevates the humerus so the head translates in a superior and posterior direction. The patient may be more comfortable with the arm hanging freely in a dependent position while kept immobile.

When mobilization is allowed, begin joint mobilization techniques using all appropriate glides except the posterior glide. Posterior glide is *contraindicated*. If adhesions develop that limit internal rotation, mobility can be regained safely by placing the shoulder in the resting position (abducted 55° and horizontally adducted 30°), internally rotating it to the limit of its range, and applying a grade III distraction force perpendicular to the treatment plane in the glenoid fossa (same as in Fig. 17.20 but with the arm internally rotated).

## Shoulder Instabilities: Surgery and Postoperative Management

Surgical stabilization procedures are often necessary to repair chronic, recurrent instabilities and acute traumatic lesions in the GH, AC, and SC joints to restore function. Background information on GH joint instabilities and injuries that frequently occur with dislocations to this joint was described in the previous sections on nonoperative management. Common lesions that occur with GH instabilities are Bankart lesions, Hill-Sachs lesions, reverse Hill-Sachs lesions, and rotator cuff tears.

### Glenohumeral Joint Stabilization Procedures and Postoperative Management

If a reasonable trial of nonoperative management has not prevented recurrence of GH joint instability, surgical stabilization may be considered. Recurrent instability after a traumatic event responds more favorably to surgical management than do chronic atraumatic instabilities.<sup>11,125</sup> Young, active patients

who have sustained an acute, traumatic, anterior dislocation for the first time may elect to undergo surgery without a prior course of rehabilitation because there is a particularly high rate of recurrence of dislocation in this group after nonoperative management.<sup>125,128</sup>

### FOCUS ON EVIDENCE

In a small randomized trial<sup>18</sup> of young athletes who had sustained a first-time, acute, traumatic anterior shoulder dislocation, one group ( $n = 14$ ) participated in a nonoperative rehabilitation program of immobilization and exercise and another group ( $n = 10$ ) underwent arthroscopic repair of a Bankart lesion plus the rehabilitation program. Participants were followed for an average of 36 months. Of the 12 non-operatively managed patients who were available for follow-up, 9 (75%) experienced recurrent instability, whereas of the 9 operatively managed patients available for follow-up, only 1 (11.1%) experienced recurrent instability. Six of the 9 non-operatively treated patients who experienced recurrent instability subsequently had an open Bankart repair.

In another randomized study<sup>102</sup> of young patients (mean age 22 years) who sustained traumatic anterior dislocations, a trial of nonoperative management was compared to immediate arthroscopic stabilization. Over a 2-year period, 47% of the patients in the non-operative group—but only 15% of the surgical group—experienced recurrence of the dislocation. These studies demonstrate that in young patients, early surgical stabilization followed by postoperative rehabilitation significantly reduces the incidence of recurrent instability compared to non-operative management.

### Indications for Surgery

The following are common indications for surgical stabilization of the GH joint.<sup>125,128,195,210,213</sup>

- Recurrent episodes of GH joint dislocation or subluxation that impair functional activities
- Unidirectional or multidirectional instability during active shoulder movements that causes apprehension about placing the arm in positions of potential dislocation, leading to compromised use of the arm for functional activities
- Instability-related impingement (secondary impingement syndrome) of the shoulder
- Significant inherent joint laxity resulting in recurrent involuntary dislocation
- High probability of subsequent episodes of recurrence of dislocation after an acute traumatic dislocation in young patients involved in high-risk (overhead), work-related, or sport activities
- Dislocations associated with significant cuff tears or displaced tuberosity or glenoid rim fractures

- Irreducible (chronic, fixed) dislocation
- Failure to resolve the instability and restore function with non-operative management

### Procedures

Procedures designed to improve stability and prevent recurrent instability of the GH joint must balance stabilization of the joint with retention of near-normal, functional mobility. Stabilization procedures, which may involve the anterior, posterior, or inferior portions of the capsule, are performed using either an arthroscopic or open approach depending on the type of lesion(s) present and type of procedure selected by the surgeon.<sup>125,128,161,190,210</sup> Open stabilization procedures are highly successful (low recurrence of dislocation) and have been considered the standard for years. However, with advances in arthroscopic techniques and methods of tissue fixation, the use and success of arthroscopic stabilization procedures is much more common.<sup>210</sup>

Recurrent anterior (unidirectional) dislocation is by far the most common form of GH instability managed with surgical stabilization.<sup>128</sup> In contrast, posterior or posteroinferior instabilities are less frequently managed with surgical stabilization.<sup>161</sup> The surgical procedures can be organized into several categories.

**Bankart repair.** This repair involves an open or arthroscopic repair of a Bankart lesion, which is the detachment of the capsulolabral complex from the anterior rim of the glenoid commonly associated with traumatic anterior dislocation (see Fig. 17.19). During the repair an anterior capsulolabral reconstruction is performed to reattach the labrum to the surface of the glenoid lip.<sup>3,65,85,90,125,175,175,210</sup>

With an open repair, the humeral insertion of the subscapularis is detached or split longitudinally for access to the lesion and capsule.<sup>67,125,172,175</sup> Occasionally, access is achieved through the rotator cuff interval, which allows the subscapularis to remain intact.<sup>125</sup> If the subscapularis is detached, it is repaired after the labrum has been reattached. With an arthroscopic approach multiple portal sites are used, and the subscapularis is not disturbed.<sup>3,210</sup> Repair of a Bankart lesion is combined with an anterior capsular shift if capsular redundancy is present.

With an open procedure, the labrum is reattached with direct transglenoid sutures or suture anchors, whereas with an arthroscopic approach transglenoid sutures, suture anchors, or tacks are used.<sup>85,210</sup> Generally, more secure fixation is achieved with an open repair than with an arthroscopic repair, although in recent years advances in arthroscopic tissue fixation have improved.<sup>210</sup>

**Capsulorrhaphy (capsular shift).** Capsulorrhaphy, which can be performed using either an open or arthroscopic approach, involves tightening the capsule to reduce capsular redundancy and overall capsule volume by incising, overlapping in a pants-and-vest manner (imbrication), and then securing the lax

or overstretched portion of the capsule (plication) with direct sutures, suture anchors, tacks, or staples.<sup>69,90,125,128,161,210,228</sup>

A capsular shift procedure is tailored to the direction(s) of instability: anterior, inferior, posterior, or multidirectional. For example, if a patient has recurrent anteroinferior multidirectional instability, an anterior or inferior capsular shift is performed in which this portion of the capsule is incised, tightened by imbrication (plication), and sutured. Most capsular shift procedures are performed to reduce anterior instability.<sup>10,125,128,228</sup>

**Electrothermally assisted capsulorrhaphy.** Electrothermally assisted capsulorrhaphy (ETAC) involves an arthroscopic approach that uses thermal energy (radiofrequency thermal delivery or nonablative laser) to shrink and tighten loose capsuloligamentous structures. The procedure—also referred to as a *thermal-assisted capsular shift* (TACS) or *thermocapsular shrinkage*—can be used alone but more often is used in conjunction with other arthroscopic procedures, such as repair of a glenoid tear, a capsular shift, débridement of a partial rotator cuff tear, or subacromial decompression.<sup>54,57,125,132,197,205,210,224</sup>

Animal and human cadaveric studies have shown that thermal energy initially makes collagen fibrils more extensible; but as the collagen tissue of the capsuloligamentous structures heals, it shortens or “shrinks,” causing a decrease in capsular laxity.<sup>84,183</sup> If one or more of the GH ligaments is detached or if rotator cuff lesions that could be contributing to the instability are detected, they are repaired arthroscopically prior to ETAC.

**Posterior capsulorrhaphy (posterior or posteroinferior capsular shift).** Recurrent, involuntary posterior or posteroinferior instability can be managed with either an open or arthroscopic capsular shift to remove posterior and inferior redundancy of the capsule.<sup>11,125,160,161,195,196,210</sup> Additional soft tissue procedures, such as repair of a posterior labral tear (reverse Bankart lesion) or, in rare instances, plication and advancement of the infraspinatus to reinforce the posterior capsule, may be necessary. Shoulders without an effective posterior glenoid can be surgically managed with capsulolabral augmentation<sup>210</sup> or occasionally with a glenoid osteotomy.<sup>125,161</sup>

With an arthroscopic posterior stabilization, a capsular shift and repair of the posterior labrum can be accomplished without disrupting the shoulder musculature.<sup>160</sup> With an open stabilization, a posterolateral incision is made; the deltoid is split; and the infraspinatus, teres minor, and posterior capsule are incised.<sup>161,196</sup> In some instances of traumatic multidirectional instability, anterior capsulorrhaphy is used to indirectly increase the tension of the posterior capsule.<sup>125,161,210</sup>

**Repair of a SLAP lesion.** A tear of the superior labrum is classified as a SLAP lesion (superior labrum extending anterior to posterior).<sup>46,195,210,225</sup> Some SLAP lesions are associated with a tear of the proximal attachment of the long head of the biceps tendon and recurrent anterior instability of the GH joint. An arthroscopic repair involves

débridement of the torn portion of the superior labrum, abrasion of the bony surface of the superior glenoid, and reattachment of the labrum and biceps tendon with tacks or suture anchors. Concomitant anterior stabilization is also performed if instability is present.

## Postoperative Management

### General Considerations

As with rehabilitation after rotator cuff repair, guidelines for postoperative management after GH joint surgical stabilization are based on many factors. These factors, all of which can influence the composition and progression of a postoperative program, are summarized in Table 17.5. Additional factors that affect rehabilitation after GH stabilization and rotator cuff repair, such as the philosophy and training of the surgeon and a number of patient-related variables (general health, medications, preinjury functional status and postoperative goals, education, and compliance) have been addressed previously (see Table 17.3).

The content in this section identifies *general* principles of management across three broad phases of postoperative rehabilitation after a variety of GH joint surgical stabilization and reconstruction procedures. These general guidelines cannot begin to address the many variations of rehabilitation programs recommended for specific stabilization procedures. However, many detailed protocols or case-based descriptions of rehabilitation programs for use after specific procedures and for specific types of shoulder instabilities and associated lesions are available in the literature.<sup>34,54,85,98,150,163,205,225,232</sup>

Regardless of the type of instability, associated pathology, or type of surgical stabilization procedure, a postoperative rehabilitation program must be based on the findings of a comprehensive examination and individualized to meet the unique needs of each patient. The focus of postoperative rehabilitation is to restore pain-free shoulder mobility and muscular strength and endurance, particularly the dynamic joint stabilizers, to meet the patient’s functional needs *while preventing recurrence of shoulder instability*.

### Immobilization

**Position.** The position in which the patient’s shoulder is immobilized after surgery is determined by the direction(s) of instability prior to surgery. After surgical reconstruction for recurrent anterior or anteroinferior instability, the shoulder is immobilized in a sling or splint with the arm at the side or in some amount of abduction and internal rotation, with the arm slightly anterior to the frontal plane of the body.<sup>90,125</sup> After surgery for posterior or posteroinferior instability, the upper extremity is supported in an orthosis with the shoulder immobilized in the “handshake” position (neutral rotation to 10° to 20° of external rotation, 20° to 30° of abduction, elbow flexed, and neutral flexion or slight extension).<sup>125,161</sup>

**Duration.** The duration of immobilization—that is, the period of time before use of the immobilizer is *completely* discontinued—is determined by many factors, including the

**TABLE 17.5** Factors That Influence the Rehabilitation Program After Surgery for Recurrent Instability of the GH Joint

Factors	Potential Impact on Rehabilitation
<ul style="list-style-type: none"> <li>■ A traumatic onset of instability</li> </ul>	<ul style="list-style-type: none"> <li>■ More conservative postoperative rehabilitation due to greater risk of recurrent dislocation<sup>125</sup></li> </ul>
<ul style="list-style-type: none"> <li>■ Severity of associated lesions</li> </ul>	<ul style="list-style-type: none"> <li>■ Increased severity or number of associated lesions will slow the progression of rehabilitation</li> </ul>
<ul style="list-style-type: none"> <li>■ Previous failure of a surgical Stabilization</li> </ul>	<ul style="list-style-type: none"> <li>■ Slower progression</li> </ul>
<ul style="list-style-type: none"> <li>■ Direction of instability</li> </ul>	<ul style="list-style-type: none"> <li>■ Stabilization of anterior instability allows more rapid advancement than stabilization of posterior or multidirectional instabilities<sup>161</sup></li> </ul>
<ul style="list-style-type: none"> <li>■ Type of surgical approach</li> </ul>	<ul style="list-style-type: none"> <li>■ Less postoperative pain with arthroscopic procedure but rate of progression essentially the same after open and arthroscopic stabilization procedures, because rate of healing of repaired tissues is the same in both procedures</li> </ul>
<ul style="list-style-type: none"> <li>■ Type of procedure</li> </ul>	<ul style="list-style-type: none"> <li>■ Electrothermally assisted capsulorrhaphy requires slower progression than arthroscopic or open capsular tightening without thermal application<sup>54,164,205</sup></li> <li>■ Bony reconstruction requires slower progression than after soft tissue reconstruction</li> </ul>
<ul style="list-style-type: none"> <li>■ Patient variables</li> <li>■ Tissue integrity</li> <li>■ Preoperative status of dynamic stabilizers</li> <li>■ Generalized joint laxity</li> </ul>	<ul style="list-style-type: none"> <li>■ The progression of postoperative rehabilitation is more conservative for the inactive patient with multidirectional atraumatic instability who has generalized joint laxity and poor pre-operative strength of the dynamic (muscular) stabilizers</li> </ul>

type of instability, the procedure(s) performed, and the surgeon's intraoperative assessment. This period can range from 1 to 3 weeks to as long as 6 to 8 weeks. However, the period of *continuous* immobilization of the operated shoulder (before shoulder motion can be initiated) depends on the type of procedure but is kept as short as possible. For example, after an anterior stabilization, the immobilizer may need to be worn continuously for only a day to a few days but in some cases up to 1 to 2 weeks.<sup>128</sup> In contrast, repairs of posterior or multidirectional instabilities, which are associated with a higher recurrence of dislocation, usually require a longer period of immobilization.<sup>125,161,196</sup> After a posterior stabilization procedure, the shoulder may be continuously immobilized and ROM delayed for up to 6 weeks postoperatively.<sup>98,161</sup>

Time frames for immobilization also vary based on the factors that influence all aspects of postoperative rehabilitation (see Table 17.4). For example, the duration of immobilization is usually shorter for an elderly patient than for a young patient, because the elderly patient is more likely to develop postoperative shoulder stiffness than the young patient. In contrast, patients with generalized hypermobility or younger patients involved in high-demand activities require longer periods of immobilization to reduce the risk of redislocation.<sup>125</sup>

### Exercise Progression

As with the position and duration of immobilization, decisions about when the arm may be temporarily removed from the immobilizer to begin shoulder exercises and the allowable shoulder motions are based on many of the factors previously summarized (see Table 17.5).

### CLINICAL TIP

During the early weeks of rehabilitation after a surgical stabilization procedure, determining what ranges fall within "safe" limits of motion is based on the extent of intraoperative ROM that was possible without placing excessive tension on the repaired, tightened, or reconstructed tissues. This information may be available in the operative report or should be communicated by the surgeon to the therapist prior to initiating postoperative exercises.

Rehabilitation after anterior stabilization (anterior capsular shift or Bankart repair) is similar after open and arthroscopic procedures. In both instances, there are precautions that must be heeded, particularly during the first 6 weeks after surgery while soft tissues are healing. During this time period

after an open procedure, the anterior capsule and the detached and repaired subscapularis must be protected from excessive stresses. With an arthroscopic anterior stabilization, although the subscapularis remains intact, it is also necessary to protect the anterior capsule fixation during the initial phase of rehabilitation, because soft tissue fixation may not be as secure as the fixation used in an open procedure.

**PRECAUTIONS:** Precautions after arthroscopic or open anterior stabilization or reconstruction procedures are summarized in Box 17.9.<sup>34,67,85,98,125,128,150,210</sup> Precautions for thermally assisted capsular tightening,<sup>54,57,164,205,224</sup> posterior stabilization procedures,<sup>98,160,161</sup> and repair of a SLAP lesion<sup>34,46,225</sup> are noted in Box 17.10.

### FOCUS ON EVIDENCE

In a study by Sachs and colleagues<sup>175</sup> with a 4-year follow-up of 30 patients who had sustained a traumatic anterior dislocation and undergone an open Bankart repair (that included takedown and repair of the subscapularis tendon), only postoperative subscapularis function was significantly correlated with the patients' perception of a successful outcome after surgery. Although only two patients (6.7%) reported recurrence of instability over the 4-year period, seven patients (23%) had incompetence of the subscapularis muscle. Specifically, the mean strength of the subscapularis in these patients

was only 27% as strong as the non-involved shoulder, compared to the remaining patients who had mean subscapularis strength of 80%. There was no significant loss of strength in other shoulder muscles in either group of patients.

Of the patients with a reasonably strong subscapularis at the 4-year follow-up, 91% reported good to excellent results, and 100% indicated that they would have the surgery again. However, among the patients with a substantially weak subscapularis, 57% reported good to excellent results, but only 57% would undergo the surgery again. The investigators suggest that the subscapularis tendon repair and protection over the first few weeks following surgery is critical to shoulder function and patient perception of successful outcomes.

### Exercise: Maximum Protection Phase

The initial phase of rehabilitation extends for about 6 weeks after surgery. Protection of the tightened capsule or repaired structures, such as the labrum or the subscapularis, is necessary during this phase while also minimizing the negative consequences of immobilization. Exercises may be initiated the day after surgery for select patients who have had an anterior stabilization procedure,<sup>39</sup> but more often are begun 1 to 2 weeks postoperatively.<sup>98,150</sup> ROM is delayed for a longer period of time after a thermally assisted stabilization,<sup>54,57,164,205,224</sup> a posterior stabilization procedure,<sup>98,160,161</sup> or repair of a SLAP lesion and torn biceps tendon<sup>34,47,225</sup> (see Box 17.10).

#### BOX 17.9 Precautions After Anterior Glenohumeral Stabilization and/or Bankart Repair\*

- Limit external rotation (ER), horizontal abduction, and extension (shoulder positions that place stress on the anterior capsule) during first 6 weeks postoperatively.
  - After an arthroscopic stabilization, although the subscapularis is intact, limit ER to 5° to 10° with the arm in slight abduction or at the side for the first 2 weeks to avoid pull-out of fixation.<sup>35</sup> Gradually progress to 45° over the next 2 to 4 weeks with the shoulder in greater abduction. With a tenuous stabilization, may need to limit ER to only neutral for the first 4 to 6 postoperative weeks.<sup>210</sup>
  - After an open procedure involving subscapularis takedown and repair, limit ER to 0° (no ER past neutral), to no more than 30° to 45° or to the "safe" limits identified during the intraoperative assessment for 4 to 6 weeks.<sup>34</sup>
  - Postpone ER combined with full shoulder abduction for at least 6 weeks.<sup>85</sup>
  - After an arthroscopic stabilization, progress forward flexion of the shoulder more cautiously than after an open stabilization.
  - After bony procedures, delay passive or assisted ROM for 6 to 8 weeks to allow time for bone healing.<sup>125,128</sup>
  - No vigorous passive stretching to increase end-range ER for 8 to 12 weeks after either arthroscopic or open procedure except for patients with hypoelectric tissue quality.<sup>210</sup>
  - When stretching is permissible, avoid positioning the shoulder in abduction and external rotation during grade III joint mobilization procedures.
  - After procedures with subscapularis detachment and repair, no *active* or *resisted* IR for 4 to 6 weeks; avoid lifting objects, especially if pushing the hands together is required.<sup>34,67,85,150</sup>
  - Avoid activities involving positions that place stress on the anterior aspect of the capsule for about 4 to 6 weeks.
    - Avoid functional activities that require ER, especially if combined with horizontal abduction during early rehabilitation as when reaching to put on a coat or shirt.
    - Avoid upper extremity weight bearing particularly if the shoulder is extended, as when pushing up from the armrests of a chair.
  - When dynamically strengthening the rotator cuff, maintain the shoulder in about 45° of abduction, rather than 90°.
- \*Precautions apply primarily to early rehabilitation during the first 6 weeks after surgery except as noted. The allowable ROM during the initial phase of rehabilitation depends on the type of pathology, surgical procedure, the patient's tissue quality (degree of hyper- or hypo-elasticity), and the intraoperative evaluation of shoulder stability.

**BOX 17.10 Precautions After Selected Glenohumeral Stabilization Procedures****Thermally Assisted Capsular Tightening**

- Be extremely cautious with ROM exercises for the first 4 to 6 weeks postoperatively because collagen in the thermally treated capsuloligamentous structures is initially more extensible (more vulnerable to stretch) until it heals. Some patients may begin ROM within protected ranges the day after surgery, whereas others may be required to postpone ROM exercises entirely for 2 weeks or more.
- While sleeping, complete immobilization (sling and swathe) for 2 weeks or more.
- Precautions for ROM depend on the direction of instability, patient's tissue quality (hyper- or hypoelastic), and the extent of concomitant surgical procedures necessary. For example, progress patients with congenital hyperelasticity more cautiously than those with hypoelasticity.

**Posterior Stabilization Procedure and/or Reverse Bankart Repair**

- Postpone all shoulder exercises or limit elevation of the arm to 90° and internal rotation (IR) to neutral or no more than 15° to 20° and horizontal adduction to neutral (up to 6 weeks postoperatively).
- Restrict upper extremity weight bearing, particularly when the shoulder is flexed, to avoid stress to the posterior aspect of the capsule, for example during closed-chain scapulothoracic and GH stabilization exercises and functional activities, for at least 6 weeks postoperatively.
- Avoid resistance exercises that direct loads and place stress on the posterior capsule, such as bench press exercises and prone push-ups until late in the rehabilitation program, if at all.

**Repair of a SLAP Lesion**

- For SLAP lesions where the biceps tendon is detached, progress rehabilitation more cautiously than when the biceps remain intact.
  - Limit passive or assisted elevation of arm to 60° for the first 2 weeks and to 90° at 3 to 4 weeks postoperatively.
  - Perform only passive assisted humeral rotation with the shoulder in the plane of the scapula for the first 2 weeks (ER to only neutral or up to 15° and IR to 45°); during weeks 3 to 4, progress ER to 30° and IR to 60°.
- Avoid positions that create tension in the biceps, such as combined elbow and shoulder extension (as when reaching behind the back), during the first 4 to 6 weeks postoperatively.
- Postpone active contractions of the biceps (elbow flexion with supination of the forearm) for 6 weeks and resisted biceps exercises or lifting and carrying weighted objects until 8 to 12 weeks postoperatively depending on the extent and type of biceps repair; then progress cautiously.
- If the mechanism of injury was a fall onto the outstretched hand and arm causing joint compression, progress weight-bearing exercises gradually.
- If anterior instability is also present, follow precautions in Box 17.11.
- Avoid positions of abduction combined with maximum external rotation, as this places torsion forces on the base of the biceps attachment on the glenoid.

**Goals and interventions.** The goals and exercises for the maximum protection phase are summarized in this section.<sup>34,54,85,150,222,232</sup>

- **Control pain and inflammation.**

- A sling for comfort when the arm is dependent or for protection when in public areas. While seated, remove the sling (if permissible) and rest the forearm on a table or wide armrest with the shoulder positioned in abduction and neutral rotation to provide support but prevent potential contracture of the subscapularis and other internal rotators of the shoulder.
- Cryotherapy and prescribed anti-inflammatory medication
- Shoulder relaxation exercises

- **Prevent or correct posture impairments.**

- Emphasis on spinal extension and scapular retraction; avoid excessive thoracic kyphosis

- **Maintain mobility and control of adjacent regions.**

- Active ROM of the cervical region, elbow, forearm, wrist, and fingers the day after surgery
- Active scapulothoracic movements

**PRECAUTION:** Initially, strengthen the scapulothoracic muscles in open-chain positions to avoid the need for weight bearing on the operated upper extremity. When weight-bearing activities are initiated, be cautious about the position of the operated shoulder for about 6 weeks postoperatively to avoid undue stress to the vulnerable portion of the capsule.

- **Restore shoulder mobility while protecting tightened or repaired tissues.**

- Pendulum exercises for the first 2 weeks postoperatively.
- Self-assisted ROM and wand exercises for the GH joint *within protected ranges* as early as 2 weeks or as late as 6 weeks postoperatively. Begin shoulder elevation in the supine position; begin humeral rotation with the shoulder in a slightly abducted and flexed position using a rolled towel under the humerus for positioning and support.
- With an anterior stabilization, gradually progress to near-complete ROM by 6 to 8 weeks except for external rotation, extension, and horizontal abduction beyond neutral.
- With a posterior stabilization, progress cautiously into flexion, horizontal adduction, and internal rotation.

- Progress to active shoulder ROM when motion can be performed without pain, apprehension, or use of substitute motions, such as elevating the scapula to initiate arm elevation.
- Use the operated arm for *nonweight-bearing, waist-level* functional activities with no external resistance by 2 to 4 weeks postoperatively.
- **Prevent reflex inhibition and disuse atrophy of GH musculature.**
  - Multiple-angle, low-intensity isometric exercises of GH musculature as early as the first week or by 3 to 4 weeks postoperatively. Use caution with resisted internal rotation after subscapularis repairs.
  - Possible initiation of dynamic exercises against *light* resistance in protected ranges of motion at 4 to 6 weeks emphasizing the GH stabilizers.
  - Be particularly cautious when applying any type of resistance to musculature that has been torn or surgically detached, incised, or advanced and then repaired. Note that following a SLAP repair, resisted elbow flexion and resisted shoulder elevation will result in increased tensile loading of the long head of the biceps tendon.

**NOTE:** In some cases, dynamic exercises against light resistance are delayed until the intermediate phase of rehabilitation (about 6 to 8 weeks postoperatively), when only moderate protection is necessary.

**Criteria to progress.** Criteria to advance to the second phases of rehabilitation are:<sup>34,54,85,98</sup>

- A well healed incision.
- Reasonable improvement in ROM.
- Minimal pain.
- No sense of apprehension about instability with active motions.

### Exercise: Moderate Protection Phase

The moderate protection phase of rehabilitation begins around 6 weeks postoperatively and continues until approximately 12 to 16 weeks. The focus is on maintaining joint stability while achieving nearly full active (unassisted) ROM of the shoulder; developing neuromuscular control, strength, and endurance of scapulothoracic and GH musculature; and using the upper extremity through greater ranges for functional activities.

**Goals and interventions.** The goals and interventions for the intermediate phase of rehabilitation are as follows.<sup>34,54,85,98,222,232</sup>

- **Regain nearly full, pain-free, active ROM of the shoulder.**
  - Continue active ROM with the goal of achieving nearly full ROM by 12 weeks.
  - Incorporate ROM gains into functional activities.
  - Stretching and grade III mobilization in positions that do not provoke instability. After an anterior stabilization procedure, pay particular attention to increasing horizontal adduction, as the posterior structures may have been tight preoperatively and continue to be so postoperatively.

- **Continue to increase strength and endurance of shoulder musculature.**

- Alternating isometrics against increasing resistance with emphasis on the scapula and rotator cuff musculature.
- Dynamic resistance exercises initiated or progressed using weights and elastic resistance with emphasis on scapulothoracic and GH stabilizers. Begin in midrange positions, progressing to end-range positions. Emphasize both the concentric and eccentric phases of muscle activation.
- Dynamic strengthening in diagonal and simulated functional movement patterns.
- Upper extremity ergometry for muscular endurance. Include forward and backward motions.
- Progressive upper extremity weight bearing during strengthening and stabilization exercises.

**PRECAUTIONS:** After anterior stabilization, do not initiate dynamic strengthening of the internal rotators from full external rotation, particularly in the 90° abducted position. When strengthening the shoulder extensors, do not extend posterior to the frontal plane. Similarly, when strengthening the horizontal abductors, do not horizontally abduct posterior to the frontal plane. In addition, maintain the shoulder in neutral rotation during horizontal abduction and adduction. After posterior stabilization, do not begin dynamic strengthening of the external rotators from a position of full internal rotation initially.

**Criteria to progress.** Criteria to progress to the final phase of rehabilitation and the focus of exercises are similar to the criteria already identified for the final phase of rehabilitation after rotator cuff repair.

### Exercise: Minimum Protection/Return to Function Phase

This phase usually begins around 12 weeks postoperatively or as late as 16 weeks, depending on individual characteristics of the patient and the surgical procedure. Stretching should continue until ROM consistent with functional needs has been attained. Gains in ROM are possible for up to 12 months as collagen tissue continues to remodel. Resistance exercises to improve strength and endurance are progressed to replicate movements involved in functional activities, including placing the joint progressively closer to positions that previously provoked instability. Plyometric training (discussed in Chapter 23) is introduced and gradually progressed, particularly in patients intending to return to high-demand sports or work-related activities. Full participation in work-related and sports activities often takes up to 6 months postoperatively.

**PRECAUTIONS:** Some patients may have permanent restrictions placed on functional activities that involve high-risk movements and that could potentially cause recurrence of the instability. After some anterior stabilization procedures, full external rotation in 90° of abduction may not be advisable or possible.<sup>98</sup>

## Outcomes

A successful postoperative outcome involves regaining the ability to participate in desired functional activities without a recurrence of GH joint instability. There are many studies describing various outcomes after stabilization procedures. However, most of the studies comparing the success of one surgical intervention with that of another are not randomized—understandably so because the surgeon's examination is the basis for determining which procedure is most appropriate and will most likely lead to successful results for each patient.

Although postoperative exercise is consistently described as essential for optimal outcomes after stabilization surgery, no current evaluations of the effectiveness of postoperative exercise programs after GH stabilization are found in the literature. As with surgical decisions, most postoperative rehabilitation programs are customized to meet each patient's needs, making comparison of outcomes difficult.

Results of surgery and postoperative rehabilitation are typically reported for specific pathologies, patient populations, and surgical procedures and a variety of outcome measures are used to evaluate effectiveness. Despite this lack of consistency in reporting, some generalizations can be made.

**Recurrence of instability.** Recurrent instability of traumatic origin responds more favorably to surgical management than does atraumatic instability.<sup>11,125</sup> In addition, the rate of recurrence of instability is substantially higher in young patients (< 30 to 40 years of age) and patients who return to high-demand, work-related activities or competitive overhead sports than less active, older patients (> 30 to 40 years of age).<sup>125,210</sup>

The recurrence of dislocation rates after open and arthroscopic procedures have also been compared with recurrence rates after arthroscopic stabilization higher than after open stabilization.<sup>35,125</sup> In a review of studies on anterior stabilization procedures, the mean recurrence rate after open stabilization (Bankart lesion repair) was 11% (range 4% to 23%), but recurrence rates after arthroscopic stabilization were 18% (range 2% to 32%) with transglenoid suture fixation and 17% (range 0% to 30%) with tack fixation.<sup>85</sup> In a more recent review, the recurrence rates of anterior instability after an arthroscopic Bankart repair ranged from 8% to 17%.<sup>210</sup> Decreasing recurrence rates after arthroscopic procedures are attributed to improved surgical techniques. Today, arthroscopic stabilization has been shown in many instances to be equal to open stabilization at preventing recurrence for patients with unidirectional, anterior instability.<sup>35,210,214</sup> However, for multidirectional instabilities, outcomes after arthroscopic stabilization are not yet equal to outcomes after open stabilization.<sup>210</sup>

Outcomes after stabilization procedures for anterior and posterior instabilities also have been compared. Surgical stabilization of a recurrent, unidirectional *anterior* instability has yielded more predictable results and lower recurrence rates than stabilization of *posterior* or *multidirectional* instabilities.<sup>11,125,161,210,228</sup> The average recurrence rate of posterior

instability after arthroscopic stabilization is particularly high. One source reported a 30% to 40% rate of redislocation,<sup>196</sup> and another reported rates as high as 50%.<sup>210</sup> In contrast, mean recurrence rates after anterior stabilization procedures have been reported at 11% and 17% to 18%, respectively, for open and arthroscopic procedures.<sup>85</sup>

As the preoperative diagnosis has improved and the selection of appropriate candidates for surgery has become better, the recurrence of instability after posterior stabilization has decreased. In a study<sup>160</sup> with a mean follow-up of 39.1 months, the recurrence rate of instability after arthroscopic posterior stabilization was only 12.1%. The patients in this study had a mean age of 25 years with a history of involuntary or voluntary dislocation of the GH joint associated with acute traumatic and chronic repetitive microtrauma.

Regarding ETAC as the primary stabilization procedure, Hawkins and colleagues<sup>82</sup> reported failure in 37 of 85 patients (35%). Failures were those procedures that resulted in the need for a revision stabilization, recurrent instabilities, or recalcitrant pain and stiffness. The authors noted that for their practice, ETAC is now reserved primarily for augmentation of plication or other procedures in special circumstances

**Shoulder ROM.** After open anterior stabilization and Bankart repair, which usually requires detachment and repair of the subscapularis, a mean loss of 12° of ER has been reported.<sup>65</sup> It has been suggested that there is less loss of shoulder ER after arthroscopic procedures than after open procedures.<sup>85</sup> However, in a nonrandomized study that compared arthroscopic and open anterior stabilization procedures, there were not statistically significant differences in ER loss between groups with mean decreases of 9° and 11°, respectively.<sup>35</sup>

After open GH stabilization for instability due to repetitive microtrauma, postoperative loss of shoulder ER is the most common reason athletes involved in overhead sports are unable to successfully return to competition. Loss of shoulder rotation is reported to be less after arthroscopic stabilization procedures, thus enabling a greater percentage of these athletes to return to competition.<sup>164</sup> Early follow-up of patients who have undergone thermally assisted capsular stabilization was encouraging,<sup>57</sup> but long-term outcomes do not support high rates of success. A large study of overhead athletes who underwent thermally assisted stabilization followed 130 patients for a mean of 29.3 months. Of these athletes, 113 (87%) returned to competition in a mean of 8.4 months. Although postoperative ROM was not reported, the implication was that the return of ROM after thermally assisted arthroscopic stabilization was sufficient for a high percentage of athletes being able to return to competition.<sup>164</sup> A recent follow-up of 101 patients with mild to moderate instability who underwent thermal capsular shrinkage for stabilization reported failure in approximately one-third of the shoulders (31%) after a mean of 39 months. The best outcomes (pain, instability, and function) were noted in those with unidirectional anterior instability or a concomitant labral repair.<sup>200</sup> In contrast, a comparison of outcomes at 2 years showed no statistical or clinical

differences between groups of subjects who were randomized into open capsular shift ( $n = 26$ ) or thermal shrinkage ( $n = 28$ ) groups for MDI and failed nonoperative treatment.<sup>134</sup>

## Acromioclavicular and Sternoclavicular Joint Stabilization Procedures and Postoperative Management

### Acromioclavicular Joint Stabilization

A grade III separation, in which the AC and coracoclavicular ligaments are completely ruptured may be surgically stabilized with a variety of techniques.<sup>147,167</sup> Surgical procedures for acute dislocations include primary stabilization of the AC joint with Kirschner wires, Steinman pins, screws, or most recently bioabsorbable tacks, sutures, or fiber wires. Other procedures include a muscle-tendon transfer that moves the tip of the coracoid process with the attached tendons of the coracobrachialis and short head of the biceps to the undersurface of the clavicle<sup>154</sup> or the Weaver-Dunn procedure, which resects the distal clavicle and transfers the CA ligament from the acromion to the shaft of the distal clavicle.<sup>147</sup> Based on a small body of evidence in the literature, it appears the best results are achieved with primary AC and coracoclavicular stabilization procedures. Chronic AC dislocations, which are usually associated with degenerative changes of the AC joint, are most often managed with distal clavicle resection coupled with coracoclavicular stabilization.<sup>153,167</sup>

### Sternoclavicular Joint Stabilization

Although most SC dislocations are managed non-operatively, an acute posterior dislocation of the SC joint that cannot be successfully reduced with a closed maneuver, or an SC joint that dislocates recurrently are both managed surgically. Surgical reduction of a traumatic anterior dislocation is not recommended.<sup>166,229</sup> Surgical options for posterior SC dislocations include open reduction with repair of the stabilizing ligaments or resection of a portion of the medial clavicle and fixation of the remaining clavicle to the first rib or sternum with a soft tissue graft.<sup>166,229</sup>

### Postoperative Management

After surgical stabilization of either the AC or SC joint, the shoulder is immobilized for up to 6 weeks.<sup>39</sup> Exercise interventions are directed toward functional recovery as healing allows. No muscles provide dynamic stabilization of the AC and SC joints, so scapular and GH strength must be developed to provide indirect stability.

During the first few weeks of immobilization, the patient is encouraged to perform active ROM of the wrist and hand. If the elbow is supported on a table, the patient is permitted to perform active ROM of the elbow and forearm. The operated extremity, if supported, may be used for light functional activities, such as holding a utensil or typing, but weight bearing and shoulder ROM are completely prohibited during the first 6 weeks.<sup>39</sup>

When the immobilization can be removed, the focus of the exercise program is restoration of shoulder and elbow mobility and neuromuscular control of the shoulder complex. Shoulder ROM (passive, progressing to assisted ROM), active scapular motions, and light isometrics of the shoulder musculature are initiated at this point. Stabilization exercises, dynamic strengthening of the shoulder and scapula musculature, and stretching to restore full ROM are also introduced and progressed. Functional activities are gradually integrated into the rehabilitation program.

## Exercise Interventions for the Shoulder Girdle

### Exercise Techniques During Acute and Early Subacute Stages of Tissue Healing

During the *protection* and *early controlled motion* phases of management, when inflammation is present or beginning to resolve and healing tissues should not be stressed, early motion may be utilized to inhibit pain, minimize muscle guarding, and help prevent the adverse effects of complete immobilization. It is also valuable to treat associated regions, such as the cervical and thoracic spine, the scapulae, and the remainder of the upper extremity, to relieve stresses to the shoulder girdle and prevent fluid stasis in the extremity.

General guidelines for management during the acute stage are described in Chapter 10, and specific precautions for various pathologies and surgical interventions in the shoulder are identified throughout the second major section of this chapter.

### Early Motion of the Glenohumeral Joint

Early motion is usually passive ROM (PROM) applied within pain-free ranges. When tolerated, active-assistive ROM (A-AROM) can be initiated. Manual PROM and A-AROM techniques are described in detail in Chapter 3. This section expands on self-assisted exercises.

### Wand Exercises

- *Patient position and procedure:* Initiate A-AROM using a cane, wand, or T-bar in the supine position to provide stabilization and control of the scapula. Motions typically performed are flexion, abduction, elevation in the plane of the scapula, and internal/external rotation (Fig. 17.21 A).
- If it is necessary to relieve stress on the anterior capsule following surgical repair of the capsule or labrum, place a folded towel under the distal humerus to position the arm anterior to the frontal plane of the body when the patient performs internal or external rotation (Fig. 17.21 B).

**FIGURE 17.21** Self-assisted shoulder rotation using a cane (**A**) with the arm at the side and (**B**) in scapular. To relieve stress on the anterior capsule, elevate the distal humerus with a folded towel.

- When treating a painful shoulder syndrome (primary or secondary), grasping the wand with the forearm supinated when performing shoulder flexion and abduction may help encourage humeral external rotation.

### Ball Rolling or Table Top Dusting

**Patient position and procedure:** Sitting with the arm resting on a table and hand placed on a 6- to 8-inch ball or towel and the humerus in the plane of the scapula. Have the patient initiate gentle circular motions of the shoulder by moving the trunk forward, backward, and to the side, allowing the hand to roll the ball or “dust the table.” As pain subsides, have the patient use the shoulder muscles to actively move the ball or cloth through greater ROMs.

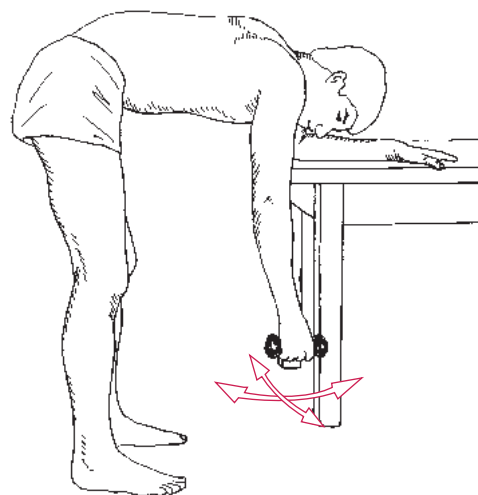

### Wall (Window) Washing

**Patient position and procedure:** Standing with the hand supporting a towel or a ball against a smooth wall. Instruct the patient to perform clockwise and counterclockwise circular motions with the hand by moving the towel or rolling the ball. Progress this activity by having the patient reach upward and outward as far as tolerated without causing symptoms.

### Pendulum (Codman’s) Exercises

**Patient position and procedure:** Standing, with the trunk flexed at the hips about 90°. The arm hangs loosely downward in a position between 60° and 90° elevation (Fig. 17.22).

- A pendulum or swinging motion of the arm is initiated by having the patient move their trunk in a rhythmic rocking

**FIGURE 17.22** Pendulum exercises. For gentle distraction, no weight is used. Use of a weight causes a grade III (stretching) distraction force.

motion. Motions of flexion, extension, and horizontal abduction, adduction, and circumduction can be done depending on the direction the trunk rocks.<sup>32</sup> Increase the arc of motion as tolerated. This technique should not cause pain.

- If the patient cannot maintain balance while leaning over, have him or her hold on to a solid structure or lie prone on a table.
- If the patient experiences back pain from bending over, use the prone position.
- Adding a weight to the hand or using wrist cuffs causes a greater distraction force on the GH joint. Weights should be used only when joint stretching maneuvers are indicated late in the subacute and chronic stages—and then only if the scapula is stabilized by the therapist or a belt is placed around the thorax and scapula, so the stretch force is directed to the joint, not the soft tissue of the scapulothoracic region.

**PRECAUTIONS:** If a patient gets dizzy when standing upright after being bent over, have the patient sit and rest. With increased pain or decreased ROM, the technique may be an inappropriate choice. Pendulum exercises are also inappropriate for a patient with peripheral edema.

### FOCUS ON EVIDENCE

An electromyographic (EMG) analysis<sup>113</sup> demonstrated peak percent maximum voluntary isometric contraction greater than 15% in the supraspinatus and infraspinatus muscles when asymptomatic subjects performed large diameter pendulum exercises, regardless of whether they were performed correctly (using trunk motion to create GH movement) or incorrectly (using shoulder muscles to create GH movement). These muscle activation levels may be too high for recently

repaired tissues. Smaller diameter exercises kept percent activation levels below 15% for infraspinatus and below 10% for supraspinatus.

### “Gear Shift” Exercises

**Patient position and procedure:** Sitting with the involved arm at the side, holding a cane or wand with the tip resting on the floor to support the weight of the arm. Instruct the patient to move the pole forward and back, diagonally, or laterally and medially in a motion similar to shifting gears in a car with a floor shift (Fig. 17.23).

**FIGURE 17.23** Gear shift exercise. Self-assisted shoulder rotation using a cane. Flexion/extension and diagonal patterns also can be done.

### Early Motion of the Scapula

PROM and A-AROM of the scapula are described in Chapter 3. During the acute phase, the side-lying position is usually more comfortable than prone-lying. If the patient can perform active scapular elevation/depression and protraction/retraction, use the sitting position.

### Early Neuromuscular Control

Frequently, the muscles of the rotator cuff are inhibited after trauma or surgery.<sup>217</sup> Initiate the following to stimulate activation and develop control in key muscles as soon as the patient tolerates it.

#### Multiple-Angle Muscle Setting

Begin gentle multiple-angle muscle-setting exercises of the internal and external rotators in pain-free positions of humeral flexion or scapular plane elevation. Activate the

scapular and remaining GH muscles with gentle muscle-setting techniques in positions that do not exacerbate symptoms.

### Protected Weight Bearing

In sitting in front of a table, have the patient lean onto his or her hands or elbows and gently move from side-to-side. This helps to seat the humeral head in the glenoid fossa and stimulate muscle action.

## Exercise Techniques to Increase Flexibility and Range of Motion

To regain neuromuscular control and function in the shoulder girdle, it may be necessary to increase flexibility in restricted muscles and fascia, so proper shoulder girdle alignment and functional ranges are possible. The principles of muscle inhibition and passive stretching are presented in Chapter 4. Techniques to stretch tight joints in the shoulder girdle are discussed earlier in this chapter with reference to Chapter 5 (joint mobilization/manipulation procedures). Specific manual and self-stretching techniques are described in this section.

### FOCUS ON EVIDENCE

In a randomized trial of 20 subjects with restricted GH joint mobility, the experimental group underwent a one-time intervention of soft tissue mobilization of the subscapularis, followed by contract-relax against manual resistance to the internal rotators, and then actively moved their extremity through the D<sub>2</sub> PNF pattern (flexion, abduction, and external rotation). The control group received no treatment; they rested for 10 minutes. The intervention group had an immediate posttreatment increase in external rotation of  $16.4^\circ \pm 5.5^\circ$  compared with  $0.9^\circ \pm 1.5^\circ$  in the control group and an increase in overhead reach of  $9.6 \pm 6.2$  cm compared with  $2.4 \pm 4.5$  cm in the control group. These increased motions for the intervention group were significantly greater than control group increases.<sup>66</sup> While this result is positive, because no long-term results were evaluated it is important to stress the need for continued self-stretching and ROM exercises as part of the patient's home exercise program.

### Self-Stretching Techniques to Increase Shoulder ROM

Teach the patient a low-intensity, prolonged stretch. Emphasize the importance of not using ballistic stretches at the end of the range.

### To Increase Flexion and Horizontal Adduction: Cross-Chest Stretch

■ *Patient position and procedure:* Sitting or standing. Teach the patient to horizontally adduct the tight shoulder by placing the arm across the chest and then applying sustained over-pressure by pulling the arm toward the chest (Fig. 17.24 A).

**NOTE:** The cross-chest stretch is used to increase mobility in the structures of the posterior GH joint, typically seen in shoulder impingement syndromes.<sup>129</sup>

■ *Patient position and procedure:* Side-lying on the affected side, with the shoulder and elbow each flexed to 90° and arm internally rotated. Have the patient stretch the affected arm into horizontal adduction by reaching across the body with the opposite arm, grasping the elbow, and lifting it off the table. This side-lying position provides stabilization to the scapula (Fig 17.24 B).<sup>226</sup>

**FIGURE 17.24** Self-stretching to increase horizontal adduction in standing (A), and in the “sleeper position” to stabilize the scapula (B).

### To Increase Flexion and Elevation of the Arm

*Patient position and procedure:* Sitting with the involved side next to the table, forearm resting along the table edge, and elbow slightly flexed (Fig. 17.25 A). Have the patient slide the forearm forward along the table while bending from the waist. Eventually, the head should be level with the shoulder (Fig. 17.25 B).

**FIGURE 17.25** (A) Beginning and (B) end positions for self-stretching to increase shoulder flexion with elevation.

### To Increase External (Lateral) Rotation

■ *Patient position and procedure:* Standing and facing a door-frame with the palm of the hand against the edge of the frame and elbow flexed 90°. While keeping the arm against the side or in slight abduction (held in abduction with a folded towel or small pillow under the axilla), have the patient turn away from the fixed hand (Fig. 17.26 A).

**FIGURE 17.26** Self-stretching to increase external rotation of the shoulder (A) with the arm at the side using a doorframe and (B) with the arm in the plane of the scapular using a table to stabilize the forearm.

- **Patient position and procedure:** Sitting at the side of a table with the forearm resting on the table and elbow flexed to 90°. Have the patient bend from the waist, bringing the head and shoulder level with the table (Fig. 17.26 B).

**PRECAUTION:** Avoid the stretch position (illustrated in Figure 17.26 B) if there is anterior GH instability.

### To Increase Internal Rotation

- **Patient position and procedure:** Standing facing a doorframe with the elbow flexed to 90° and the back of the hand against the frame. Have the patient turn his or her trunk toward the fixed hand.
- **Patient position and procedure:** Side-lying on the affected side, with the shoulder and elbow each flexed to 90° and arm internally rotated to end position (“sleeper” position). Have the patient then push the forearm toward the table with the opposite hand (Fig. 17.27).

**FIGURE 17.27** Self-stretching in the “sleeper position” to increase internal rotation of the shoulder using a table to stabilize the humerus.

### FOCUS ON EVIDENCE

The horizontal cross-chest stretch described earlier in this section (see Fig 17.24) can also increase GH internal rotation ROM. In subjects with loss of GH internal rotation of at least 10° compared to their contralateral shoulder, performing this stretch five times daily for 30 seconds over a 4-week duration significantly increased GH internal rotation and total GH rotation compared to the opposite shoulder and to a control group.<sup>129</sup> Similar results were reported in another study using the horizontal adduction stretch,<sup>122</sup> while the side-lying “sleeper” stretch (see Fig. 17.24B) has also been shown to effectively increase GH internal rotation, total GH rotation, and reaching up the back compared to the opposite shoulder.<sup>129</sup>

### To Increase Abduction and Elevation of the Arm

**Patient position and procedure:** Sitting with the side next to a table, the forearm resting with palm up (supinated) on the table and pointing toward the opposite side of the table

(Fig. 17.28 A). Have the patient slide his or her arm across the table as the head is brought down toward the arm and the thorax moves away from the table (Fig. 17.28 B).

**FIGURE 17.28** (A) Beginning and (B) end positions for self-stretching to increase shoulder abduction with elevation.

### To Increase Extension of the Arm

**Patient position and procedure:** Standing with the back to the table, both hands grasping the edge with the fingers facing forward (Fig. 17.29 A). Have the patient begin to squat while letting the elbows flex (Fig. 17.29 B).

**FIGURE 17.29** (A) Beginning and (B) end positions for self-stretching to increase shoulder extension.

**PRECAUTION:** If a patient is prone to anterior subluxation or dislocation, this stretching technique should not be done.

## To Increase Internal Rotation, Extension, and Scapular Tilting

**Patient position and procedure:** Sitting or standing. Have the patient hold each end of a towel or a wand with one arm overhead and the arm to be stretched behind the lower back, and then pull up on the towel (or wand) with the overhead hand (see position in Fig. 17.13). This stretch is used to increase the ability to reach behind the back. It is a generalized stretch that does not isolate specific tight tissues. Before using it, each component of the motion should be stretched, so no one component becomes overstretched relative to the other components.

**PRECAUTION:** If a patient has anterior or multidirectional GH joint instability or has had recent anterior stabilization surgery to correct a dislocated shoulder, this stretch should not be done until late in the rehabilitation program when the capsule is well healed, because it forces the head of the humerus against the anterior capsule.

## Manual and Self-Stretching Exercises for Specific Muscles

Manual stretching of specific multijoint muscles that affect alignment of the shoulder girdle are presented in this section along with self-stretching techniques for these muscles.

### To Stretch the Latissimus Dorsi Muscle

#### Manual Stretch

**Patient position and procedure:** Supine, with hips and knees flexed so the pelvis is stabilized in a posterior pelvic tilt. If necessary, provide additional stabilization to the pelvis with one hand. With the other hand, grasp the distal humerus and flex, laterally rotate, and partially abduct the shoulder to the end of the available range. Have the patient contract into extension, adduction, and medial rotation while providing resistance for a hold-relax maneuver. During the relaxation phase, elongate the muscle (see Fig. 4.16 B).

#### Self-Stretch

- **Patient position and procedure:** Hook-lying with the pelvis stabilized in a posterior pelvic tilt and the arms flexed, laterally rotated, and slightly abducted overhead as far as possible (thumbs pointing toward floor). Allow gravity to provide the stretch force. Instruct the patient not to allow the back to arch.
- **Patient position and procedure:** Standing with back to a wall and feet forward enough to allow the hips and knees to partially flex and flatten the low back against the wall, with the arms in a “hold-up” position (abducted 90° and laterally rotated 90° if possible). Tell the patient to slide the back of the hands up the wall as far as possible without allowing the back to arch.

**NOTE:** This exercise is also used to activate the lower trapezius and serratus anterior, as they upwardly rotate and depress the scapulae during humeral abduction.

## To Stretch the Pectoralis Major Muscles

#### Manual Stretch

**Patient position and procedure:** Sitting on a treatment table or mat, with the hands behind the head. Kneel behind the patient and grasp the patient’s elbows (Fig. 17.30). Have the patient breathe in as he or she brings the elbows out to the side (horizontal abduction and scapular adduction). Hold the elbows at this end point as the patient breathes out. No forceful stretch is needed against the elbows, because the rib cage is elongating the proximal attachment of the pectoralis major muscles bilaterally. As the patient repeats the inhalation, again move the elbows up and out to the end of the available range and hold as the patient breathes out. Repeat only three times in succession to avoid hyperventilation.

**FIGURE 17.30** Active stretching of the pectoralis major muscle. The therapist gently pulls the elbows posteriorly while the patient breathes in and then holds the elbows at the end point as the patient breathes out.

**PRECAUTION:** Hyperventilation should not occur, because the breathing is slow and comfortable. If the patient does become dizzy, allow time to rest; then reinstruct for proper technique. Be sure the patient maintains the head and neck in the neutral position, not forward.

#### Self-Stretch

- **Patient position and procedure:** Standing, facing a corner or open door, with the arms in a reverse T or a V against the wall (Fig. 17.31 A & B). Have the patient lean the entire body forward from the ankles (knees slightly flexed). The degree of stretch can be adjusted by the amount of forward movement.
- **Patient position and procedure:** Sitting or standing and grasping the wand with the forearms pronated and elbows flexed 90°. Have the patient then elevate the shoulders and bring the wand behind the head and shoulders (Fig. 17.32).

**FIGURE 17.31** Self-stretching the pectoralis major muscle with the arms in a reverse-T position to stretch **(A)** the clavicular portion and in a V-position to stretch **(B)** the sternal portion.

**FIGURE 17.32** Wand exercises to stretch the pectoralis major muscle.

**FIGURE 17.33** Active stretching of the pectoralis minor muscle. The therapist holds the scapular and coracoid process at the end point as the patient breathes out.

The scapulae are adducted, and the elbows are brought out to the side. Combine with breathing by having the patient inhale as he or she brings the wand into position behind the shoulders; then exhale while holding this stretched position.

### To Stretch the Pectoralis Minor Muscle

#### Manual Stretch [VIDEO 17.1](#)

**Patient position and procedure:** Sitting, place one hand posterior on the scapula and the other hand anterior on the shoulder just above the coracoid process (Fig. 17.33). As the patient breathes in, tip the scapula posteriorly by pressing up

and back against the coracoid process while pressing downward against the inferior angle of the scapula; then hold it at the end position while the patient breathes out. Repeat, readjusting the end position with each inhalation and stabilizing as the patient exhales.

#### Self-Stretch

**Patient position and procedure:** Standing with the involved humerus at 90° abduction and elbow at 90° flexion and the forearm stabilized against a doorway. Instruct the patient to rotate the trunk away from the involved shoulder until a stretch is

felt.<sup>17</sup> Note that this stretch may not be appropriate for patients with anterior instability, as this is their position of apprehension and it may overly strain the anterior GH joint restraints.

### To Stretch the Levator Scapulae Muscle

**NOTE:** The levator scapulae muscle attaches to the superior angle of the scapula and causes it to rotate downward and elevate; it also attaches to the transverse processes of the upper cervical vertebrae and causes them to backward bend and rotate to the ipsilateral side. To minimize stress to the cervical spine, it is recommended that the cervical spine and head be placed at end-range and stabilized and that the stretch force be applied against the scapula.

#### Manual Stretch VIDEO 17.1

**Patient position and procedure:** Sitting with the head rotated opposite to side of tightness (looking away from the tight side) and forward bent until a slight pull is felt in the posterolateral aspect of the neck. The arm on the side of tightness is abducted, and the hand is placed behind the head to help stabilize it in the rotated position. Stand behind the patient and stabilize with one arm; place the other hand (same side as the tight muscle) over the superior angle of the scapula (Fig. 17.34). With the muscle now in its stretched position, have the patient breathe in, then out. Hold the shoulder and scapula down to maintain the stretch as the patient breathes in again (he or she contracts the muscle against the resistance of the fixating hand). To increase the stretch, press down against the superior angle of the scapula. This is not a forceful stretch but a gentle hold-relax maneuver. Do not stretch the muscle by forcing rotation on the head and neck.

**FIGURE 17.34** Stretching of the levator scapulae muscle. The therapist stabilizes the head and scapula as the patient breathes in, contracting the muscle against the resistance. As the patient relaxes, the rib cage and scapula depress, which stretches the muscle.

#### Self-Stretch

■ **Patient position and procedure:** Standing with the head side bent and rotated away from the tight side, place the ipsilateral hand behind the head and the bent elbow against a

wall. The other hand can be placed across the forehead to stabilize the rotated head. Instruct the patient to slide the elbow up the wall as he or she takes in a breath, then hold the position while exhaling (Fig. 17.35 A).

■ **Patient position and procedure:** Sitting with head side bent and rotated away from the tight side. To stabilize the scapula, have the patient reach down and back with the hand on the side of the tightness and hold onto the seat of the chair. The other hand is placed on the head to gently pull it forward and to the side in an oblique direction opposite the line of pull of the tight muscle (Fig. 17.35 B).

**FIGURE 17.35** Self-stretching of the levator scapulae muscle (A) using upward rotation of the scapula and (B) using depression of the scapula.

### To Stretch the Upper Trapezius Muscle

#### Manual Stretch

■ **Patient position and procedure:** Sitting with the ipsilateral hand behind the back to stabilize the scapula and the head rotated to the tight side. Stand behind the patient and apply the stretch by adding a combination of cervical flexion, further rotation to the tight side, and side bending away from the tight side. A more aggressive manual stretch can be performed by using the other hand to depress the distal clavicle and the scapula.

**PRECAUTION:** Applying a stretch force against the head should not be done if the patient has cervical symptoms.

#### Self-Stretch

**Patient position and procedure:** Sitting or standing with the ipsilateral hand behind the back to stabilize the scapula. Instruct the patient to rotate his neck toward the tight side, then side bend away from the tight side and then add neck flexion. The patient may use the contralateral arm to grasp his or her own head to apply the stretch (Fig. 17.36).

**FIGURE 17.36** Self-stretching of the upper trapezius muscle.

## Exercises to Develop and Improve Muscle Performance and Functional Control

Developing control of the scapulothoracic and GH musculature is fundamental to correcting pathomechanics of the shoulder girdle and for improving strength, muscle endurance, power, and performance of functional activities. During observation of scapular alignment and movement, if excessive scapular tilting, winging, or poorly coordinated scapulohumeral rhythm during humeral elevation is identified, it is important to correct these faulty mechanics with properly chosen exercises. Likewise, insufficient stabilization and control of GH rotation and translation during humeral elevation necessitate the selection of exercises that emphasize training the rotator cuff musculature.

- The exercises described in the following sections begin at the simplest or least stressful level and progress to more complex and difficult levels.
- Exercises also progress from uniplanar or isolated muscle activation to use of combined, functional patterns.
- Initially, choose exercises that help the patient focus on activating correct muscles with appropriate timing and sequencing to counteract the identified impairments.
- Then increase the challenge by emphasizing patterns of exercises that prepare the musculature to respond to functional demands.

Regardless of the level of exercise, it is important to challenge patients at intensities they can meet so they can safely progress to more intense levels. Before teaching the resistance exercises and functional training activities presented in this section, it is important that the reader understands and applies the principles of resistance exercise, open- and closed-chain training, specificity of training, aerobic conditioning, and balance training described in Chapters 6 through 8. It is also important to apply the principles of tissue healing described in Chapter 10 and integrate the precautions for exercise associated with various shoulder pathologies and surgical interventions presented in this chapter. Because posture has a direct effect on the function

of the shoulder complex, refer to Chapters 14 and 16 for principles and exercises to correct postural impairments that might underlie faulty shoulder mechanics. In addition to the exercises described in this section, high-demand exercises, such as plyometric training<sup>216</sup> and advanced activities for balance and stability, that may be appropriate in a shoulder rehabilitation program for selected individuals are presented in Chapter 23.

Box 17.11 summarizes a sequence for progressing exercises to improve muscle performance and shoulder girdle function and move an individual toward functional recovery.

### Isometric Exercises

Isometric exercises are applied along a continuum of very gentle to maximum contraction, and they are applied at varying muscle lengths by changing joint angles. Choice of the intensity, muscle length, or joint angle and the number of repetitions is based on current strength, stage of recovery after injury or surgery, and/or the pathomechanics of the region.

#### BOX 17.11 Summary of Exercise Progressions for Shoulder Function

- Develop awareness and control of weak or disused muscles. Place emphasis on activating scapulothoracic and trunk musculature prior to glenohumeral musculature.
- For weak or surgically repaired musculature, begin with setting exercises and multiple-angle isometrics against minimal resistance and active-assistive ROM in open- and closed-chain positions within pain-free or protected ranges.
- Provide just enough resistance and repetitions to challenge the muscles without provoking symptoms.
- Include concentric and eccentric exercises.
- Develop control in postural muscles for stability of scapular and glenohumeral joints with stabilization exercises in both open- and closed-chain positions.
- As stabilizing control develops in the scapula and GH muscles, progress to dynamic resistance exercises, emphasizing scapular and rotator cuff muscle control during open- and closed-chain motions.
- First isolate and strengthen weak motions and muscles so substitute motions and inappropriate timing of muscle actions do not dominate.
- Develop muscle endurance simultaneously with muscle strength.
- Progress to combined movement patterns that simulate functional activities and train muscle groups to function in a coordinated sequence of control and motion.
- Integrate simple functional tasks into the exercise program and progress to more complex and challenging activities, always incorporating proper body mechanics.
- Implement total body exercises to improve cardiopulmonary endurance and balance.
- As necessary, based on functional goals, incorporate high-intensity eccentric exercises and plyometric training (stretch-shortening drills)<sup>216</sup> and agility drills at increasing speeds of movement into the shoulder rehabilitation program.

## Scapular Muscles

**Patient position and procedure:** Side-lying, prone-lying, or sitting, with the arm supported if necessary. Resist elevation, depression, protraction, or retraction with pressure directly on the scapula in the direction opposite the motion.

**Depression (lower trapezius).** Activation of the lower trapezius is indicated when there is anterior tilting and delayed upward rotation of the scapula often seen with impingement syndromes. Apply resistance against the inferior angle of the scapula (Fig. 17.37 A).

**Protraction (serratus anterior).** Activation of the serratus anterior is emphasized when there is scapular winging, delayed or incomplete upward rotation of the scapula with GH elevation, or with accelerated downward rotation (“dumping”) of the scapula during arm lowering. Apply resistance against the axillary border of the scapula or coracoid process or indirectly against the humerus positioned in the plane of the scapula (Fig. 17.37 B).

**Retraction (rhomboids and trapezius).** Activation of the rhomboids and trapezius muscle groups is emphasized when

**FIGURE 17.37** Isometric or dynamic manual resistance to scapular muscles. (A) Resistance to elevation/depression. (B) Resistance to protraction/retraction. Direct the patient to reach across the therapist’s shoulder to protract the scapula while the therapist resists against the coracoid and acromion process. The therapist’s other hand is placed behind the scapula to resist retraction.

the scapular posture is protracted (abducted), as typically seen with a forward head and increased kyphotic posture. Apply resistance against the medial border of the scapula.

## Multiple-Angle Isometrics: GH Muscles

**Patient position and procedure:** Supine, sitting, or standing. If pain from joint compression occurs, a slight distractive force to the GH joint as resistance is applied may decrease patient discomfort.

**External and internal rotation.** Position the humerus at the patient’s side in slight flexion, slight abduction, or slight scapular plane elevation and the elbow flexed 90°. Apply resistance against the dorsal surface of the forearm to resist external rotation (Fig. 17.38 A) and to the volar surface to resist internal rotation (Fig. 17.38 B).

**Abduction.** Maintain the humerus neutral to rotation and resist abduction at 0°, 30°, 45°, and 60°. If there are no

**FIGURE 17.38** Isometric or dynamic resistance to shoulder rotation. (A) External rotation with the shoulder in the plane of the scapula. (B) Internal rotation with the shoulder at 90° abduction.

contraindications to motion above 90°, preposition the humerus in external rotation before elevating the humerus and resisting above 90° abduction.

**Scapular plane elevation.** Position midway between flexion and abduction and resist at various positions in the range, such as 30° and 60° in the plane of the scapula (Fig. 17.39).

**FIGURE 17.39** Isometric resistance in scapular plane elevation. The shoulder is positioned between 30° and 60° degrees of elevation, and controlled manual resistance is applied against the humerus.

**Extension.** Position the humerus at the side or in various positions of flexion and apply resistance against the humerus.

**Adduction.** Position the humerus between 15° and 30° abduction and apply resistance against the humerus.

**Elbow flexion with forearm supination.** Position the humerus at the side and neutral to rotation. Apply resistance to forearm flexion, causing tension in the long head of the biceps. Change the position of the shoulder into more flexion or extension and repeat the isometric resistance to elbow flexion.

### Self-Applied Multiple-Angle Isometrics

Teach the patient how to independently apply isometric resistance using positions and intensities consistent with therapeutic goals. The patient can use the opposite hand (Fig. 17.40) or a stationary object, such as a wall or door frame (Fig. 17.41).

### Stabilization Exercises

The application of alternating isometrics and rhythmic stabilization techniques (described in Chapter 6) is designed to develop strength and stability of proximal muscle groups in response to shifting loads. The shoulder girdle functions in both open- and closed-chain activities, and therefore, the muscles should be trained to respond to both situations.

- Begin training the scapular muscles so that when the muscles of the GH joint contract, they have a stable base on which to produce force (scapular stability).
- Initially, apply the alternating resistance slowly and instruct the patient to “hold” against the resistance.
- At the beginning of training, it also may be necessary to tell the patient which way you are going to push to help the patient focus on the contracting muscles and alternating forces.
- As the patient learns to respond by contracting the proper muscles and stabilizing the joints, increase the rapidity of the shifting resistance and decrease the verbal cues to enhance automatic responses.

**FIGURE 17.40** Self-resistance for isometric shoulder (A) flexion, (B) abduction, and (C) rotation.

**FIGURE 17.41** Using a wall to provide resistance for isometric shoulder (A) flexion, (B) abduction, and (C) rotation.

### Open-Chain Stabilization Exercises for the Scapular Muscles **VIDEO 17.2**

Begin with the patient side-lying, with the affected extremity up. Drape the forearm of the involved extremity over your shoulder. The degree of shoulder flexion, scaption, or abduction can be controlled by your stance and the relative position of the patient. Progress to sitting with the patient's arm draped over your shoulder; apply resistance to all scapular motions in the same manner as described previously.

**Scapular elevation/depression.** Place your top hand superiorly and the other hand inferiorly around the scapula to provide manual resistance (see Fig. 17.37 A).

**Scapular protraction/retraction.** Place your top hand along the medial border and the other around the coracoid process to provide resistance (see Fig. 17.37 B).

**Scapular upward and downward rotation.** Place one hand around the inferior angle and the other hand around the acromion and coracoid process to provide resistance.

### Open-Chain Stabilization Exercises for the Shoulder Girdle

**Patient position and procedure:** Supine holding a rod or ball with elbows extended and shoulders flexed to 90°. Stand at the patient's head and grasp the rod; instruct the patient to hold against or match the resistance you provide. Push, pull, and rotate the rod in various directions (Fig. 17.42). Resistance can also be applied directly against the arm or forearm.

- If too much assistance is being provided by the normal extremity, apply the stabilization technique to just the involved extremity.
- As the patient gains control, progress to sitting and then standing and have the patient hold the arm in various positions as alternating resistance is applied. Observe the scapula to be sure there is good stabilization. If not, return to the exercises described above or decrease the intensity

**FIGURE 17.42** Stabilization exercises. The patient stabilizes with the shoulder girdle musculature (isometrically) against the resistance imposed by the therapist. Resistance to flexion/extension, abduction/adduction, and rotation is applied in a rhythmic sequence.

of resistance. Progress these exercises to functional patterns as strength and control improve.

#### CLINICAL TIP

Studies have documented that when healthy individuals<sup>110</sup> or patients with shoulder instability<sup>26</sup> use the BodyBlade® during dynamic GH exercises (see Fig. 23.17), such as shoulder flexion and abduction, the scapulothoracic stabilizing muscles are activated to a greater extent than when the exercises are performed using weights or elastic resistance.

### Static Closed-Chain (Weight-Bearing) Stabilization Exercises

Weight bearing activates the stabilizing muscles in proximal joints and may be a stimulus for improving fluid dynamics of articular cartilage as described in Chapter 5. Early during the controlled motion phase of management, it may be beneficial to initiate stabilization exercises in protected weight-bearing positions if tolerated by the healing tissues. The amount and intensity of weight bearing and resistance are progressively increased as tissues heal.

**NOTE:** If scapular winging occurs when the patient is weight bearing, do not progress these exercises until there is enough strength to stabilize the scapula against the rib cage.

#### FOCUS ON EVIDENCE

To help determine when upper extremity weight-bearing exercises could be included in an exercise program, Uhl and colleagues<sup>206</sup> analyzed the pectoralis major, anterior and posterior deltoid, supraspinatus, and infraspinatus with surface EMG in a progression of static exercises in 18 healthy subjects. Positions for isometric exercises included the prayer position (to simulate weight bearing against a wall), quadruped, tripod, pointer, push-up position (shoulders flexed to 90°), push-up position with feet elevated 18 inches (45 cm), and one-arm push-up position. There was a significant correlation between the increasing weight-bearing postures and increased muscular activity ( $r = 0.97, p < 0.01$ ) in all the muscles. Also, the infraspinatus was the most active of the muscles tested in all positions except the prayer position (in which the pectoralis major was most active).

The authors suggest that the prayer and quadruped positions were appropriate for early rehabilitation owing to the

low-activity level in all the muscles; that the tripod and pointer positions placed an intermediate demand on the infraspinatus and deltoid musculature; and that the push-up positions placed a high demand on the infraspinatus. They also conclude that the two-handed positions required less demand on the posterior deltoid but more load on the anterior deltoid and pectoralis muscles and that the one-arm push-up placed a high demand on all muscles except the supraspinatus.

#### ■ Scapular stabilization.

**Patient position and procedure:** Side-lying on the uninvolved side. Both the elbow and shoulder of the involved arm are flexed to 90°, with the hand placed on the table and bearing some weight. Resist the scapular motions of elevation/depression and retraction directly against the scapula; resist protraction by pushing against the elbow.

#### ■ Alternating isometrics in protected weight bearing. VIDEO 17.3

**Patient position and procedure:** Sitting with forearms placed on thighs or a table or standing with hands placed on a table. Lean forward slightly to place light body weight through the extremities. Apply gentle resistance against the shoulders and ask the patient to match the resistance and “hold.” Apply resistance in various directions.

#### ■ Progression of closed-chain stabilization exercises.

**Patient position and procedure:** Standing with shoulder at 90° and one or both hands leaning against a wall or on a ball (Fig. 17.43).

- Additional, more advanced activities include having the patient assume the quadruped (all-fours) position with hands on the floor. Apply alternating resistance against

**FIGURE 17.43** Closed-chain scapular and glenohumeral stabilization exercises. (A) Bilateral support in a minimal weight-bearing position with both hands against a wall. (B) Unilateral support on a less stable surface (ball). The therapist applies alternating resistance while the patient stabilizes against the resistance, or the therapist applies resistance as the patient moves from side-to-side.

the shoulders or trunk and ask the patient to “hold” against the force. Pressing forward against the trunk increases the effect of body weight through the upper extremities and requires the serratus anterior to stabilize more strongly against the additional force. As already noted, if scapular winging occurs, reduce the resistance or the degree of weight bearing.

- Progress further by placing hands on unstable surfaces, such as a rocker or wobble board or on a ball, to require greater neuromuscular control and balance reactions. Each of these activities also can be done with weight bearing on only the involved upper extremity.

### Dynamic Closed-Chain (Weight-Bearing) Stabilization Exercises

Dynamic stabilization in weight-bearing positions requires the stabilizing muscles to maintain control of the scapula and GH joint while moving the body weight over the fixed extremity or extremities.

- *Patient position and procedure:* Standing with shoulders flexed 90° and hands supported against a wall or leaning into hands on a table. Have the patient shift his or her body weight from one extremity to the other (rock back and forth). Apply resistance against the shoulders (see Fig. 17.43).
- *Progression:* Have the patient alternately lift one upper extremity and then the other, so that one extremity bears the body weight and stabilizes against the shifting load.
  - Apply manual resistance to the shoulders or strap a weight around each wrist.
  - Apply manual resistance to the shoulders or trunk that becomes more variable in direction, timing, and amount of force.
- *Patient position and procedure:* Quadruped (all-fours) position with both hands on a stable surface; have the patient raise the ipsilateral and then contralateral leg to increase serratus activity and lower trapezius activity respectively.<sup>118</sup>
  - *Progression:* Perform with both hands on a rocker board, wobble board, or BOSU™ or perform alternating leg raises while only one hand bears weight on a stable or unstable support surface (see Chapter 23).

### Dynamic Strengthening Exercises: Scapular Muscles

It is imperative that the proximal stabilizing muscles of the thorax, neck, and scapula function properly before initiating dynamic strengthening of the muscles that move the GH joint through the ROM to avoid faulty mechanics. Strengthening exercises can be performed in both open- and closed-chain positions. Progress exercises with repetitions and resistance within the mechanical limits of the involved tissues.

Initially apply light resistance with multiple repetitions for dynamic control and muscular endurance. As control develops, progress to combined patterns of motion and training for muscle groups to function in a coordinated sequence. Begin with simple functional activities and progress to more complex and challenging activities. Both muscular endurance

and strength are necessary for postural and dynamic control of activities.

### FOCUS ON EVIDENCE

A number of studies have been carried out to identify muscle activation during a variety of exercises for the shoulder girdle. Two EMG studies<sup>51,86</sup> analyzed exercises often used to strengthen the scapular muscles using either free weights or elastic tubing against maximum resistance. The findings of these two studies and a subsequent review of the literature<sup>162</sup> report the degree of trapezius and serratus anterior muscle activation during the following exercises:

- *Shoulder shrug, standing:* strongly activates the upper trapezius.
- *Full elevation of the arm above the head in the prone-lying position:* activates all three portions of the trapezius and serratus anterior when the humerus is in line with the fibers of the lower trapezius.
- *External rotation in the prone-lying position with the shoulder positioned at 90° abduction and the elbow flexed 90°:* strongly activates the lower trapezius. This position is the “best exercise” to cause maximum depression of the scapula and isolation of the lower trapezius from the middle and upper portions.<sup>51</sup>
- *Horizontal abduction in the prone-lying position with the shoulder in external rotation:* activates the middle and lower trapezius.
- *Rowing action, seated or prone-lying:* emphasizes the middle trapezius over the upper and lower trapezius.<sup>162</sup>
- *Push-up with a plus:* strong activation of serratus anterior.<sup>162</sup>
- *Diagonal exercises and shoulder abduction in the plane of the scapula above 120°:* higher activity in the serratus anterior than in the trapezius.
- *Isolated protraction exercises:* do not activate the serratus anterior to as great a degree as arm elevation exercises.<sup>51</sup>

In another study, based on evidence suggesting that upper trapezius activation should be minimized compared to activation of other scapulothoracic muscles during movement, Cools and associates<sup>36</sup> examined several exercises for the activation ratios among the muscles. Favorable exercises (those with decreased upper trapezius activation and increased lower or middle trapezius activation) included side-lying flexion, side-lying external rotation, prone horizontal abduction with humeral external rotation, and prone extension. Favorable exercises for decreased upper trapezius and increased serratus anterior activation included high rowing and arm elevation with humeral external rotation in both the sagittal and scapular planes.

### Scapular Retraction (Rhomboids and Middle Trapezius)

The following exercises are designed to isolate scapular retraction. Once the patient is able to retract the scapula against resistance, combine patterns with the GH joint to progress

strength and functional patterns as described in the next sections.

- **Patient position and procedure:** Prone, sitting, and standing. Instruct the patient to clasp the hands together behind the low back. This activity should cause scapular adduction. Draw attention to the adducted scapulae and have the patient hold the adducted position of the scapulae while the arms are lowered to the sides. Have the patient repeat the activity without arm motion.
- **Patient position and procedure:** Prone with the arm over the edge of the table in a dependent position and a weight in the hand. Instruct the patient to pinch the scapulae together (Fig. 17.44). Progress this exercise to prone rowing and horizontal abduction against gravity (described below).

**FIGURE 17.44** Scapular retraction against handheld resistance in the prone position.

- **Patient position and procedure:** Sitting or standing with the shoulder flexed to 90° and elbows extended. Have the patient grasp each end of an elastic band or tubing that has been secured at shoulder level or a two-handled pulley that is at shoulder level, and pinch the scapulae together by pulling against the resistance.

### Scapular Retraction Combined With Shoulder Horizontal Abduction/Extension (Rhomboids, Middle Trapezius, Posterior Deltoid)

- **Patient position and procedure:** Prone with shoulders abducted 90°, elbows flexed, and forearms perpendicular to the floor. Instruct the patient to perform horizontal abduction with scapular retraction. This exercise can also be done with the elbows extended for greater resistance (Fig. 17.45). Progress this exercise by adding weights and then by having the patient perform the rowing motion standing or sitting in front of a length of elastic resistance that has been secured at shoulder level.

**FIGURE 17.45** Horizontal abduction and scapular retraction exercises, with the arms positioned for maximal resistance from gravity. External rotation of the shoulders (thumbs pointing upward) emphasizes the middle and lower trapezius. To progress the exercise further, weights can be placed in the patient's hands.

### ■ Corner press-out.

**Patient position and procedure:** Standing with the back toward a corner, shoulders abducted 90°, and elbows flexed. Instruct the patient to press the elbows into the walls and push the body weight away from the corner (Fig. 17.46).

**FIGURE 17.46** Corner press-out to strengthen scapular retraction and shoulder horizontal abduction (view from above).

### Scapular Retraction and Shoulder Horizontal Abduction Combined With External Rotation (Rhomboids, Trapezius, Posterior Deltoid, Infraspinatus, Teres Minor)

- **Patient position and procedure:** Prone with shoulders abducted 90° and externally rotated 90° (90/90 position). The elbows can be flexed 90° (easier position) or extended (more difficult position). Instruct the patient to lift the arm a few degrees off the table. To do this correctly, the scapulae must adduct simultaneously. Greater ROM can be used if these exercises are done on a narrow bench so the arm can begin in a horizontally adducted position.
- **Patient position and procedure:** Sitting or standing with shoulders in the 90/90 position. Secure the middle of a piece of elastic resistance in front of the patient slightly above the shoulders and have the patient grasp each end of

the resistance. Then have the patient pull the hands and elbows back (moving into horizontal abduction and external rotation of the shoulder) while simultaneously adducting the scapulae (Fig. 17.47). **VIDEO 17.4**

**FIGURE 17.47** Combined scapular retraction with shoulder horizontal abduction and external rotation against resistance.

### Scapular Protraction (Serratus Anterior)

- **Patient position and procedure:** Sitting or standing with shoulder flexed approximately 90° and elbow extended. Secure a piece of elastic resistance behind the patient at shoulder level or use a pulley system. Have the patient “push” outward against the resistance without rotating the body (Fig. 17.48).
- **Patient position and procedure:** Supine with the arm flexed 90° and slightly abducted and the elbow extended. Place a light weight in the hand if resistance is tolerated and have the patient “push” the weight upward without rotating the body.

**FIGURE 17.48** Scapular protraction; pushing against elastic resistance.

Then have the patient “give an extra push” to protract the scapulae. Progress wall push-ups to table push-ups, then to prone push-ups on the knees, and finally prone push-ups on the toes with knees extended (Fig. 17.49). Add weight around the trunk if the patient is able to tolerate greater resistance.

**FIGURE 17.49** Push-ups with a “plus” to strengthen scapular protraction.

### CLINICAL TIP

According to a study by Ekstrom and colleagues,<sup>51</sup> isolated protraction exercises do not activate the serratus anterior as effectively as exercises that involve dynamic upward rotation of the scapula as occurs during arm elevation.

### ■ Push-ups with a “plus.” **VIDEO 17.5**

**Patient position and procedure:** Standing and leaning on forearms or hands against a wall. Have the patient place his or her forearms or hands directly in front or slightly to the side of the shoulders and push the trunk away from the wall.

### ■ Push-ups with a “plus” with leg lifts.

**Patient position and procedure:** Quadrupedal (all-fours) position. Perform a push-up with a “plus” on a stable surface. Then alternately lift the lower extremities. Progress to an unstable surface (see Chapter 23 for examples).

### CLINICAL TIP

A study examining scapulothoracic muscle activation compared activation during variations of the push-up with a “plus” exercise performed while in the quadrupedal position. The findings of this study demonstrated that raising the ipsilateral leg

during the push-up with a “plus” increased serratus anterior activity, whereas raising the contralateral leg increased lower trapezius activity.<sup>118</sup>

### Scapular Depression (Lower Trapezius, Lower Serratus Anterior)

- **Patient position and procedure:** Sitting with elbow flexed. Provide manual resistance in an upward direction under the elbow, and ask the patient to push down into your hands. Caudal gliding of the humeral head may also occur (Fig. 17.50 A).

A

A

**FIGURE 17.50** Exercises that emphasize the lower trapezius. **(A)** Shoulder girdle depression against manual resistance. **(B)** Closed-chain shoulder girdle depression using body weight for resistance.

### ■ Upright press-up. VIDEO 17.5

**Patient position and procedure:** Sitting or standing with both hands on blocks, the armrests of a chair, or parallel bars. Have the patient push down on the hands and lift the body. After the elbows are fully extended, emphasize scapular depression. (Fig. 17.50 B).

### Scapular Upward Rotation With Depression (Lower Trapezius, Serratus Anterior)

Scapular upward rotation with depression cannot be isolated from movement of the humerus. The upward rotation action of the trapezius and serratus anterior requires coordination with humeral elevation. As noted elsewhere in this chapter, a patient may substitute with scapular elevation, primarily using the upper trapezius, so this exercise draws attention to maintaining the scapula in depression while upwardly rotating.

### ■ Arm slide against a wall.

**Patient position and procedure:** Standing with the back to the wall, heels away from the wall enough to comfortably do a posterior pelvic tilt and maintain the back flat against the wall. Begin with arms slightly abducted and externally rotated and the elbows flexed 90°. The backs of the arms should be against the wall. Have the patient slide the hands and arms up the wall (abduction) as far as possible while maintaining the back flat against the wall.

### ■ “Superman” motion prone.

**Patient position and procedure:** Prone, with humerus elevated overhead. Ask the patient to barely lift the arm off the table. This end-range motion may not be possible for patients with restricted GH mobility or impingement syndrome.

### ■ “Superman” motion upright.

**Patient position and procedure:** Sitting or standing with arms in a comfortable overhead position. (This position can be used if the patient has a tight shoulder and cannot assume the “superman motion” while lying prone.) Secure elastic resistance overhead in front of the patient. Instruct the patient to move the shoulder into greater flexion with scapular depression. The scapular depression is most important; it may be necessary to use tactile cues on the lower trapezius to help the patient focus on scapular depression, not scapular elevation (Fig. 17.51).

## Dynamic Strengthening Exercises: Glenohumeral Muscles

Dynamic strength of GH musculature coupled with strength of the scapular stabilizers is necessary for active, pain-free movement of the shoulder girdle during functional activities. Open- and closed-chain strengthening exercises should be incorporated into a shoulder rehabilitation and injury prevention program. Many of the exercises used to strengthen scapular muscles in nonweight-bearing and weight-bearing positions, described in the previous section, also dynamically strengthen some GH muscles. Additional exercises to improve dynamic strength of the shoulder girdle in anatomical and diagonal movement patterns are described in this section.

**FIGURE 17.51** Scapular depression with upward rotation of the scapula against elastic resistance (also activates the upper and middle trapezius and serratus anterior).

### FOCUS ON EVIDENCE

Several EMG studies have investigated exercises commonly used to activate and strengthen shoulder muscles using either free weights or elastic resistance.<sup>8,14,86,162,163</sup> The findings of these studies indicate the extent of activation of the rotator cuff, deltoid, pectoralis major, and latissimus dorsi muscles under maximum load conditions during the following exercises.

- **Shoulder shrug:** causes highest activation in the subscapularis, trapezius, and latissimus dorsi; also activates the supraspinatus, infraspinatus, and serratus anterior.<sup>86</sup>
- **Middle-grip and narrow-grip seated rowing:** activates subscapularis.<sup>86</sup>
- **Wide-grip seated rowing:** activates the infraspinatus and trapezius and to a lesser extent the supraspinatus.<sup>86</sup>
- **External rotation in prone and side-lying positions and in the plane of the scapula:** activates the infraspinatus and teres minor.<sup>8,14,162,163</sup>
- **Internal rotation:** movement of the forearm across the body with arm at side and elbow flexed 90° activates the subscapularis and pectoralis major.<sup>86,162</sup>
- **Forward punch:** causes highest activation in the supraspinatus and anterior deltoid; resistance also activates the pectoralis major and infraspinatus.<sup>86</sup>
- **Horizontal abduction at 100° with full external rotation:** activates the supraspinatus, middle, and posterior deltoid.<sup>163</sup>

### Shoulder External Rotation (Infraspinatus, Teres Minor) VIDEO 17.6

Position the arm at the patient's side or in various positions of abduction, scapular plane elevation, or flexion. Flex the elbow to 90° and apply the resistive force at right angles to the forearm. Be sure the patient rotates the humerus and does not extend the elbow. When the arm is positioned at the patient's side, a folded towel placed between the elbow and side of the rib cage reminds the patient to keep the elbow at the side and ensures proper technique.<sup>162</sup> However, it does not significantly alter recruitment of the external rotators.<sup>163</sup> As indicated in the supporting evidence just presented, external rotation applied in the side-lying position (arm at side), prone-lying in the 90/90 position, and standing with the humerus in scapular plane (45° abduction, 30° horizontal adduction) produces the strongest contractions of these muscles compared with other external rotation exercises.<sup>162,163</sup>

- **Patient position and procedure:** Sitting or standing, using elastic resistance or a wall pulley in front of the body at elbow level. Have the patient grasp the elastic material or the pulley handle and rotate his or her arm outward (Fig. 17.52 A).
- **Patient position and procedure:** Side-lying on the uninvolved side with the involved shoulder up, the arm resting on the side of the thorax, and a rolled towel under the elbow. Have the patient use a handheld weight, cuff weight, or elastic resistance and rotate the arm through the desired ROM.
- **Patient position and procedure:** Prone on a table, upper arm resting on the table with the shoulder at 90° if possible, elbow flexed with forearm over the edge of the table. Lift the weight as far as possible by rotating the shoulder, not extending the elbow (Fig. 17.52 B).

**A**

**FIGURE 17.52** Resisted external rotation with (A) the arm at the side using elastic resistance,

**FIGURE 17.52—cont'd (B)** the arm at 90° using a free weight and the patient lying prone, and **(C)** with the shoulder in scapular plane elevation using a free weight and the patient sitting.

- **Patient position and procedure:** Sitting with elbow flexed 90° and supported on a table so the shoulder is in the resting position (plane of the scapula). The patient lifts the weight from the table by rotating the shoulder (Fig. 17.52 C).

### Shoulder Internal Rotation (Subscapularis)

Position the arm at the patient's side or in various positions of flexion, abduction, or scapular plane elevation. The elbow is flexed to 90°, and the resistive force is held in the hand.

- **Patient position and procedure:** Side-lying on the involved side with the arm forward in partial flexion. Have the patient lift the weight upward off the table into internal rotation (Fig. 17.53).
- **Patient position and procedure:** Sitting or standing using elastic resistance or a pulley system with the line of force out to the side and at the level of the elbow. Have the patient pull across the front of the trunk into internal rotation.

**FIGURE 17.53** Resisted internal rotation of the shoulder using a handheld weight. To resist external rotation, place the weight in the patient's upper hand.

### Shoulder Abduction and Elevation of the Arm in Scapular Plane (Deltoid and Supraspinatus)

Abduction exercises are classically done with the humerus moving in the frontal plane. It is commonly accepted that most functional activities occur with the humerus 30° to 45° forward to the frontal plane in which the arc of motion is more in line with the glenoid fossa of the scapula. Many abduction exercises can be adapted to be performed in the plane of the scapula.

**PRECAUTION:** Teach the patient that whenever the shoulder elevates beyond 90°, it must externally rotate to avoid impingement of the greater tubercle against the acromion. If the patient has impingement syndrome, limit the range to avoid the painful arc.

- **Patient position and procedure:** Sitting or standing with a weight in hand. Have the patient abduct the arm to 90° and then externally rotate and elevate the arm through the rest of the range. This same motion can be performed with elastic resistance secured under the patient's foot, but be cautious in that the greater the elastic stretch, the greater the resistance. The patient may not be able to complete the ROM because of increased resistance at the end of the range.
- **Patient position and procedure:** Side-lying with the involved arm uppermost and elbow extended. Have the patient lift a weight up to 90°. The greatest effect of the resistance is at the beginning of the range. At 90°, all of the force is through the long axis of the bone.
- **Patient position and procedure:** Standing with the humerus externally rotated (*full can position*). Have the patient raise the arm away from the side in the plane of the scapula, halfway between abduction and flexion (Fig. 17.54). Apply

**FIGURE 17.54** Abduction in the plane of the scapula. This is called the “full can” exercise because the shoulder is held in external rotation as if lifting a full can. **(A)** Front view. **(B)** Top view. If the shoulder is held in internal rotation, the exercise is called an “empty can” exercise.

resistance with a handheld weight or elastic resistance secured under the patient’s foot. “Full can” elevation of the arm may also be performed in the prone position with the arm over the side of the table.

### **FOCUS ON EVIDENCE**

EMG studies have confirmed that no one exercise isolates the action of the supraspinatus muscle from the other rotator cuff or deltoid muscles.<sup>120,201</sup> The supraspinatus muscle is effectively activated in both the “empty can” (humerus internally rotated)<sup>91,217</sup> and “full can”<sup>89,120,201</sup> exercises. It also contracts strongly with the military press-up<sup>201</sup> and horizontal abduction with external rotation exercises.<sup>14,120,230</sup> These findings appear to give the therapist several choices of exercises for strengthening the supraspinatus. However, several authors,<sup>45,52,87,89,192</sup> as well as the authors of this text, suggest that the “empty can” exercise should not be used for shoulder rehabilitation because it may cause impingement of the suprahumeral tissues, especially as the arm approaches and elevates above 90°. In support of this, when compared to the “full can” exercise, the “empty can”

exercise has been demonstrated to orient the scapula in greater amounts of internal rotation and anterior tilting, positions believed to increase the risk of subacromial impingement.<sup>192</sup> In contrast, the “full can” position minimizes the chance of impingement.<sup>45,89,162</sup>

### **Shoulder Flexion (Anterior Deltoid, Rotator Cuff, Serratus Anterior)**

**Patient position and procedure:** Sitting, standing, or supine and elbow extended and thumb pointing forward. Have the patient move into forward flexion of the shoulder. If a free weight is used when supine, the greatest resistance is experienced at the beginning of the range; during standing, the greatest resistive force is encountered when the shoulder is flexed to the 90° position. Elastic resistance also can be used if secured under the patient’s foot or a solid object on the floor.

#### ■ **Military press-up.**

**Patient position and procedure:** Sitting, arm at the side in neutral to slight external rotation with elbow flexed and forearm in mid-position (thumb pointing posterior). Have the patient lift the weight vertically to the overhead position (Fig. 17.55).

**FIGURE 17.55** Military press-up. Beginning with the arm at the side in neutral to slight external rotation with elbow flexed and forearm in mid-position (thumb pointing posteriorly), the weight is lifted overhead.

### Shoulder Adduction (Pectoralis Major, Teres Major, Latissimus Dorsi)

**Patient position and procedure:** Sitting or standing with the arm abducted. Have the patient pull down against a pulley force or elastic resistance tied overhead. The greatest resistance is when the line of the resistive force is at right angles to the patient's arm.

### Shoulder Horizontal Adduction (Anterior Deltoid, Coracobrachialis, Pectoralis Major)

**Patient position and procedure:** Supine. Begin with one or both arms out to the side in horizontal abduction. Have the patient bring the arms forward into horizontal adduction until the arms are vertical.

### Shoulder Extension (Posterior Deltoid, Latissimus Dorsi, Rhomboids)

- **Patient position and procedure:** Prone with the arm over the side of the table in 90° flexion. Have the patient lift the weight and extend the shoulder. Simultaneous elbow flexion while extending the shoulder is easier (shorter lever arm); maintaining elbow extension while extending the shoulder is more difficult (longer lever arm).
- **Patient position and procedure:** Sitting or standing with the arm flexed. A pulley or elastic resistance is secured overhead. Have the patient pull down against the resistance into extension.

### Elbow Flexion (Biceps Brachii)

#### ■ Biceps curl.

**Patient position and procedure:** Sitting or standing. Have the patient flex the elbow while holding a handheld weight and keeping the forearm supinated and the arm at the side or with the shoulder moving into slight extension (see Fig. 18.11).

**NOTE:** Because the biceps brachii is a two-joint muscle, the muscle not only serves to flex the elbow as its primary function, the long head assists the rotator cuff muscles by acting as an additional dynamic stabilizer of the GH joint by approximating the humeral head against the glenoid fossa and by depressing the head of the humerus as the arm elevates and the scapula upwardly rotates.<sup>116</sup> As such, the biceps brachii must be strengthened in a shoulder rehabilitation program.

### Exercises Using Diagonal (PNF) Movement Patterns [VIDEO 17.4](#)

Proprioceptive neuromuscular facilitation (PNF) patterns involve use of the entire upper extremity or address specific regions, such as the scapula. Apply resistance manually to emphasize specific muscles in the pattern by adjusting hand placement and resistance (see Chapter 6 for complete description of patterns). As control improves, teach the patient exercises in diagonal patterns using weights or elastic resistance (Fig. 17.56).

**FIGURE 17.56** PNF pattern (D<sub>2</sub> flexion), emphasizing shoulder flexion, abduction, and external rotation against elastic resistance.

## Functional Progression for the Shoulder Complex

An essential element of a shoulder rehabilitation and injury prevention program is a sequence of carefully progressed exercises and activities designed to achieve necessary and desired functional outcomes. The final section of this chapter provides a summary of key components of a functional progression for the shoulder. This progression typically includes a variety of open- and closed-chain exercises in combined movement patterns that simulate functional activities and further improve strength, power, and muscular endurance. Integrated into the functional progression are activities for balance, coordination, and skill and aerobic conditioning. A few examples of activities are presented here. Refer to Chapter 23 for further examples of activities for advanced functional training.

### Exercises Using Combined Movement Patterns With Functional Activities

Exercises in combined movement patterns typically require coordination between the stabilizing and dynamic functions of the scapulothoracic and GH muscles and involve control of the entire upper extremity and trunk and sometimes of the lower extremities. Some of the strengthening exercises already presented in this chapter resist combined movements.

Component motions in functional activities, such as pulling, pushing, lifting, lowering, and carrying, involve combined movement patterns and should be practiced under

progressively challenging conditions. Several examples follow:

#### ■ **Rowing.**

*Patient position and procedure:* Long-sitting. Secure elastic resistance under the feet or around a solid object. Grasp both ends of the elastic material, and pull backward with the arms in a rowing action (Fig. 17.57). Vary the grip width. For a greater challenge, perform the rowing motion while seated on an unstable surface, such as a Swiss ball. As an alternative, a weight-cable system can be used for resistance.

**FIGURE 17.57** Simulated rowing motion against elastic resistance.

#### ■ **“Lawnmower pull.”**

*Patient position and procedure:* Standing with hips partially flexed and holding onto a table or chair for balance with the hand of the sound upper extremity. Have the patient reach diagonally across the midline and grasp a piece of elastic tubing that is secured under the foot of the sound side or attached to the leg of a couch or bed. Then have the patient pull diagonally and upward as if starting a lawnmower (see Fig. 18.19). This combined movement pattern may also be simulated with a free weight.

#### ■ **Pushing a weighted cart.**

*Patient position and procedure:* Standing with a stable base of support. Begin by pushing the cart on a flat surface with light loads on the cart (Fig. 17.58). Emphasize proper body mechanics. Initially use both arms to push; then progress by pushing with one hand or by pushing heavier loads on uneven surfaces. Vary the activity by adjusting the width of the grip, the position of the arms, or by alternating between pushing and pulling.

**FIGURE 17.58** Pushing a weighted cart to simulate a functional activity and incorporate proper body mechanics.

### Equipment

A variety of exercise devices can be used or adapted for shoulder girdle strengthening using combined movement patterns. Creativity in adapting equipment and exercises to meet progressive upper extremity challenges without exacerbating or causing recurrence of symptoms is a must. Examples of equipment and potential uses are identified in Table 17.6. Many of the activities noted are described and shown in detail in Chapter 23.

### Integration of Functional Activities

Functional progression in a shoulder rehabilitation program must integrate principles of task-specific training by including a sequence of simple and easy to perform activities then progressing to complex and challenging functional activities. It is important to have the patient use the actual patterns and types of muscle contraction that will occur in their necessary and desired functional activities.

First, simulated activities should be performed with supervision and the therapist’s guidance to avoid painful positions or faulty mechanics during movements of the shoulder. Then the activity can be performed independently at home or work. For example, begin by having the patient simulate the motions involved in unloading a dishwasher and placing the dishes on a low shelf or washing windows using small circular motions. If catching and throwing or swinging a bat or golf club are necessary, total body patterns are practiced.

**TABLE 17.6** Exercise Devices and Potential Uses for Shoulder Girdle Rehabilitation

Exercise Device	Potential Use
BodyBlade™	Move the arm in anatomical and diagonal planes of movement, in circular (clockwise or counterclockwise) patterns, or while moving the blade away from or toward the body, as if pushing or pulling.
Rowing machine	Use as designed for endurance training and upper extremity and trunk strengthening. Emphasizes scapular retraction and trunk stabilization when pulling backward.
Upper body ergometer	Forward or backward cycling (pushing or pulling movements) against progressive resistance over an extended time period for muscular and cardiopulmonary endurance. For a patient with an impingement syndrome, place emphasis on backward cycling for scapular retraction and to target weak or underused posterior shoulder structures and minimize action of tight and overused anterior structures.
Foam roll, small ball, balance equipment (rocker or wobble board or BOSU™)	Stabilization exercises or perturbation training in prone-propping or quadruped positions on one or both hands. Emphasize upper extremity weight shifting or alternating arm or leg movements.
Stepping machine	While kneeling, perform upper extremity “climbing” motions by pushing with the hands on the steps. Emphasizes scapular protraction during pushing.
Treadmill	Kneel at the end of the treadmill and perform forward and backward hand-walking.
ProFitter™	While kneeling on the floor next to the device, place hands on the platform and slide the platform side-to-side or forward-backward using quick changes of direction.

An individual who has a sedentary lifestyle may require postural adaptations and ergonomic analysis of his or her home environment or workstation to change repetitive stress. In contrast, an athlete or industrial worker, who must perform

high-demand activities over an extended time period, may require muscular and cardiopulmonary endurance or high-intensity training, such as plyometric exercises, to develop power and skill.

## Independent Learning Activities

### Critical Thinking and Discussion

- Describe how the scapulothoracic and GH musculature function as dynamic stabilizers of the shoulder.
- Which factors may alter normal upward rotation of the scapula, and how does inadequate upward rotation of the scapula adversely affect elevation of the arm?
- Describe the relationships among cervical and thoracic posture, scapula orientation, and elevation of the arm.
- Which mechanisms and structures could be sources of pain in extrinsic impingement syndrome?
- How are impingement and instability related to each other in secondary impingement syndrome?
- Describe the differences and similarities between atraumatic and traumatic instability of the GH joint.
- A patient experienced a traumatic shoulder injury when falling down five cement steps 2 weeks ago. She now has a capsular pattern, decreased joint play, and muscle guarding with passive GH motions. She does not actively use the extremity because of pain. You observe edema in the hand. What potential complications could develop if left untreated? Design an exercise program for this patient at her present level of involvement. What would you teach the patient about her symptoms, impairments, and parameters for recovery?

8. An individual with a history of diabetes has developed a frozen shoulder. She has had shoulder discomfort for several months, but she did not seek treatment until 1 week ago when she was unable to wash or fix her hair with her left hand. Describe your intervention plan and instructions for this patient. Explain how you will determine the level of aggressiveness with which to address her ROM loss.
  9. For patients with a history of recurrent anterior dislocation of the GH joint, what types of functional activities (ADL, work related, or sport related) should initially be avoided or modified during the early and intermediate stages of a rehabilitation program? What would differ with a patient with a history of recurrent posterior dislocation of the GH joint?
  10. What criteria should patients with each of the following shoulder diagnoses meet before progressing to *overhead* exercises and functional activities: primary impingement syndrome, anterior GH instability, frozen shoulder, S/P rotator cuff repair?
10. Develop a series of functional activities to complement the self-stretching and self-strengthening exercises you have taught your partner.

## Case Studies

1. A patient referral states: Evaluate and treat shoulder pain S/P motor vehicle accident. She was the driver of the car in a head-on collision. The patient describes shoulder pain whenever reaching overhead. She is a nurse and finds symptoms worsen when placing solutions on an IV pole, a frequent activity for her. Examination reveals painful resisted scapular protraction, elbow extension, and shoulder extension with pain on palpation of the long head of the triceps near its insertion on the inferior glenoid as well as pain in the serratus anterior in the axilla. Other impairments include weak rhomboids and lower trapezius muscles (4-/5).
  - Explain the potential mechanism of injury to these muscles from this type of accident.
  - Explain why this patient's reaching tasks would perpetuate these symptoms.
  - Outline a treatment plan that manages the acute symptoms and progresses to a therapeutic exercise program.
  - Identify a measurable functional outcome goal and interventions you would use to reach the goal.
  - As the patient's symptoms subside, how would you progress her exercise program?
2. Your patient describes pain whenever reaching overhead. He likes to play volleyball in a weekend league but otherwise has a sedentary lifestyle. On examination, you observe moderate atrophy in the infraspinous fossa, a protracted scapula, and thoracic kyphosis with forward head. You have him assume the quadruped position in anticipation of instruction in closed-chain rhythmic stabilization and scapular protraction exercises and note significant winging of the scapula.
  - Describe what muscles are likely to test weak based on these observations.
  - How would you adapt the quadruped exercise to develop control and strength in the involved muscles at a safe resistance level?
  - Based on your assumptions of muscle involvement, develop an intervention plan for this patient that includes a home exercise program. Indicate parameters (frequency, repetitions), positions, safety, and progressions.
3. You have received a referral to "evaluate and treat" a 62-year-old patient who underwent total shoulder arthroplasty for OA 2 weeks ago. The patient has been wearing a sling to support and protect the operated shoulder but has been allowed to remove the sling for daily pendulum exercises and active ROM of the elbow, wrist, and hand.
  - Prior to initiating your examination and developing an exercise program, what additional information would you like to learn from the surgeon?

## Laboratory Practice

1. With your laboratory partner, review and practice key tests and measurements that you might need to do to determine what is causing shoulder pain and/or diminished upper extremity function. What does each of those tests indicate?
2. Mobilize the scapula with manual techniques.
3. Mobilize the GH joint capsule with manual techniques; practice the MWM techniques for the shoulder.
4. Teach your partner a series of self-mobilization techniques for the GH joint capsule.
5. Using appropriate stabilization, manually stretch all major muscle groups of the shoulder.
6. Teach your partner effective self-stretching techniques for each of these muscle groups.
7. Practice a sequence of exercises to strengthen the muscles of the scapula using manual resistance (applied by the therapist). Use open-chain and closed-chain positions.
8. Teach your partner a progressive sequence of strengthening exercises that he or she could do in a home exercise program to develop stability and dynamic control of the scapula. Apply perturbation techniques that will challenge the ability of the scapulothoracic muscles to stabilize the scapulothoracic articulation.
9. Teach your partner a progressive sequence of strengthening exercises that he or she could do in a home exercise program to develop strength, stability, and endurance of the GH muscles. Have your partner perform each exercise for a specified number of repetitions and at a specified level of resistance.
  - Describe faulty postures or motions that you will be looking for as your partner executes each exercise.
  - Describe the signs of fatigue that you may observe and the indicators of poor exercise technique.

- What information do you want to gather from the patient?
  - What examination procedures would you wish to perform during the patient's initial visit?
  - Develop, implement, teach, and then progress a series of exercises over a period of six visits with the patient.
4. Six months ago your patient underwent surgery for repair of a Bankart lesion and stabilization of the anterior capsule

(capsular shift) after a traumatic anterior dislocation of the GH joint. The patient now has full ROM and 90% strength in the shoulder after a program of rehabilitation. Your patient wants to return to recreational sports, such as tennis, softball, and volleyball, but is apprehensive that the shoulder might dislocate during these activities. Design an advanced rehabilitation program to gradually return the patient to the desired recreational activities.

### Independent Learning Activities 653

A freely mobile but strong and stable elbow complex is required for normal upper extremity function. The design of the elbow and forearm adds to the mobility of the hand in space by shortening and lengthening the upper extremity and by rotating the forearm. The muscles provide control and stability to the region as the hand is used for various activities, from eating, dressing, and grooming to pushing, pulling, turning, lifting, throwing, catching, and reaching for objects to coordinated use of equipment, tools, and machines.<sup>78,82,84</sup> Most activities of daily living require a 100° arc of flexion and extension at the elbow, specifically between 30° and 130°, as well as 100° of forearm rotation, equally divided between pronation and supination.<sup>78,82</sup> Tasks such as drinking and eating primarily require elbow

flexion, whereas a task such as reaching to tie shoelaces requires substantial elbow extension.

Injury or disease of bony, articular, or soft tissue structures of the elbow and forearm can cause pain and compromised mobility, strength, stability, and functional use of the upper extremity. Loss of active or passive elbow flexion interferes with grooming and eating, whereas loss of elbow extension restricts a person's ability to push up from a chair or reach out for objects. In general, loss of terminal flexion of the elbow contributes to greater limitation of function than loss of terminal extension.<sup>78,82</sup>

The anatomical and kinesiological relationships of the elbow and forearm are outlined in the first section of this chapter. Chapter 10 presents information on principles of soft

tissue healing and management; the reader should be familiar with that material before establishing a therapeutic exercise program to improve function of the elbow and forearm.

## Structure and Function of the Elbow and Forearm

The distal end of the humerus has two articular surfaces: the trochlea, which articulates with the ulna, and the capitulum, which articulates with the head of the radius (Fig. 18.1). Flexion and extension occur between these two joint surfaces. The radius also articulates with the radial notch on the ulna at the proximal radioulnar joint. This joint contributes to pronation and supination along with the distal radioulnar joint. The capsule of the elbow encloses the humeroulnar, humeroradial, and proximal radioulnar articulations. The distal radioulnar joint is structurally separate from the elbow complex even though its function is directly related to the proximal radioulnar joint.<sup>82</sup>

## Joints of the Elbow and Forearm

There are four joints involved in elbow and forearm function: the humeroulnar, humeroradial, proximal radioulnar, and distal radial ulnar joints.

### Elbow Joint Characteristics and Arthrokinematics

The elbow is a compound joint with a lax joint capsule, supported by two major ligaments—the medial (ulnar) and lateral (radial) collateral—which provide medial and lateral stability, respectively.<sup>82,84</sup>

**FIGURE 18.1** Bones and joints of the elbow and forearm.

### Humeroulnar Articulation

**Characteristics.** The humeroulnar (HU) articulation is classified as a modified hinge joint. The medially placed hourglass-shaped trochlea at the distal end of the humerus is convex. The trochlear notch on the proximal ulna is concave (see Fig. 5.27). The primary motions at this articulation are flexion and extension.

**Arthrokinematics.** During flexion/extension the concave trochlear notch rolls and glides in the same direction in which the ulna moves, so with elbow flexion, the notch rolls and glides around the convex trochlea in an anterior direction. With elbow extension, the notch rolls and glides in a posterior direction.<sup>82</sup>

The axis of rotation courses slightly superior from medial to lateral due to the distal elongation of the trochlea. This asymmetry in the trochlea guides the ulna to deviate laterally relative to the humerus during extension, which is referred to as normal cubital valgus or “carrying angle.” This also results in a varus angulation with elbow flexion.<sup>82,84</sup>

The arthrokinematics are summarized in ONLINE Box 18.1 on the FA Davis website associated with this book.

### Humeroradial Articulation

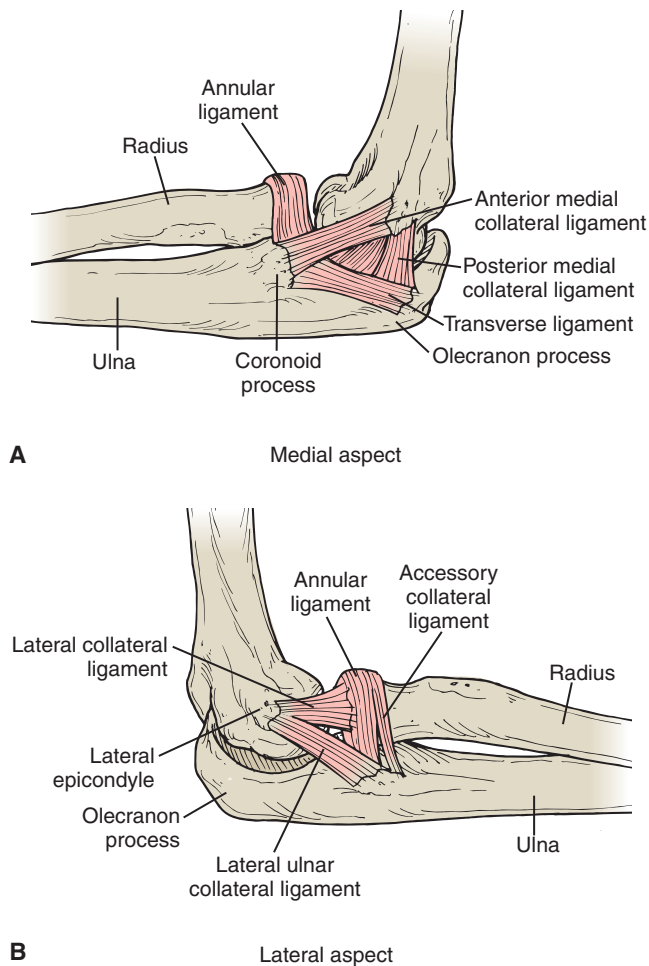

**Characteristics.** The humeroradial (HR) articulation is classified as a modified hinge-pivot joint. The laterally placed, spherical capitulum at the distal end of the humerus is convex. The concave bony partner, the head of the radius, is located at the proximal end of the radius. Flexion/extension and pronation/supination occur at this articulation.

**Arthrokinematics.** As the elbow flexes and extends, the concave radial head glides in the same direction as the motion of the radius, so with elbow flexion, the concave radial head glides anteriorly, and with elbow extension, it glides posteriorly. With pronation and supination of the forearm, the radial head spins on the capitulum (see ONLINE Box 18.1).<sup>82</sup>

### Ligaments of the Elbow

**Medial (ulnar) collateral ligament.** The medial (ulnar) collateral ligament complex consists of bundles of fibers that may be differentiated into anterior, posterior, and transverse portions (Fig. 18.2 A). Various portions of the ligament are taut in different ranges of motion (ROMs), providing medial support to the elbow against valgus stresses and limiting end-range elbow extension. The ligament also keeps the joint surfaces in approximation. Activities, such as throwing and golfing, impose significant stresses on the medial (ulnar) collateral ligament complex.<sup>84</sup>

**Lateral (radial) collateral ligament.** The lateral (radial) collateral ligament complex, a fan-shaped ligament on the lateral surface of the elbow, is composed of the lateral collateral ligament, the lateral ulnar collateral ligament, and the annular ligament. This complex provides stability to the lateral aspect of the elbow against varus and supination forces, stabilizes the humeroradial joint, resists longitudinal distraction, and prevents posterior translation of the radial head (Fig. 18.2 B).<sup>84</sup>

**FIGURE 18.2 (A)** The three parts of the medial (ulnar) collateral ligament are shown on the medial aspect of the right elbow. The musculature and joint capsule have been removed to show the ligament's attachments. **(B)** The lateral collateral ligament complex includes the lateral (radial) collateral ligament, lateral ulnar collateral ligament, and annular ligament. The musculature and joint capsule have been removed to show the ligaments' attachments. (From Norkin, CC: *The elbow complex*. In Levangie, PK, and Norkin, CC (eds): *Joint Structure and Function: A Comprehensive Analysis*, ed. 5. Philadelphia: F.A. Davis, 2011, p 277, with permission.)

## Forearm Joint Characteristics and Arthrokinematics

Both the proximal and distal radioulnar joints are uniaxial pivot joints that function together to produce pronation and supination (rotation) of the forearm.<sup>84</sup>

### Proximal (Superior) Radioulnar Articulation

The proximal radioulnar (RU) articulation is within the capsule of the elbow joint but is a distinct articulation.

**Characteristics.** The convex rim of the radial head articulates with the relatively fixed concave radial notch on the ulna and the annular ligament. This ligament encircles the rim of the radial head and stabilizes it against the ulna (see Fig. 18.2). The primary motion of the proximal RU joint is pronation/supination.

**Arthrokinematics.** As the forearm rotates into pronation and supination, the convex rim of the radial head rolls and glides opposite the motion of the radius, so with pronation, the radial head rolls anteriorly (volarly) and glides posteriorly (dorsally) on the radial notch, and with supination, it rolls posteriorly (dorsally) and glides anteriorly (volarly) as the radius crosses over the relatively fixed ulna. In addition, at the humeroradial joint the radial head spins on the capitulum within the annular ligament during pronation and supination<sup>82</sup> (see ONLINE Box 18.1).

### Distal (Inferior) Radioulnar Articulation

**Characteristics.** The distal RU joint is an anatomically separate joint at the distal end of the radius and ulna. The concave ulnar notch on the distal radius articulates with the convex notch on the head of the ulna. The distal RU joint, along with the proximal RU joint, participates primarily in pronation/supination.

**Arthrokinematics.** As the forearm rotates, the concave radius glides in the same direction as the physiological motion. It glides anterior (volar) with pronation and posterior (dorsal) with supination (see ONLINE Box 18.1).<sup>82,84</sup>

## Muscle Function at the Elbow and Forearm

Muscles in the elbow region not only affect the function of the elbow and forearm, but also wrist and finger function.

## Primary Actions at the Elbow and Forearm

### Elbow Flexion

**Brachialis.** The brachialis is a one-joint muscle that lies deep to the biceps brachii and inserts close to the axis of motion on the ulna, so it is unaffected by the position of the forearm or the shoulder. Due to its large cross-sectional area it generates the greatest force of all the muscles that cross the elbow and its sole function is flexion of the elbow.<sup>68,82,84</sup>

**Biceps brachii.** The biceps is a two-joint muscle that crosses both the shoulder and elbow and inserts close to the axis of motion on the radius, so it also acts as a supinator of the forearm. It functions most effectively as a flexor of the elbow between 80° and 100° of flexion. For the optimal length-tension relationship, the shoulder extends to lengthen the muscle when it contracts forcefully for elbow and forearm function.<sup>82,84</sup>

**Brachioradialis.** With its insertion a great distance from the elbow on the distal radius, the brachioradialis functions to provide compression of the joint surfaces and stability to the joint. The brachioradialis is a primary elbow flexor especially during rapid movements against high resistance and acts as a pronator when the forearm is in supination and a supinator

when the forearm is in pronation especially during rapid supination/pronation motions.<sup>82,84</sup>

### Elbow Extension

**Triceps brachii.** The long head of the triceps brachii crosses both the shoulder and elbow; the medial and lateral heads are uniaxial and only cross the elbow joint. The long head functions most effectively as an elbow extensor if the shoulder simultaneously flexes and adducts. This maintains an optimal length-tension relationship in the muscle. Because the triceps attaches to the ulna and not the radius, it has no role in forearm rotation.<sup>82,84</sup>

**Anconeus.** The primary function of the anconeus muscle is to stabilize the elbow during extension activities as well as during active forearm supination and pronation.<sup>68,82</sup>

### Forearm Supination

**Supinator.** The supinator muscle has an extensive proximal attachment and inserts distally along the proximal one third of the radius. It is capable of generating significant force regardless of the elbow position, speed, or power of the motion.<sup>82,84</sup>

**Biceps brachii.** The biceps muscle acts as a supinator if the elbow simultaneously flexes or during moderate to high powered supination activities when the elbow is flexed to 90°.<sup>82,84</sup>

**Brachioradialis.** The brachioradialis contributes to pronation and supination during short-arc, high power motions. Regardless of the position of the forearm, the brachioradialis rotates the forearm to the neutral, thumbs-up position from a fully supinated or pronated position.<sup>82</sup>

### Forearm Pronation

**Pronator teres.** The pronator muscle pronates the forearm as well as stabilizes the proximal radioulnar joint by helping the radial head to maintain contact with the capitulum. The pronator teres is most active in higher-power pronation activities.<sup>82,84</sup>

**Pronator quadratus.** The pronator quadratus is the most active and consistently used pronator muscle. It also stabilizes the distal RU joint by compressing the ulnar notch of the radius against the ulnar head during pronation activities.<sup>82,84</sup>

## Relationship of Wrist and Hand Muscles to the Elbow

Many muscles that act on the wrist and hand are attached on the medial and lateral epicondyles of the humerus. This allows for effective movement of the fingers and wrist, whether the forearm is in pronation or supination. The muscles provide stability to the elbow but contribute little to motion of the elbow. The position of the elbow affects the length-tension relationship of the muscles during their actions on the wrist

and hand.<sup>60,84</sup> See Chapter 19 for information on the function of the wrist and hand.

**Wrist flexor muscles.** The flexor carpi radialis, flexor carpi ulnaris, palmaris longus, and flexor digitorum superficialis and profundus originate on the *medial epicondyle*.

**Wrist extensor muscles.** The extensor carpi radialis longus and brevis, extensor carpi ulnaris, and extensor digitorum originate on the *lateral epicondyle*.

## Referred Pain and Nerve Injury in the Elbow Region

For a detailed description of referred pain patterns and injuries to the peripheral nerves coursing through the elbow and forearm region, see Chapter 13. ONLINE Table 13.1 summarizes the muscle involvement and functional loss that occur with each of the nerve injuries.

### Common Sources of Referred Pain Into the Elbow Region

Radicular symptoms from the C5 and C6 nerve roots have been reported in patients with lateral elbow pain and from the C6 and C7 nerve roots with medial elbow pain.<sup>2,22,96</sup>

### Nerve Disorders in the Elbow Region

**Ulnar nerve.** The ulnar nerve courses posteromedial to the olecranon process where it enters the cubital tunnel. After leaving the cubital tunnel, it passes between the two heads of the origin of the flexor carpi ulnaris. The most common sites for compression of the ulnar nerve in the elbow region are in the cubital tunnel and between the two heads of the flexor carpi ulnaris.<sup>10,18</sup>

**Radial nerve.** The radial nerve pierces the lateral muscular septum anterior to the lateral epicondyle and passes between the brachialis and biceps medially and the brachioradialis, extensor carpi radialis longus, and extensor carpi radialis brevis laterally. Within an area 3 cm proximal or distal to the elbow, it branches into the posterior interosseous nerve and superficial sensory nerve. The posterior interosseous nerve branch travels posterior to enter the radial/supinator tunnel (canal) between the two heads of the supinator at the arcade of Fröhse. Common sites of compression include under the extensor carpi radialis brevis, at the Arcade of Fröhse, and at the distal edge of the supinator muscle.<sup>63,90</sup>

**Median nerve.** The median nerve courses anteriorly deep in the cubital fossa, medial to the tendon of the biceps and brachial artery, where it is well protected. The nerve then progresses between the ulnar and humeral heads of the pronator teres muscle and dips under the flexor digitorum profundus muscle. Entrapment may occur between the

heads of the pronator teres muscle, under the Ligament of Struthers, by the bicipital aponeurosis or deep to the flexor digitorum superficialis.<sup>10</sup>

## Management of Elbow and Forearm Disorders and Surgeries

In order to make sound clinical decisions when treating patients with elbow and forearm disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and to identify presenting structural and functional impairments, activity limitations, and participation restrictions (functional limitations and possible disabilities). In this section, pathologies and surgical procedures are presented. Conservative and postoperative guidelines for managing these conditions are described in this section.

## Joint Hypomobility: Nonoperative Management

### Related Pathologies and Etiology of Symptoms

Pathologies, such as rheumatoid arthritis (RA), juvenile rheumatoid arthritis (JRA), and degenerative joint disease, as well as acute joint reactions after trauma, dislocations, or fractures, affect this joint complex. Postimmobilization contractures and adhesions develop in the joint capsule and surrounding tissues any time the joint is immobilized in a cast or orthosis. This typically occurs after dislocations and fractures of the humerus, radius, or ulna. The reader is referred to Chapter 11 for background information on arthritis and fractures.

### Common Impairments of Structure and Function

**Acute stage.** When symptoms are acute, joint effusion, muscle guarding, and pain restrict elbow motion, and usually there is pain at rest. Fractures and dislocations require medical intervention; however, with proper training, therapists are capable of manipulating subluxations such as a pushed or pulled elbow (see Figs. 5.29 and 5.31, respectively).

**Subacute and chronic stages.** A capsular pattern usually exists in the subacute or chronic stages of tissue healing. Elbow flexion is more restricted than extension. There is a firm end-feel and decreased joint play. In long-standing arthritis of the elbow, pronation and supination also become restricted with a firm end-feel and decreased joint play in the proximal RU joint. Arthritis of the distal RU joint results in pain on overpressure.

## Common Activity Limitations and Participation Restrictions

- Difficulty turning a doorknob or key in the ignition
- Difficulty or pain with pushing and pulling activities, such as opening and closing doors
- Restricted hand-to-mouth activities for eating and drinking and hand-to-head activities for personal grooming and using a telephone
- Difficulty or pain when pushing up from a chair
- Inability to carry objects with a straight arm
- Limited reach

## Joint Hypomobility: Management—Protection Phase

See the Guidelines for Management Related to the Stages of Tissue Healing in Chapter 10, Box 10.1.

### Educate the Patient

- Inform the patient regarding the anticipated length of acute symptoms and teach methods of joint protection and how to modify activities of daily living. For example, the patient should avoid activities that involve lifting or pushing off with the involved upper extremity.
- Instruct the patient to avoid excessive fatigue by performing exercises frequently during the day but limiting the number of repetitions during each bout (set) of exercises.

### Reduce Effects of Inflammation or Synovial Effusion and Protect the Area

- Intermittent or limited immobilization in a sling or static orthosis provides rest to the elbow, but complete immobilization can lead to joint hypomobility, contractures, and limited motion; therefore, frequent periods of controlled movement within a pain-free range should be performed.

### CLINICAL TIP

Posttraumatic pain and stiffness are common following both operative and nonoperative treatment of fractures and dislocations. Soft tissue structures, including muscles and ligaments, are also subject to damage with these injuries. To restore function of the elbow, good communication between the therapist and physician is critical for optimal outcomes. The key to minimizing stiffness is early motion. Minimizing immobilization by using a hinged orthosis, while limiting extension allows for early motion and provides joint protection.

- Gentle grade I or II joint distraction and oscillation techniques in the resting position may inhibit pain and move synovial fluid for nutrition in the involved joints (see Chapter 5 for principles of application and techniques).

### Maintain Soft Tissue and Joint Mobility

- Passive or active-assistive ROM within limits of pain, including flexion/extension and pronation/supination
- Multiple-angle submaximal isometrics for elbow flexors, extensors, pronators, supinators, and wrist flexors and extensors in pain-free positions

### Maintain Integrity and Function of Related Areas

- Shoulder, wrist, and hand ROM and activities should be encouraged within the tolerance of the individual.
- If edema develops in the hand, the arm should be elevated whenever possible. Consider retrograde massage as described in Chapter 26.

## Joint Hypomobility: Management—Controlled Motion Phase

If joint hypomobility exists, ROM is increased by utilizing joint mobilization techniques as well as passive stretching and muscle inhibition techniques following the principles described in Chapters 4 and 5. Box 18.1 highlights several important precautions if joint restrictions are related to trauma.

### Increase Soft Tissue and Joint Mobility

The intensity of stretching and mobilization techniques is dictated by the healing tissues, the specific pathology, and the surgical technique, as well as the amount of pain, motion, and end feel. Vigorous stretching should not be undertaken until later stages of healing. As noted in Box 18.1, high-intensity stretching of the elbow flexors is contraindicated following trauma because of the potential for development of heterotopic bone formation.

- **Passive joint mobilization techniques.** Because several articulations are involved with each motion at the elbow,

#### BOX 18.1 Precautions Following Traumatic Injury to the Elbow

- Heterotopic ossification of the injured tissue is a potential complication and presents itself as local soft tissue swelling, warmth, and tenderness. When this occurs, stretching is ineffective and contraindicated.
- After healing of fractures in the elbow and forearm, malunion is not unusual, preventing full ROM. A bony block end-feel or an abnormal appearance of the elbow or forearm should alert the therapist to the cause of this impairment. Radiographical imaging is helpful in verifying the problem. No amount of stretching or mobilizing changes the patient's ROM. Indiscriminate stretching may lead to hypermobility of related joints, which could cause additional trauma and pain.

it is important to identify which of the articulations have reduced joint play. For specific techniques to use, see Figures 5.28 through 5.33 and their descriptions in Chapter 5. Progress each technique by positioning the joint at the end of its available range before applying the mobilization technique.

#### CLINICAL TIP

To progress joint mobility in the terminal ranges of flexion and extension, it may be necessary to emphasize the accessory motions of varus and valgus, respectively. This is accomplished with ulnar glide (for limited extension) and radial (for limited flexion) techniques.

- **Manipulation to reduce a “pushed elbow.”** Proximal subluxation of the radius may result from falling on an outstretched hand. The radial head is pushed proximally in the annular ligament and impinges against the capitulum. This injury sometimes accompanies a fracture of the distal radius (Colles' fracture) or scaphoid and is not identified as an impairment until after the fracture has healed and the cast is removed. It is often overlooked due to the focus on the fracture site as well as soft tissue and joint restrictions caused by limited elbow motion during fracture healing. Palpation of joint space will reveal decreased space on the involved side as compared to the uninvolved side. There may be limited flexion or extension of the elbow, limited wrist flexion, and limited pronation.

#### CLINICAL TIP

For an acute “pushed elbow” (and no fracture), apply a distal traction to the radius to reposition the radial head. If chronic, repetitive stretching with sustained grade III distal traction to the radius is necessary (see Fig. 5.29) in addition to the soft tissue stretching and strengthening techniques needed for increasing motion.

- **Manipulation to reduce a “pulled elbow.”** Distal subluxation of the radius is usually seen as an acute injury in children and is sometimes labeled “tennis elbow” when it occurs in adults. It occurs as a result of a forceful pull on the hand such as would occur when a child jerks away from a parent or caregiver or when an individual applies a quick force to lift a heavy object. The force causes the radius to move distally with respect to the ulna. The head of the radius is unable to glide proximally in the annular ligament when supination is attempted,

resulting in the person holding the forearm in pronation. Either supination is restricted, or the patient guards against the motion.

### CLINICAL TIP

With the child distracted, a quick, compressive manipulation (high-velocity thrust) of the radial head concurrently with supination is applied (see Fig. 5.31) to reposition the radial head when there is a “pulled elbow.” There may be soft tissue trauma associated with the injury, which may be treated with cold and compression.

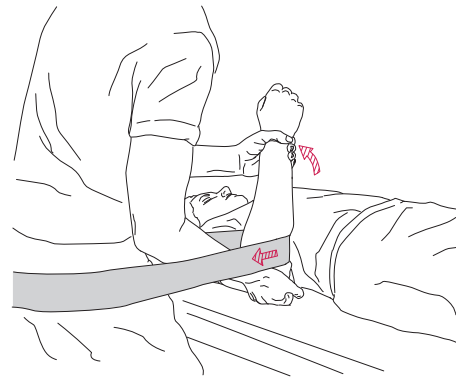

- **Manual stretching and self-stretching.** Use manual stretching and inhibition techniques to increase the flexibility of any periarticular tissues that are restricting mobility. Use of a light cuff weight placed around the distal forearm with the patient carefully positioned for an effective stretch provides a low-intensity, long-duration stretch and is an alternative to manual passive stretching. If elbow ROM does not steadily improve after acute symptoms have subsided, the patient may need to begin wearing a static progressive orthosis that applies a low-load, prolonged stretch force over an extended period of time. These stretching interventions are described in Chapter 4.
- **Home instructions.** Teach the patient self-stretching maneuvers followed by active exercise that utilizes the new range. Suggestions are provided in the last section of this chapter.

### Improve Joint Tracking of the Elbow

A mobilization with movement (MWM) technique consisting of a gentle radial glide combined with the pain-free active movement of elbow flexion or extension, or pain-free gripping (depending on the patient's impairment or functional limitation) with pain-free passive overpressure, may improve articular surface tracking by allowing the muscles to move the joint in a pain-free manner.<sup>20,21,107</sup> (Refer to the principles of MWM in Chapter 5.)

- **Patient position and maneuver:** Supine with elbow either flexed or extended to the end of the available range. Secure a mobilization belt around the patient's proximal forearm at the joint line and your hips such that the belt is horizontal. Stabilize the distal humerus by reaching inside the belt and grasping the humeral condyles. With your other hand stabilize the forearm at the wrist. Apply a gentle lateral glide to the proximal ulna with the belt by slowly moving your hips, taking care not to glide the joint too aggressively. Have the patient actively flex or extend the elbow applying a gentle passive overpressure at end range. With extension be sure to account for the carrying angle

of the elbow, which may alter the treatment plane. Repeat the movement 6-10 times for up to three sets (Fig. 18.3). This is a pain-free technique.<sup>20,21,79,107</sup>

**FIGURE 18.3** Mobilization with movement (MWM) to improve elbow flexion. A lateral glide is applied to the proximal ulna while the patient actively flexes their elbow, followed by a passive end-range stretch.

### Improve Muscle Performance and Functional Abilities

Initiate active and low-load resistance exercises in open- and closed-chain positions to develop control, muscular endurance, and strength in the muscles of the elbow and forearm. As the patient improves, adapt the exercises to progress toward functional activities. Specific exercises are described in the exercise section of this chapter. Include the shoulder girdle, wrist, and hand in the exercise program as their flexibility and strength have an influence on the recovery of elbow function.

### Joint Hypomobility: Management—Return to Function Phase

#### Improve Muscle Performance

Progress strengthening exercises as the joint tissue tolerates. Teach the patient safe progressions and exercise strategies that promote return to function. To prepare the joints and muscles for specific tasks, use exercises that replicate the repetitions and demands of daily activities, such as pushing, pulling, lifting, carrying, and gripping.

#### Restore Functional Mobility of Joints and Soft Tissues

If restrictions remain, use more vigorous manual or mechanical stretching and joint mobilization techniques.

#### Promote Joint Protection

Chronic arthritic conditions may require modification of high-load activities to minimize deforming stresses on the involved joints.

## Joint Surgery and Postoperative Management

Intra-articular or extra-articular surgical intervention is often necessary for management of severe fractures or dislocations that affect the joints of the elbow and surrounding soft tissues. These injuries may require open reduction with internal fixation or arthroscopic or open excision of bone fragments. In adults, the most common fracture in the elbow region is a fracture of the head and neck of the radius. This type of fracture accounts for over one-third of all elbow fractures.<sup>57,87,99,101,106,112</sup> This injury usually occurs when a person falls on an outstretched hand when the elbow is extended and the forearm pronated, causing a fracture of the radial head with possible concurrent injuries about the elbow to include other fractures, dislocations, or ligamentous injuries.<sup>49,57,101,106,112</sup>

If the proximal radius is displaced and the radial head fracture is comminuted, either open reduction internal fixation, low-profile fixation, excision of the fragments of the radial head, radial head excision, or arthroplasty of the radial head are surgical options. Box 18.2 summarizes the advantages and disadvantages of surgical options for management of displaced fractures of the radial head. Radial head fractures in children, however, are relatively uncommon. When they do occur, closed reduction is preferred.<sup>99</sup>

Small osteochondral defects of one or more of the articular surfaces of the elbow complex occur in the skeletally mature and immature individual (often in the throwing athlete) as

the result of repetitive trauma. Such defects, depending on their size, characteristics, and location, may require surgical intervention, such as removal or internal fixation of a fragment, microfracture, or autologous osteochondral or chondrocyte implantation, if nonoperative measures have been ineffective.<sup>1,31,45,89</sup>

Early-stage or long-standing joint disease (RA, JRA, post-traumatic arthritis) associated with synovial proliferation and destruction of articular surfaces of the elbow joints leading to pain, limitation of motion, and impaired upper extremity function may also need to be managed with extra-articular or intra-articular surgery. For example, with early-stage RA in which synovial proliferation is present but joint surfaces are still in good condition, *arthroscopic* or *open synovectomy* is the procedure of choice for relief of pain if medications have not controlled the disease.<sup>22,26,98</sup> Occasionally, advanced arthritis is managed surgically by *interposition arthroplasty* (only in the patient younger than 40 on a selective basis),<sup>72,98</sup> *resection of the radial head* with or without prosthetic implant and concomitant synovectomy, or *arthrodesis* (as a salvage procedure).<sup>12,67</sup> However, today, the most common surgical procedure used to manage severe destruction of the elbow joint is *total elbow arthroplasty* (TEA).<sup>29,48,98</sup> Table 18.1 summarizes how the severity of joint disease and the extent of soft tissue involvement influence the choice of surgical procedure for the elbow complex.<sup>33,46,98</sup>

The goals of surgery of the elbow joint complex and postoperative rehabilitation include (1) relief of pain, (2) restoration of bony alignment and joint stability, and (3) sufficient strength and ROM to allow functional use of the elbow and

### BOX 18.2 Surgical Options for Displaced Fractures of the Radial Head

#### Open Reduction and Internal Fixation

- **Advantages:** Preferable technique if stable fixation can be achieved and if able to repair significant ligamentous damage; early protective postoperative motion permissible.
- **Disadvantages:** Not amenable to nonreducible fractures and less practical than radial head excision or implant for severely comminuted fractures or osteoporosis.

#### Low-Profile Fixation

- **Advantages:** Improved forearm rotation and flexion motion with decreased scarring as compared to other techniques. Immediate mobilization of the elbow joint is permissible.
- **Disadvantages:** Early in development including biocompatibility, which may be an issue unique to this technique.

#### Excision of the Radial Head

- **Advantages:** For severely comminuted, nonreducible, and unstable fractures; no potential for mechanical blockage of joint motion from malalignment of fracture fragments or internal fixation; early ROM permissible.
- **Disadvantages:** Increased valgus deformity possible with potential for early degenerative changes of the humeroulnar

joint. Persistent pain and limited motion with this technique. Even with intact ligaments an alteration of the kinematics and stability of the elbow has been shown.

#### Excision of Fragments of the Radial Head

- **Advantages:** Not as commonly used due to improvements in fixation systems. However, technique used when small displaced fragments that block motion or loose fragments are present. Used when other fixation systems are not feasible due to small fragment size, comminution, or osteopenia.
- **Disadvantages:** Fragments that articulate with the proximal radioulnar joint should not be excised due to interference with forearm rotation.

#### Arthroplasty of the Radial Head

- **Advantages:** Indicated for displaced comminuted fractures of the radial head and neck where an anatomic reduction and stable internal fixation is not possible and there are associated soft tissue injuries. Radial head implants have been shown to restore the kinematics and stability of the radial head.
- **Disadvantages:** Many implants available with no studies comparing clinical outcomes or long-term results.

**TABLE 18.1** Severity of Elbow Joint Disease and Selection of Surgical Procedure

Severity of Joint Disease	Selection of Surgical Procedure
<ul style="list-style-type: none"> <li>■ Mild synovitis: joint surfaces normal or with minimal degeneration, osteoporosis</li> </ul>	<ul style="list-style-type: none"> <li>■ Nonoperative/medical management</li> </ul>

upper extremity. Surgical procedures done to relieve pain and improve elbow stability tend to be more successful than procedures done solely to increase ROM. Heterotopic bone formation, which leads to joint stiffness, is often a complication of elbow fractures, dislocations, and elbow joint surgery.<sup>4,86</sup> Therefore, the single goal of improving ROM is rarely an indication for surgery.

## Radial Head Excision or Arthroplasty

### Indications for Surgery

The following are frequently cited indications for radial head excision or arthroplasty.

- Severely comminuted fracture or fracture-dislocations of the head or neck of the radius that cannot be reconstructed and stabilized with internal fixation.<sup>57,67,87,101,106,112</sup>
- Chronic synovitis and mild deterioration of the articular surfaces associated with arthritis of the HR and proximal RU joints resulting in joint pain at rest or with motion, possible subluxation of the head of the radius, and significant loss of upper extremity function.<sup>57,106</sup>

**CONTRAINDICATIONS:** Radial head excision is contraindicated in the growing child.<sup>99</sup> Excision without replacement of the radial head is not an appropriate option in the presence of elbow instability; a displaced, comminuted fracture; and where a stable internal fixation is not achievable.<sup>57,74,112</sup> As with other joints, arthroplasty is also contraindicated in the presence of an active infection.

## Procedure

### Background

**Selection of procedure.** Depending on the integrity of the ligaments and stability of the elbow complex, a radial head excision may be selected or implant arthroplasty may be the better choice. Results from biomechanical studies demonstrate altered kinematics and stability after radial head excision whereas an implant restores stability and kinematics

similar to the native radial head.<sup>13,57</sup> The use of a prosthetic implant is considered when there is more than three fracture fragments, when there is a fracture of more than 20% to 50% of the coronoid with radial head fracture, and when there is clinical instability of the elbow as the result of disruption of the supporting ligaments.<sup>57,74,75,87</sup>

**Implant designs, materials, and fixation.** There is an increasing number of prosthetic radial head implants available to surgeons. There are three major considerations for choosing the appropriate implant: (1) sizing, (2) alignment, and (3) stem fixation. Current available implants include spacer implants, press-fit and ingrowth stems, and bipolar and ceramic articulations. Silicone implants are no longer used due to significant incidence of failure producing silicone synovitis. Modular metallic (titanium) radial head implants with separate heads and stems are now used allowing for improved sizing and ease of implantation. However, the optimal radial head implant has yet to be designed and fabricated.<sup>15,57,74,75</sup>

### Overview of Operative Procedure

The current implantation techniques vary due to the variety of implants available; however, some surgeons use an extensor digitorum splitting approach and divide the radial collateral and annular ligaments while preserving the integrity of the radial ulnar collateral ligament.<sup>57</sup> Others expose the joint through a posterolateral (Kocher) approach between the extensor carpi ulnaris and anconeus muscles,<sup>87,112</sup> while others prefer the Kaplan approach between the extensor digitorum and the extensor carpi radialis bravis.<sup>101</sup> Regardless of the approach, the radial head is exposed, and a radial osteotomy is performed at the level of the annular ligament to resect the head. For a severe fracture, a portion of the radial neck may also need to be excised. When exposing the operative field, effort is made not to detach intact ligaments. A concomitant synovectomy is done if proliferative synovitis is present (typically seen in RA and JRA).<sup>57,74</sup>

If an implant is to be inserted, the medullary canal of the radius is prepared to accept the stem of the prosthesis. If the elbow is unstable, ligamentous structures are repaired. If

the radial ulnar collateral ligament is insufficient, it may be reinforced with a palmaris longus autograft or allograft.<sup>57,74,75</sup>

## Complications

**Intraoperative complications.** Damage to the posterior interosseous nerve is a concern during surgical excision of the radial head regardless of whether a radial head implant is included in the procedure.<sup>67</sup> If an implant is inserted, malpositioning or inaccurate sizing can cause postoperative pain and humeroradial instability, compromise ROM, and eventually contribute to premature implant wear.<sup>15,87,101,112</sup>

**Postoperative complications.** Postoperatively complications of excision with or without implant may include delayed wound closure, infection, limited ROM of the elbow and/or forearm, radial tunnel syndrome, cubital laxity, persistent pain, and a sense of instability. Slight proximal migration of the radius may occur if resection does not include implantation of a prosthetic radial head.<sup>57,74,112</sup> This complication may or may not be associated with elbow or wrist pain. Following excision for a severe radial head fracture, osteoarthritis of the HR joint also may develop over time.<sup>67</sup>

As with all types of implant arthroplasty, aseptic loosening or long-term implant wear and breakage are complications that may occur, necessitating revision arthroplasty.

## Postoperative Management

The goals and interventions, the rate of progression, and the length of the rehabilitation program, as well as final outcomes, are highly dependent on the extent of damage to soft tissues from injury or chronic inflammation; the integrity of repaired soft tissues, particularly the supporting ligaments of the elbow complex; the philosophy of the surgeon; and the patient's expectations of the surgery and response to treatment.

### Immobilization

Depending on the extent of the surgery and the procedure performed, the elbow may be immobilized in a long arm orthosis or a hinged protective orthosis with an extension block for up to 3 weeks. The elbow is positioned at 45° to 90° with the forearm in mid pronation and the wrist in neutral. When elbow motion is permissible (often as early as 1 to 3 days after surgery or longer if significant reconstruction of ligaments was necessary), the non-hinged orthosis is removed for exercise in a protected arc of motion, but is replaced after exercise and worn at night for an extended period of time to protect healing tissues. If the stability of the elbow is in question, the patient may wear the hinged orthosis continuously to support the healing tissue, which is then adjusted to allow increased ROM as the tissue tensile strength improves.<sup>15,35,112</sup>

### Exercise: Maximum Protection Phase

**Goals and interventions.** The first phase of rehabilitation (inflammatory phase) extends for the first 2 to 3 weeks after surgery and focuses on patient education that emphasizes wound care, control of pain, edema reduction, and exercises to offset the adverse effects of immobilization while protecting

repaired soft tissues that maintain the stability of the elbow. The following goals and exercise-related interventions typically are included in this initial phase.<sup>11,35</sup>

- **Manage edema.** Have the patient elevate their arm above the heart (wrist above the elbow; elbow above the shoulder) and place the arm in a compressive sleeve.
- **Maintain mobility of uninvolved joints.** Active ROM exercises of the shoulder, wrist, and hand immediately after surgery.
- **Maintain mobility of the elbow and forearm.** Initiate gentle protected ROM within 2 to 3 days postoperatively. Depending on the extent of the surgical procedure or healing tissue, have the patient remove the static orthosis several times daily for self-ROM (passive or active-assisted) of the elbow and forearm within a pain-free limited arc of motion (limit extension to protect healing tissue). Active ROM is generally allowed within 1 week postoperatively and begins no longer than 3 weeks postoperatively if there was an unstable fracture or dislocation requiring immobilization. However, as noted previously, some patients must wear a hinged orthosis (with an extension block) for additional stability during ROM exercises if associated ligamentous or soft tissue reconstruction occurred.

## CLINICAL TIP

Some specific motions may need to be restricted initially to prevent excessive stress on reconstructed ligaments. Restrictions vary depending on the extent of ligament disruption and the ligament (s) repaired. For example, if the radial collateral ligament complex was repaired, perform ROM exercises with the forearm in pronation to protect the healing ligament.<sup>35</sup>

- **Minimize muscle atrophy.** Submaximal, pain-free, multiple-angle isometric exercises of elbow and forearm musculature.

### Exercise: Moderate and Minimum Protection Phase Goals and interventions.

The intermediate phase (fibroplastic phase) of rehabilitation begins when wound healing is satisfactory and active movements of the elbow are relatively pain free (approximately 2 to 3 weeks postoperatively) and lasts until approximately 8 weeks postoperatively. This phase of rehabilitation is characterized by continued efforts to restore nearly full or at least functional ROM for everyday activities while maintaining stability of the elbow. Exercises to improve upper extremity strength and muscular endurance and use of the involved elbow for light functional activities are introduced and progressed.

- **Increase ROM,** particularly if contractures were noted preoperatively.
  - Gentle (low-intensity, prolonged stretch) manual stretching, hold-relax techniques, or self-stretching

- Grade II joint mobilization techniques initially, followed by grade III mobilizations after bony and soft tissue healing has occurred

**CONTRAINDICATION:** When applying joint mobilization techniques, do not perform valgus/varus stretches in terminal extension/flexion, particularly if the radial head was not replaced with a prosthetic implant or if the integrity of the supporting ligaments and stability of the elbow is in question.

- Low-load, long-duration, static progressive orthotic intervention
- **Improve functional strength and muscular endurance.**
  - Low-load (pain-free) resistance exercises (maximum 1 to 2 lb), emphasizing high repetitions
  - Initiate grip and pinch resistance exercises
  - Use of the postsurgical upper extremity for *light* activities of daily living (ADLs)

#### Exercise: Minimum to No Protection Phase

**Goals and interventions.** The final phase (remodeling phase) ranges from 2 to 6 months. The goals of this phase are to maximize ROM, increase strength and endurance, and increase function.

- **Maximize ROM**
  - Initiate more aggressive techniques, avoiding overstretching of soft tissue and inciting an inflammatory response.
  - Progress joint mobilization techniques to grades III and IV combined with manual stretching and hold-relax techniques at end ROM.
  - Employ radial (lateral) and ulnar (medial) gapping techniques to restore end-range flexion and extension, respectively.
  - Orthotic intervention should be initiated by 8 weeks after injury or surgery if not already done so. A static progressive (more effective for extension) orthosis or a dynamic orthosis (more effective for flexion) should begin, and a wearing schedule should be determined.
- **Restore strength and endurance**
  - Progress a resistive program using free weights, resistive bands, and/or weight machines that includes the entire upper extremity.
- **Resumption of recreational and work-related activities.** Patient education is a key element of helping the patient return safely to physical activities. A graded return to higher level functional activities is initiated that incorporates specific return to work and/or sport specific activities with emphasis on muscle performance.

#### Outcomes

The anticipated outcomes after surgical repair of the radial head following a severely displaced and comminuted fracture or due to advanced arthritis are a stable elbow and pain-free movement (flexion/extension and pronation/supination) within functional ranges. Short-term postoperative outcomes of excision arthroplasty with and without implant are similar

with regard to relief of pain and functional motion. However, patients with preoperative instability necessitating an implant with ligamentous reconstruction and those with a tenuous repair of ligamentous structures have less satisfactory results than those with a stable elbow.

Some patients may develop a slight increase (about 5° to 10°) in valgus laxity of the elbow, without complaints of instability during functional activities if ligaments are intact prior to surgery or repaired at the time of surgery. Others may experience pain and instability associated with the increased laxity, thus compromising outcomes. In a study by Hall and coinvestigators, posterolateral rotary instability associated with a deficient lateral ulnar collateral ligament was identified at a mean of 44 months in only 16.6% of patients (7 of 42) who reported lateral elbow pain and a sense of instability or weakness after radial head resection (without implant).<sup>49</sup>

Short-term and long-term outcomes after open reduction and internal fixation for radial head fractures have been good when anatomic reduction and rigid internal fixation have been achieved and early motion has been initiated postoperatively. Outcomes for procedures using rigid metal radial head implants have also been favorable. Outcomes include pain relief, stability, and sufficient elbow and forearm ROM for functional activities, leading to relatively high patient satisfaction.<sup>57,74</sup>

## Total Elbow Arthroplasty

### Indications for Surgery

TEA is a treatment option for patients with RA; patients with debilitating, late-stage elbow arthritis; patients with a non-union distal humerus fracture; those with bony tumors, osteonecrosis, or with dysfunctional instability; as well as for those patients who have had unsuccessful nonoperative management or unsuccessful previous surgical procedures, who are over 60 to 65 years of age and whose physical demands are relatively low.<sup>14,27,29,51,58</sup> However, since the first cemented TEA was introduced several decades ago, the indications for this procedure have broadened considerably as the design of prosthetic implants and surgical techniques have evolved. TEA is now considered for the younger patient depending on their postoperative demands.<sup>25,28,46,88</sup> A long-term follow-up of patients, who had undergone TEA at or before the age of 40 for various types of elbow arthritis, showed that 93% continued to have good to excellent outcomes at a mean duration of 91 months after surgery.<sup>25,88</sup>

In addition to management of advanced arthritis, TEA is now considered a preferred surgical alternative to open reduction and internal fixation for management of severely comminuted, intra-articular distal humeral fractures sustained by elderly patients.<sup>27,29,66</sup>

**CONTRAINDICATIONS:** Absolute and relative contraindications for TEA are identified in Box 18.3.<sup>29,71</sup> It is important to note, however, with the exception of active infection, there is lack of agreement as to which contraindications are absolute versus relative.

### BOX 18.3 Contraindications to Total Elbow Arthroplasty

#### Absolute

- The presence of active (acute or subacute) infection in the skin, soft tissue, or bone
- Complete ankylosis of the neuropathic elbow joint
- Severely contracted, scarred, or burned skin resulting in poor-quality soft tissue at the elbow
- Inadequate muscle power of the elbow musculature

#### Relative

- Lack of patient compliance
- History of previous elbow infection
- Chronic instability
- Heterotopic ossification or pain-free ankylosis
- Insufficient bone stock
- Dysfunctional hand
- The younger patient with high demand

## Procedure

### Background

The complex structural relationships among the HU, HR, and proximal RU joints have made developing a prosthetic elbow joint a challenging task. Following introduction and use of early cemented elbow replacements,<sup>33</sup> incremental improvements in design, materials, fixation, and surgical technique have contributed to increasingly predictable and successful outcomes.<sup>29,33</sup> Elbow replacement systems include a humeral and an ulnar implant (Fig. 18.4), and some designs also include replacement of the head of the radius.<sup>33,58,61,73,76</sup>

**Implant design and selection considerations.** Early designs were *hinged (linked, articulated)* and *fully constrained* metal-to-metal humeral and ulnar implants that allowed only flexion and extension of the elbow joint.<sup>29,33,46,93</sup> These designs made no allowances for normal varus and valgus and rotational movements, and hence, the implants rapidly loosened at the bone-cement interface. Metal fatigue at the linkage of the prosthetic components and joint dislocation also were common complications.<sup>9,27</sup> As more accurate information about the biomechanical characteristics of the elbow joint became known, the design of prosthetic replacements evolved. In addition to a functional arc of flexion and extension, contemporary designs provide 5° to 10° of varus and valgus as well as rotational motion (Fig. 18.5).<sup>27,33,56,58</sup>

The designs of total elbow replacement can be classified into two broad categories: *linked (articulated)* and *unlinked (nonarticulated)*. Rather than being fully constrained, as the early components were, linked humeral and ulnar implants are now loosely constrained and, as such, are referred to as *semiconstrained* designs.<sup>8,58,73,76</sup> Designs classified as unlinked favor a more anatomic and bone-preserving humeroulnar articulation with an additional radial head component in an effort to increase stability.<sup>8,34,46,58</sup> The most recent advance in

**FIGURE 18.4 (A)** Anteroposterior and **(B)** lateral radiographs following placement of a Conrad-Morrey (linked/semiconstrained) total elbow arthroplasty. (From Field, LD, and Savoie, FH, III: *Master Cases: Shoulder and Elbow Surgery*. New York: Thieme, 2003, with permission.)

implant design is the convertible or hybrid implant, which can be inserted as either a linked or unlinked replacement system. Use of a convertible or hybrid implant enables the surgeon to determine the more appropriate design based on intraoperative observations and evaluation.<sup>8,58</sup>

**FIGURE 18.5** A linked, semiconstrained design is characterized by varus-valgus and axial rotation tolerances of several degrees at the articulation. (From Morrey, BF [ed]: *The Elbow and Its Disorders*, ed. 4. Philadelphia: Saunders Elsevier, 2009, p 766, with permission from the Mayo Clinic Foundation.)

The criteria for use of a linked or unlinked TEA are based in part on the characteristics of these designs with respect to stability. Linked designs derive inherent stability from one or two pins, which couple the humeral and ulnar components.<sup>73</sup> In addition, some semiconstrained designs have an anterior flange to enhance joint stability and decrease the risk of posterior dislocation.<sup>33,77</sup> Unlinked implant systems, although sometimes referred to as unconstrained, actually have varying degrees of constraint built into their designs based on the degree of congruency of the articulating surfaces.<sup>34,58,61</sup> The less constraining the articular surfaces of the implants, the more reliant the replacement system is on the surrounding soft tissues, particularly the collateral ligaments, for joint stability.

Semiconstrained (*linked*) implants are the most common types of elbow prostheses used in North America. Overall, linked designs, because of their inherent stability, are considered appropriate for use with a broader spectrum of patients, including those with unstable elbows, than unlinked designs.<sup>29,33,56,58</sup> Although both linked and unlinked designs derive some degree of stability from the supporting capsuloligamentous structures and elbow musculature, the integrity of these soft tissues is far more critical for successful use of unlinked than linked designs.<sup>8,29,33,56,58</sup>

In addition to considerations related to stability, the etiology and extent of joint destruction, the degree of deformity, the quality of the available bone stock, and the training and experience of the surgeon are factors that influence the type of replacement system used.<sup>33</sup>

**Materials and fixation.** A stemmed titanium humeral component that has a cobalt-chrome alloy articulating surface interfaces with a high-density polyethylene articulating surface of a stemmed ulnar component.<sup>8,33</sup> Currently, prosthetic components are cemented in place with polymethyl methacrylate, an acrylic cement. Some designs also have a porous-coated extramedullary flange for osseous ingrowth. To date, all-cementless fixation has not yet been developed for TEA.<sup>29,33</sup>

### Operative Overview

The following is a brief overview of typical elements involved in a TEA.<sup>29,3,34,46,61,73,76</sup> A longitudinal incision is made at the posterior aspect of the elbow, either slightly lateral or medial to the olecranon process. The ulnar nerve is isolated, temporarily displaced, and protected throughout the procedure. The distal attachment of the triceps is detached and reflected laterally with a *triceps-reflecting approach* or split longitudinally and retracted along the midline with a *triceps-splitting approach*.<sup>29,34,76</sup> The more recently developed *triceps-sparing (triceps-preserving) approach* is also an option. It involves incisions on the medial and lateral aspects of the elbow joint. This approach preserves the attachment of the triceps tendon on the olecranon but makes insertion of the implants more technically challenging.<sup>9,46</sup>

As the procedure progresses, ligaments and other soft tissues are released as necessary; the posterior aspect of the capsule is incised and retracted and the joint is dislocated. In preparation for the implants, small portions of the distal humerus and proximal ulna are resected. Depending on the status of the radial head, the integrity of the collateral ligaments, and the design of the prosthesis, the head of the radius may or may not be excised. Then the intramedullary canals of the humerus and ulna and possibly the radius are prepared, and trial components are inserted. The available ROM and stability of the prosthetic joint are checked intraoperatively and x-rays are taken to confirm proper alignment of the implants. The components are then cemented in place, and the capsule and any ligaments that had ruptured prior to surgery or were released during the procedure are repaired to the extent possible or necessary based on the design of the prosthesis and the quality of the structures. If detached or split, the extensor mechanism is securely reattached or meticulously repaired. Following possible anterior transposition and careful placement of the ulnar nerve in a subcutaneous pocket, the incision is closed, and a sterile compressive dressing and posterior and/or anterior orthosis are applied to immobilize the elbow and forearm. The arm is elevated to control peripheral edema.<sup>29</sup>

### Complications

Although the incidence of complications has declined steadily over the past few decades as selection of patients, prosthetic design, and surgical technique have improved, complications after TEA continue to occur more frequently than after total hip, knee, or shoulder arthroplasty.<sup>56,108</sup>

## FOCUS ON EVIDENCE

In the mid-1990s, a comprehensive review of the literature indicated that the overall rates of complications following TEA ranged from 20% to 45%. A recent systematic review of the results of subsequent studies (published from 1993 to 2009), however, indicated that the mean overall rate of complications after contemporary, primary TEA (semiconstrained and nonconstrained designs) was 24.3% ( $\pm$  5.8%).<sup>108</sup>

Complications are categorized as intraoperative and postoperative—early or late (before or after 6 weeks).<sup>85</sup>

**Intraoperative complications.** Intraoperative complications, such as fracture and component malpositioning, can significantly affect short- and long-term outcomes. Ulnar nerve damage or irritation, either transient or permanent, can also occur intraoperatively from handling or during the early weeks after surgery from compression,<sup>9,56,85,108</sup> typically causing paresthesia but not weakness.<sup>97</sup>

**Postoperative complications.** Deep infection, a concern after any surgery, is reported to occur in an average of 3.3% ( $\pm$  2.9%) of cases following current-day TEA.<sup>56,108</sup> This rate is higher for TEA than large joint arthroplasties, owing to the thin layer of soft tissues covering the elbow joint and because the majority of patients undergoing TEA have inflammatory arthritis and a compromised immune system due to medication.<sup>56,97,108</sup>

Other postoperative complications, including joint instability, wound healing problems, and triceps insufficiency, are of particular concern during the early and intermediate phases of rehabilitation. Despite continuing improvements in implant design and fixation and surgical techniques, some complications develop several months or even years after surgery. These complications include aseptic (biomechanical) loosening of the prosthetic implants over time at the bone-cement interface (the most common long-term complication and reason for revision arthroplasty), periprosthetic fracture, and mechanical failure or premature wear of the components.<sup>9,43,46,56,108</sup>

It is important for a therapist to be familiar with the incidence and possible causes of complications after TEA in order to effectively structure and progress a postoperative rehabilitation program that decreases at least some of the risk factors associated with these complications. The incidence and characteristics of selected postoperative complications (joint instability, triceps insufficiency, prosthetic loosening) after TEA and factors that contribute to these complications are summarized in Box 18.4.<sup>9,85,97,108</sup> Precautions to reduce the risk of these and other complications are addressed in the following section on postoperative management.

## Postoperative Management

The overall goal of rehabilitation after TEA is to achieve pain-free ROM of the elbow joints as well as strength of the upper extremity sufficient for functional activities while minimizing

the risk of early or late postoperative complications. This goal is best achieved with an individualized rehabilitation program based on a thorough examination of each patient's postoperative status.

### Immobilization

As noted previously, a soft compression dressing is applied at the close of surgery. A well-padded anterior, posterior, or hinged orthosis is used to immobilize the elbow and maintain stability and protect structures as they heal. Recommendations for the positions and duration of immobilization vary.

**Position.** The position of immobilization is based on a number of factors, including the surgical approach, the implant design, and which soft tissues were repaired and require protection.<sup>7,29,34</sup> If, for example, a triceps-reflecting approach was used for a linked TEA, full or almost full elbow extension and a neutral position of the forearm typically will be selected to protect the reattached triceps tendon.<sup>7,29,34,51,73,77</sup> In contrast, with an unlinked TEA, which typically requires repair of the lateral ligament complex, because of preoperative damage, or release for operative exposure of the joint, the position of immobilization is a moderate degree of flexion with limitation of full forearm supination to lessen stress on the repaired ligaments.<sup>7,85</sup> If a patient had a significant preoperative elbow flexion contracture that was surgically released, an anterior orthosis may be selected with the elbow placed in the available amount of extension. An extended position is also indicated if symptoms of ulnar neuropathy are present to alleviate pressure in the cubital tunnel.<sup>9,77,85</sup>

**Duration.** The period of continuous immobilization after surgery, which is kept as short as possible to avoid stiffness, also varies widely, ranging from 1 to 2 days to several weeks (in patients who are immunosuppressed or have RA with thin, friable skin).<sup>29</sup> This time period depends on the design of the prosthesis, the surgical approach, the integrity of ligamentous structures, intraoperative observations by the surgeon, and the integrity of the skin and subsequent wound healing. In general, unlinked/resurfacing designs, which have little inherent stability, require a longer period of immobilization than linked/semiconstrained designs.<sup>9</sup>

If there is increased risk of delayed wound healing because of poor skin quality or a patient's history of diabetes, smoking, or use of steroids, the elbow may be continuously maintained in extension for 10 to 14 days postoperatively to limit stress on the posterior incision.<sup>3,77,85</sup> Even after it is permissible to remove the orthosis for exercise or self-care, the patient is advised to continue to wear the orthosis at night for protection for up to 6 weeks.<sup>7,29,51</sup> If there was a preoperative flexion contracture, an adjustable orthosis that maintains the elbow in extension is worn periodically during the day for a prolonged stretch and a static (resting) orthosis is worn at night to hold the arm in a comfortably extended position. This regimen may be followed for 8 to 12 weeks postoperatively to prevent recurrence of the contracture.<sup>29,51,73,77</sup>

**BOX 18.4 Analysis of Three Potential Complications After Total Elbow Arthroplasty****Joint Instability**

- **Incidence.** One of the more common complications after TEA; predominantly a problem in unlinked arthroplasty;<sup>9,56,108</sup> overall rate of dislocation and symptomatic instability of contemporary TEA, an average of 3.3% ( $\pm$  2.9%).<sup>108</sup>
- Higher incidence with prior radial head resection.
- Higher rate in unlinked implants (reported at 4% to 15%, mean 8%)<sup>61</sup> than in linked implants (reported at 0% to 14%, mean 3.5%).<sup>55</sup>
- **Characteristics.** Early or late onset; associated with pain and loss of function.
  - Disruption of a repaired LCL complex  $\rightarrow$  posterolateral, rotary, and varus instability; disruption of a repaired MCL complex  $\rightarrow$  posteromedial and valgus instability.
  - Disruption of triceps mechanism  $\rightarrow$  diminished dynamic compressive forces across the joint.
- **Contributing factors.** Excessive release or inadequate or failed soft tissue repair  $\rightarrow$  deficient static or dynamic stabilizers (possibly due to inadequate postoperative immobilization and excessive postoperative stresses across the elbow, particularly during the early postoperative period before soft tissue repairs have healed), malpositioning of implants, and long-term polyethylene wear of the ulnar component increase the risk of instability.<sup>9,61,85</sup>

**Triceps Insufficiency**

- **Incidence.** Primarily occurs after surgical approaches that disrupt the triceps mechanism; occurs in both linked and unlinked arthroplasty, usually during the first postoperative year.<sup>97</sup> Examples of rates of occurrence reported in separate retrospective studies: 1.8% of 887 elbows,<sup>24</sup> and 11% of 28 elbows,<sup>55</sup> and 2.4% ( $\pm$  2.4%) of 2,938 elbows reported in a recent systematic literature review of contemporary TEA.<sup>108</sup>
- Higher overall risk in patients with previous elbow surgery before TEA.<sup>24</sup>

- **Characteristics.** Partial or complete rupture, or avulsion, of the extensor mechanism (during the early or late postoperative period), weakness (particularly in terminal extension), often posterior elbow pain, and difficulty with pushing activities and overhead functions, such as combing one's hair.
- **Contributing factors.** Occasionally postoperative trauma but most commonly a failed surgical reattachment or repair of a poor quality tendon; premature or excessive ROM or loads on the extensor mechanism during early rehabilitation or during long-term functional use of the arm.<sup>61</sup>

**Implant Loosening**

- **Incidence.** The most common postoperative complication, occurring in linked (semiconstrained) more than unlinked (nonconstrained) implants. Overall rates are lower with contemporary TEA designs (mean, 5.1%,  $\pm$  3.4%)<sup>56,108</sup> than earlier designs but remain higher than after hip, knee, and shoulder arthroplasty.<sup>85</sup> The more constrained the design, the greater the risk of loosening.
  - Rate of clinical loosening reported in individual studies of contemporary implants up to a 6-year follow-up has been reported to range from 0% to 6%.<sup>55,77</sup>
  - Rates of 0% to 3% reported in patients with RA over a mean follow-up of 3.8 years<sup>56,77</sup> and in patients with posttraumatic arthritis with a mean follow-up of 5 years.
  - The incidence of radiological loosening is consistently higher than clinical loosening (when the patient becomes symptomatic).
- **Characteristics.** Aseptic (biomechanical) loosening, a late complication, occurs at the bone-cement interface typically of the ulnar component;<sup>46,56</sup> clinical loosening is associated with pain. Excludes loosening caused by infection.<sup>9,56</sup>
- **Contributing factors.** Inadequate cementing technique, implant malpositioning, and lack of adherence to postoperative activity modification. High-load, high-impact activities place patient at higher risk of loosening.

**Exercise Progression**

The progression of a postoperative exercise program after TEA varies considerably based on many factors. Key factors and their impact on postoperative rehabilitation are identified in Table 18.2.<sup>7,34,110</sup> The rehabilitation process proceeds most rapidly when a triceps-sparing approach is used to insert a linked replacement in a patient whose incision is healing well. On the other end of the spectrum, in which rehabilitation must progress more cautiously, is the use of a triceps-reflecting approach for an unlinked replacement, requiring release and repair of the lateral ligament complex in a patient with poor skin quality.

Just as the progression of exercise is based on the unique features of each patient's surgery, precautions are determined in a similar manner. It is particularly important for the therapist to know the status of repaired soft tissues to incorporate the necessary precautions into the exercise program. Information in the operative report and close communication with

the surgeon are the best sources for these details. Specific precautions for exercise and functional use of the operated upper extremity are summarized in Box 18.5.<sup>7,14,73,97,110</sup> Patient education about these precautions should occur throughout the rehabilitation program. A patient's adherence to precautions ensures more positive outcomes and lessens the likelihood of short- or long-term postoperative complications related to exercise and use of the operated arm for functional activities.

**Exercise: Maximum Protection Phase**

The focus during the first phase of rehabilitation, which extends approximately over a 4-week period, includes control of inflammation, pain, and edema with use of medication as needed, application of cold, and regular elevation of the post-surgical arm. Emphasis is also placed on careful inspection of the wound, protection of repaired soft tissues as they begin to heal, and early ROM exercises to offset the adverse effects of immobilization without jeopardizing the stability of the

**TABLE 18.2** Factors That Influence the Progression of Exercise After Total Elbow Arthroplasty

Factors	Impact on Rehabilitation
<ul style="list-style-type: none"> <li>■ Design of prosthesis: linked/semiconstrained vs. unlinked/resurfacing</li> </ul>	<ul style="list-style-type: none"> <li>■ Earlier ROM and use of the operated upper extremity for light ADL with linked/semiconstrained replacements, which typically do not require ligament repair for joint stability</li> <li>■ More protected, controlled motion during exercise and delayed use for ADLs with unlinked/resurfacing replacements, which typically require repair of supporting ligaments for stability</li> </ul>
<ul style="list-style-type: none"> <li>■ Surgical approach: triceps-sparing vs. triceps-splitting or triceps-reflecting</li> </ul>	<ul style="list-style-type: none"> <li>■ Initial postoperative ROM permissible through a greater range of flexion and earlier active antigravity elbow extension, low-load resistance exercise, and light ADL with triceps-sparing approach</li> </ul>

**BOX 18.5 Specific Precautions After Total Elbow Arthroplasty****ROM Exercise**

- Perform ROM exercises only within the arc of motion achieved during surgery.
- To reduce postoperative stress on a repaired triceps mechanism, avoid end-range flexion during assisted ROM and active, antigravity elbow extension for 3 to 4 weeks.
- Also avoid early, end-range elbow flexion to decrease stress on the incision and reduce the risk of compromising wound healing.
- If elbow stability is questionable after an unlinked total elbow arthroplasty, limit full extension of the elbow and rotation of the forearm, particularly supination past neutral, to avoid overload on repaired lateral ligaments for 4 weeks. With an unlinked replacement, the greatest risk of instability is when the elbow is extended beyond 40° to 50°.7
- If symptoms of ulnar nerve compression are noted, avoid prolonged positioning or stretching into end-range flexion.

**Strengthening Exercises**

- Postpone resisted elbow extension for 6 weeks (or as long as 12 weeks) if a triceps-reflecting approach was used.
- When strengthening the shoulder, apply resistance above the elbow to eliminate stresses across the elbow joint.

- Weight training using moderate and high-loads is not appropriate after total elbow arthroplasty.

**Functional Activities**

- Avoid lifting or carrying any objects with the operated extremity for 6 weeks or objects greater than 1 lb for 3 months.
- If the triceps mechanism was detached and repaired, avoid pushing motions, including propelling a wheelchair; pushing up from a chair; and using a walker, crutches (other than forearm platform design), or a cane for at least 6 weeks or as long as 3 months.
- If an unlinked replacement was implanted, do not lift weighted objects during daily tasks with the elbow extended to avoid shear forces across the lateral ligament repair, which could contribute to posterolateral instability.
- Limit repetitive lifting to 1 lb for the first 3 months, 2 lb for the first 6 months, and no more than 5 lb thereafter. Never lift more than 10 to 15 lb in a single lift.7,34,61
- Do not participate in recreational activities, such as golf, volleyball, and racquet sports, that place high-loads or impact across the elbow.

prosthetic joint. Assisted ROM as tolerated and within the ranges achieved intraoperatively is typically initiated 2 to 3 days after linked TEA and a few days later after unlinked TEA if the elbow is stable.<sup>7,29,37</sup>

### CLINICAL TIP

If there was significant preoperative instability of the elbow or if the repair of ligaments released during surgery is in question, elbow ROM typically is delayed for 7 to 10 days. When motion is initiated, the patient may need to wear a hinged orthosis for 4 to 5 weeks that allows only flexion and extension and restricts rotation of the forearm.<sup>7,14,37</sup>

**Goals and interventions.** The goals and exercise interventions during this first phase include the following:<sup>7,14,37,51,61,73,77</sup>

- **Maintain mobility of the shoulder, wrist, and hand.**
  - Active ROM of these regions during the immediate postoperative period. This is particularly important for the patient with RA or JRA involving these joints.
- **Regain motion of the elbow and forearm.**
  - After a linked TEA or if the elbow is stable after an unlinked TEA, start with gentle self-assisted elbow flexion/extension and pronation/supination with the elbow comfortably flexed and the forearm in mid-position, progressing to active ROM as tolerated. As acute symptoms subside, have the patient maintain the end-range position to apply a very low-intensity stretch.
  - If the triceps mechanism was reflected and repaired, limit assisted flexion to 90° to 100° for the first 3 to 4 weeks to avoid excessive stretch on the repaired triceps tendon. Perform active elbow flexion/extension in a seated or standing—rather than supine—position for the same time frame to avoid antigravity extension, which also could cause excessive stress to the reattached triceps mechanism and subsequent insufficiency.<sup>7</sup> While sitting and standing, elbow extension is a gravity-assist extension and is controlled by an eccentric contraction of the elbow flexors.
  - If a linked replacement was implanted using a triceps-sparing approach, there is little to no risk of early postoperative instability or disruption of the triceps mechanism. Therefore, active ROM in all planes of motion is permissible immediately.

**NOTE:** Some sources recommend after linked arthroplasty involving a triceps-reflecting approach—and if secure reattachment of the triceps tendon was achieved—that ROM exercises progress as tolerated without restriction.<sup>14,29,77</sup>

- **Minimize atrophy of upper extremity musculature.**
  - Gentle, pain-free muscle-setting exercises of elbow musculature (against no resistance) while in the orthosis and later, multiple-angle setting exercises when the orthosis can be removed.

- Low-intensity, isometric resistance exercises of the shoulder, wrist, and hand.
- Use of the hand for light functional activities as early as 1 to 2 weeks postoperatively if a linked replacement was inserted but several weeks later after an unlinked TEA.<sup>14,29,37,73,77</sup>

### Exercise: Moderate and Minimum Protection Phases

By about 4 to 6 weeks postoperatively, soft tissues have healed sufficiently to withstand increasing stresses. By 12 weeks, barring complications, only minimum protection is necessary; therefore, a patient typically can resume most functional activities with some imposed restrictions (see Box 18.6). However, the recommended timeline for return to a reasonably full level of activity with ongoing lifting restrictions varies from 6 weeks<sup>34,61,73</sup> to 3 to 4 months.<sup>7,14,29</sup>

**Goals and interventions.** The focus of rehabilitation during the intermediate and final phases is to improve ROM to the extent achieved intraoperatively, regain strength and endurance of elbow musculature, and use of the operated arm for functional activities with a permanent lifting restriction of 5 pounds.<sup>14,29</sup> However, these goals must be reached without disrupting repaired soft tissues or compromising the stability of the elbow prosthesis. Strength and muscular endurance usually continue to improve up to 6 to 12 months postoperatively by cautious use of the operated arm for functional activities.

Patient education, especially with regard to the resumption of functional activities, is ongoing until the patient is discharged from therapy. The following goals and interventions are added during the moderate and minimum protection phases of rehabilitation.<sup>7</sup>

- **Increase ROM of the elbow.**

**NOTE:** It is the opinion of the authors that use of joint mobilization techniques to increase ROM of the elbow or forearm is inappropriate after TEA, particularly with linked implants and/or if the stability of the elbow is questionable. It is a more prudent choice to forego full elbow motion than to jeopardize the stability of the joint.

- Low-intensity, manual self-stretching.
- Low-load, long-duration static dynamic orthotic intervention,<sup>104</sup> as described and illustrated in Chapter 4 (see Fig. 4.13), or alternating use of static orthoses, fabricated in maximum but comfortable extension primarily at night.<sup>29</sup>

**PRECAUTIONS:** Emphasize end-range extension before end-range flexion to protect the posterior capsule and the triceps mechanism. If symptoms of cubital tunnel syndrome are present (aching along the ulnar forearm and hand, paresthesia, or hyperesthesia due to compression or entrapment of the ulnar nerve), avoid prolonged or repeated end-range positioning or stretching to increase elbow flexion.<sup>3,14,18</sup>

- **Regain functional strength and muscular endurance of the operated extremity.**

**NOTE:** Some sources advocate progressive use of the postsurgical upper extremity to regain strength and muscular endurance rather than an exercise program.<sup>61,73,77</sup>

- Resisted, multiple-angle isometric exercises at 5 weeks if not initiated previously.
- *Light* ADLs (initially <1 lb of weight) performed with the arm positioned along the side of the trunk and the elbow flexed. If a triceps-reflecting approach was used, incorporate activities that require elbow flexion, such as eating, drinking or brushing teeth, before elbow extension. Initially modify activities to avoid those that require lifting with the elbow extended and pushing motions, such as pushing up from a chair or using a walker, axillary crutches, or a cane.
- Dynamic, open-chain resistance exercises no earlier than 6 weeks and often later using a light-weight (1 lb) or light-grade elastic resistance. Emphasize gradually increasing repetitions rather than resistance.
- Repetitive lifting during exercise and functional activities limited to 1 lb for the first 3 months and 2 lb for the next 3 months. Permanently limit repetitive lifting to no more than 5 lb and a single lift to no more than 10 to 15 lb.<sup>7,14,29,34,61</sup> (See Box 18.5 for additional restrictions to strengthening exercises and functional activities.)
- Low-load, closed-chain activities, such as wall push-ups, after 6 weeks or later (when the triceps mechanism and posterior capsule have healed).

**CONTRAINDICATIONS:** High-load progressive resistive exercise (PRE), heavy lifting during home- and work-related activities, and recreational activities that place high-loads or impact on the upper extremities (e.g., racquet and throwing sports or golf) are not allowed after TEA. These activities must be permanently avoided to reduce the risk of complications, such as elbow instability, implant loosening, and polyethylene wear.<sup>28,37,56,59,61,108</sup>

## Outcomes

Although the results of the early use of TEA during the 1970s were unsatisfactory, improvements in prosthetic design and fixation, surgical techniques, postoperative management, and criteria for patient selection have made this procedure a reliable means for relieving pain, restoring joint stability, improving physical function and regaining patient participation.

The outcomes of TEA and postoperative rehabilitation typically are assessed by a combination of patient self-report instruments that address pain relief, function, and quality of life (e.g., the Patient Related Elbow Evaluation form or the Disabilities of the Arm, Shoulder, and Hand [DASH] questionnaire), and physician-administered tools (e.g., the American Shoulder and Elbow Surgeons Questionnaire or the Mayo Elbow Performance Score, which also include measurements of ROM, strength, and specific shoulder and elbow functions).<sup>6,56,88,91</sup>

Because of the variety of tools used, direct comparison among studies is often difficult.

**Pain relief and patient satisfaction.** Complete or nearly complete relief of pain is the most consistently positive and predictable outcome after elbow arthroplasty, occurring in more than 85% to 95% of patients.<sup>29,91</sup>

As noted at the beginning of this discussion on TEA, although the indications have broadened over the past four decades, elbow arthroplasty continues to be used most frequently in patients with RA followed by patients with post-traumatic arthritis. Follow-up studies of patients with these and other underlying pathologies who have undergone linked or unlinked TEA indicate an overall high rate of patient satisfaction, with 80% to 100% of patients reporting “good” or “excellent” results after linked<sup>25,48,55,91</sup> and unlinked<sup>34,61,88,91</sup> TEA.

**ROM and functional use of the upper extremity.** Improvements in elbow ROM after TEA have improved along with the improvements in implants and surgical techniques, although decreasing pain and maintaining stability of the prosthetic elbow postoperatively are a higher priority than gaining full ROM. Results of most studies of linked<sup>48,55,91</sup> and unlinked<sup>57,91</sup> arthroplasty indicate an increase in the arc of elbow extension/flexion and forearm rotation in patients with late-stage posttraumatic arthritis, RA, and JRA. Anecdotal evidence suggests that most gains are achieved within 6 to 12 weeks but occasionally up to 6 months postoperatively. Patients with little active movement of the elbow because of preoperative instability have exhibited marked improvement of active motion postoperatively. Examples of the arc of extension/flexion achieved after TEA are 15° to 133°,<sup>37,50</sup> 19° to 140°,<sup>55</sup> 22° to 135°,<sup>27</sup> and 28° to 131°, with pronation/supination of 68° and 62°, respectively.<sup>48</sup> Remember that arcs of 100° (from 30° to 130° of extension/flexion and 50° each of pronation/supination) are necessary for most functional activities.<sup>78</sup> Therefore, in all of these studies, functional ROM for extension and flexion was achieved.

It is important to note that when reviewing the literature for this summary of outcomes, there were no studies that compared outcomes after different approaches to rehabilitation.

**TEA survival rates.** “Survival rate” (the point at which revision arthroplasty is necessary) following current-day TEA appears to depend more on a patient’s underlying pathology than on the type of prostheses implanted.<sup>46</sup> Relatively recent long-term studies of patients with RA, for example, have indicated that the survival rate of implants is 90% to 92% at a mean of 5 years<sup>43,55,91</sup> and 86% at a minimum of 10 years<sup>43,48,91</sup> after linked (semiconstrained) arthroplasty and after unlinked arthroplasty. Overall prosthetic survivorship rates tend to be lower and the risk of revision arthroplasty higher in patients with posttraumatic arthritis or primary osteoarthritis than in patients with RA. This may be because of generally higher activity levels—and therefore, greater loads placed across the elbow—in those with posttraumatic arthritis than in those with inflammatory disease.<sup>43,108</sup>

There is general consensus that for the best long-term results, a patient must be selective in the type of work-related or recreational activities performed, modifying some activities and eliminating those that impose high-loads and high impact on the elbow.

As with all types of total joint arthroplasty, TEA survival rates deteriorate over time regardless of underlying pathology, type of implant, and the extent of stress placed on the elbow.<sup>43</sup>

## Myositis Ossificans

The terms *myositis ossificans* and *heterotopic ossification* (HO) or *ectopic bone formation* are often used interchangeably to describe the formation of bone in atypical locations of the body.<sup>70</sup> Some resources use the term myositis ossificans to denote only ossification of muscle. More often, the term is used generally to characterize HO or bone formation in the muscle-tendon unit, capsule, or ligamentous structures. In this text, the terms myositis ossificans and heterotopic ossification are used synonymously.

### Etiology of Symptoms

The prevalence of HO following elbow fracture has been reported to be as high as 40% and is most commonly located at the posteromedial aspect of the elbow.<sup>94</sup> HO may develop after a comminuted fracture of the radial head, a fracture-dislocation (supracondylar or radial head fracture) of the elbow, or a tear of the brachialis tendon.<sup>53,70,81,94</sup> Patients with concurrent traumatic brain injury or spinal cord injury, or patients with burns to the extremities, have a much higher risk in developing this complication.<sup>53,70,81,94</sup> Additional risk factors for developing HO include delayed internal fixation and use of bone graft and/or bone-graft substitute. More severe HO is associated with concomitant distal humeral fracture, triad injury, and elbow fracture-dislocation. Delay in intervention increases the risk of HO.<sup>81,94</sup> While some believe that too much motion or aggressive stretching following injury exacerbates HO, others believe that HO occurs due to a lack of motion. There is no evidence or consensus to indicate that overstretching or participation in physical therapy contributes to HO.<sup>94</sup>

Clinical presentation of HO involves a restriction of joint motion after an inciting trauma. Palpation of a locking sensation at terminal extension or flexion is also an indication of HO rather than of joint contracture.<sup>94</sup> Heterotopic ossification begins approximately 2 weeks after the injury, and the patient often presents with swelling, warmth, and pain. As the process continues, the warmth, erythema, and swelling will gradually resolve, which may be accompanied by a gradual loss of elbow motion.<sup>70</sup> Palpation of the distal brachialis muscle is tender. After the acute inflammatory period, heterotopic bone formation is laid down in muscle between, not within,

individual muscle fibers or around the joint capsule within a 2- to 4-week period. This makes the muscle extremely firm to touch. Although this condition can permanently restrict elbow motion, in most cases, the heterotopic bone is largely reabsorbed over several months and motion usually returns to near normal.<sup>70</sup>

### Management

Prophylaxis use of NSAIDs should be considered for those at high risk for developing HO. If there are gastrointestinal contraindications, radiation therapy may also be considered. Surgical excision may be considered when the HO is symptomatic and/or restricts the functional arc of motion at the elbow, especially if it interferes with the patient's activities or ability to participate. When considering surgical intervention a risk-benefit ratio must be considered.<sup>70,81</sup> If treated operatively, the elbow is frequently managed with continuous passive motion and a hinged adjustable orthoses. Passive stretching should be introduced with extreme caution in the inflamed, posttraumatic, and/or postsurgical elbow when ROM is initiated to avoid exacerbating the inflammation, which may result in elbow contracture.<sup>69</sup>

## Overuse Syndromes: Repetitive Trauma Syndromes

Overuse can occur in any musculotendinous structure in the elbow region, including the flexors and extensors of the elbow; however, it most commonly occurs in the muscles attached to the lateral or medial epicondyles in response to repetitive stressful forearm and wrist motions. Current evidence has shown that the traditional terms, *tendinitis* or *epicondylitis*, do not accurately reflect the true pathology of these conditions. The evidence has demonstrated that these conditions are degenerative in nature and do not reflect an inflammatory process as indicated by a lack of inflammatory cells, but rather involve dysfunctional vascular and fibrous tissue and disorganized collagen.<sup>39,40,83</sup> The terms *tendinosis* and *tendinopathy* refer to the degenerative changes in the tendon tissue, which includes immature fibroblastic and vascular elements, resulting in weakening of the tendinous structure.<sup>38-40,83,105</sup>

### Related Pathologies

#### Lateral Elbow Tendinopathy (Tennis Elbow)

Tennis elbow is commonly referred to as lateral epicondylitis (despite current literature), lateral epicondylalgia, lateral epicondylosis, or lateral elbow tendinopathy.<sup>100,105</sup> Symptoms include pain over the lateral epicondyle of the humerus, primarily with gripping activities. Activities

requiring firm wrist stability, such as the backhand stroke in tennis, or repetitive work tasks that require repeated wrist extension, such as computer work or pulling weeds in a garden, can stress the musculotendinous unit and cause symptoms. The primary structure involved is the origin of the extensor carpi radialis brevis muscle,<sup>38,73,105</sup> although the extensor digitorum is also involved in approximately 50% of patients.<sup>83</sup>

Positive tests of provocation include palpation tenderness on or near the lateral epicondyle, pain with resisted wrist extension performed with the elbow extended, pain with resisted middle finger extension, and pain with passive wrist flexion with the elbow extended and forearm pronated.<sup>39,63</sup>

**NOTE:** Pulled elbow, pushed elbow, radial head arthritis, radial head fracture, pinched synovial fringe, radial tunnel syndrome, cervical root compression, and periosteal bruise are also possible sources of lateral elbow pain and are sometimes inaccurately diagnosed as tennis elbow.<sup>16,83</sup>

### Medial Elbow Tendinopathy (Golfer's Elbow)

Golfer's elbow, also known as medial epicondylitis, medial epicondylalgia, or medial epicondylosis, involves the common flexor/pronator tendon at the tenoperiosteal junction near the medial epicondyle. It is associated with repetitive movements into wrist flexion, such as swinging a golf club, pitching a ball, or work-related grasping and lifting heavy objects. Concomitant ulnar neuropathy may be an associated finding.<sup>5,83</sup>

Positive tests of provocation include palpation tenderness on or near the medial epicondyle, pain with resisted wrist flexion performed with the elbow extended, and pain with passive wrist extension performed with the elbow extended.

### Etiology of Symptoms

The most common cause of medial or lateral epicondylalgia is excessive repetitive use or eccentric strain of the wrist or forearm muscles. The result is micro damage and partial tears, usually near the musculotendinous junction when the strain exceeds the strength of the tissues and when the demand exceeds the repair process. With repetitive trauma, fibroblastic activity and collagen weakening occurs. Recurring problems are seen because the resulting immobile or immature scar is redamaged when returning to activities before there is sufficient healing or mobility in the surrounding tissue.

Mechanical nerve pain hypersensitivity over the radial and ulnar nerves and their nerve trunks has been reported in patients with medial and lateral epicondylalgia. These findings suggest the presence of central and peripheral sensitization mechanisms in this patient population.<sup>16,32,41,42,59,83</sup>

### Common Impairments of Structure and Function

- Gradually increasing pain in the elbow region after excessive activity of the wrist and hand
- Pain when the involved muscle is stretched or when it contracts against resistance
- Decreased muscle strength and endurance for the demand
- Decreased grip strength, limited by pain
- Proximal weakness of shoulder and scapular musculature
- Decreased mobility of the lower cervical and upper thoracic spine
- Tenderness with palpation over the lateral or medial epicondyle or tendon origin

### Common Activity Limitations and Participation Restrictions

- Inability to participate in provoking activities, such as racket sports, throwing, or golf.
- Difficulty with repetitive forearm/wrist tasks, such as sorting or assembling small parts, typing on a keyboard or using a computer mouse, gripping activities, using a hammer, turning a screwdriver, shuffling papers, or playing a percussion instrument.

### Nonoperative Management of Overuse Syndromes: Protection Phase

#### Decrease Pain

- **Immobilization.** Rest the muscles by immobilizing the wrist at night in an orthosis such as a wrist extension or “cock-up” orthosis.<sup>19,20</sup>
- **Pain reduction.** Use of a counterforce brace (nonarticular, proximal forearm orthosis) has demonstrated a decrease in pain and increased pain-free grip strength and function by reducing force transmission to the common tendon.<sup>19,47,52,83,96,111</sup>
- **Patient instruction.** Instruct the patient in “relative rest”—that is, to keep moving and using that arm but to avoid aggravating activities such as strong or repetitive gripping actions.<sup>39,83</sup>
- **Cryotherapy.** Use ice to help manage pain.<sup>64</sup>

#### Develop Soft Tissue and Joint Mobility

- **Cross-friction massage.** Apply cross-friction massage at the site of the lesion. For lateral elbow tendinopathy, find the proximal tendon of the ECRB by locating the radial head, slide dorsally around the radial head, and dive deep into the soft tissue adjacent to the radial head. Ensure you are on the correct tendon by having the patient lift the middle finger. Teach the patient cross-friction massage techniques in a home exercise program.<sup>54,80</sup>

- **Neuromobilization.** If increased symptoms occur with upper limb neurodynamic testing, use neuromobilization techniques as described in Chapter 13.
- **Soft-tissue mobilization.** Apply soft tissue mobilization to the wrist extensors or flexors to decrease soft tissue tightness and trigger points commonly associated with lateral and medial elbow tendinopathy.
- **Muscle mobility techniques.** Apply gentle hold-relax techniques to either the wrist extensor or flexor muscles (see Chapter 6). Begin with the respective muscles in the shortened position with the elbow flexed and wrist either in extension (for wrist extensor technique) or flexion (for the wrist flexor technique). Repeat the gentle resistance for five to six contractions then move the wrist toward neutral and repeat the contractions. Continue to progress the range of wrist motion without going into the painful range. Once gentle contractions in the full range of wrist motion are possible without pain, progress to lengthening the muscle across the elbow by increasing elbow extension. This progression may take several weeks. Follow the gentle hold-relax techniques with pain-free passive stretching as described in the following bullet.
- **Passive stretching.** Use gentle pain-free passive stretching techniques to elongate tight muscles. Hold stretches at least 20 to 30 seconds. Educate your patients that it is better to do fewer repetitions and hold them a full 20 to 30 seconds, then to perform short, quick stretches.
  - *To stretch the wrist extensors,* extend the elbow, pronate the forearm, flex and ulnarly deviate the wrist, flex the fingers, and gently press on the back of the hand until a pain-free stretch is felt in the forearm.
  - *To stretch the wrist flexors,* extend the elbow, supinate the forearm, extend and radially deviate the wrist, extend the fingers, and gently press on the palm of the hand until a pain-free stretch is felt in the forearm.

### Maintain Upper Extremity Function

- **Active ROM.** Have the patient perform ROM to all joints to maintain the integrity of the upper extremity.
- **Resistive exercises.** Have the patient perform shoulder and scapular stabilization exercises with resistance applied proximal to the elbow.<sup>17,62</sup>

## Nonoperative Management: Controlled Motion and Return to Function Phases

Utilize the following management guidelines and interventions when pain has resolved.

### Increase Muscle Flexibility

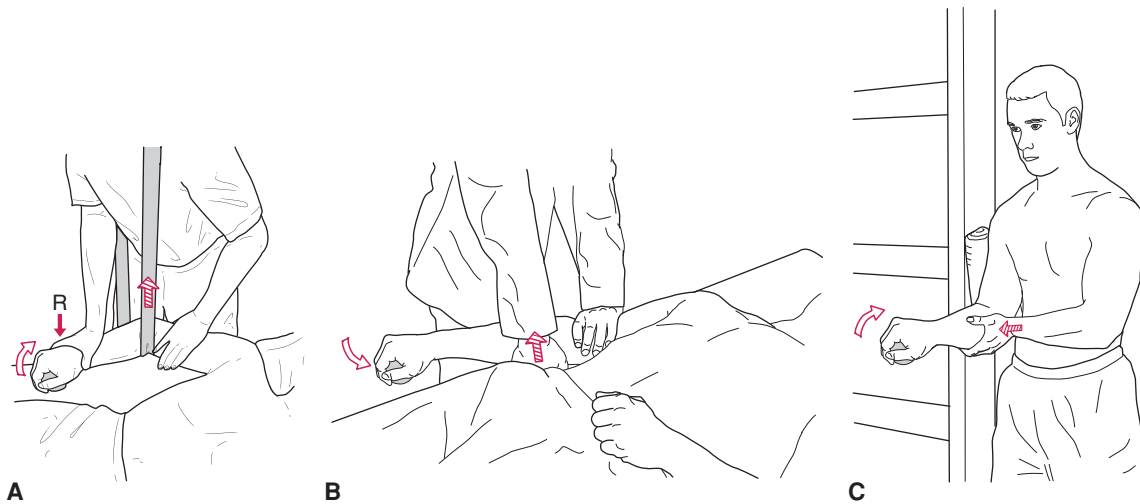

- **Manual stretching techniques.** Continue with passive stretching as described above. In addition, use agonist contract and hold-relax techniques to elongate the tight

musculature at an intensity that causes a stretching sensation but does not increase pain (principles for application of these techniques are described in Chapter 4).

- **Self-stretching techniques.** The patient may use a wall (see Fig. 18.10) and slide the hand along the wall until a stretch force is experienced, or the patient may use the opposite hand to apply the stretch force. These techniques are described in the self-stretching section later in the chapter.
- **Cross-fiber (friction) massage.** Continue with this technique as described above.

### Restore Joint Tracking at the RU Joint

- **MWM.** These pain-free techniques are used to correct a positional fault and to bring about immediate improvement in the patient's condition.<sup>79</sup> Several researchers have reported decreased pain and increased grip strength during or shortly after MWM at the elbow.<sup>20,21,107</sup> The following techniques are used if the patient experiences pain when making a fist or with resisted wrist extension. If immediate results do not occur, either the technique is not appropriate for the patient or the technique is not being done in the correct plane, grade, or direction of mobilization.<sup>79</sup>
  - **Patient position and procedure:** Supine with the forearm pronated, the elbow in slight flexion, and the shoulder in internal rotation. Place the mobilization belt around the patient's proximal forearm at the joint line and over your opposite shoulder facing toward the patient's feet. Stabilize the distal humerus with the proximal hand and utilize the other hand to either stabilize the wrist during a gripping motion or to provide resistance to wrist extension depending on the patient's comparable sign. Apply a gentle lateral sustained glide to the proximal forearm with the mobilization belt while the patient slowly extends their wrist 6-10 times. Build up to 3 sets of 10 repetitions. Apply pain-free resistance to wrist extension when tolerated. The lateral glide and the muscle contraction must be pain free (A).
  - **Alternative method:** Stabilize the distal humerus with the outside hand and apply gentle lateral glide of the proximal forearm with the inside hand. Have the patient slowly extend their wrist or squeeze a foam ball 6-10 times increasing to 3 sets of 10 as tolerated (Fig. 18.6 B). Both the lateral glide and the muscle contraction must be pain free. Add a light weight to provide resistance to wrist extension when tolerated.
- **Self-MWM.** The patient stands with the humerus of the involved elbow stabilized against a doorframe and the forearm in the opening. The elbow is positioned at 90° with the forearm in pronation and parallel to the floor. The patient applies a gentle lateral glide to the proximal forearm with the contralateral hand and then does slow, gentle gripping of a squeezable ball (Fig. 18.6 C).

**FIGURE 18.6** MWM for lateral epicondylitis. Lateral glide is applied to the proximal forearm (A) with active wrist extension, (B) with patient squeezing a ball, and (C) with self-mobilization.

### Improve Muscle Performance and Function

- **Counter force elbow sleeve or strap.** Use an elbow orthosis to help reduce the load on the musculotendinous unit. This type of orthosis has been shown to have the immediate effect of improving pain-free grip strength in individuals with lateral epicondylitis.<sup>47,52,96,111</sup>
- **Dynamic resistance exercise.** Progress to dynamic exercises against manual or elastic resistance or free weights through pain-free ranges. Initially, use low-intensity resistance with multiple repetitions for muscular endurance, then progress to more intense resistance to strengthen the muscles in preparation for functional demands.
  - **Eccentric training.** Incorporate a progression of eccentric contractions of the involved musculotendinous unit, first within a comfortable wrist ROM against a low-intensity load, at a slow speed, and preferably with the elbow in a relatively extended position.<sup>20,92,100,103</sup> Use of an isokinetic dynamometer enables the patient to perform repetitive, eccentric-only contractions.<sup>30</sup> If elastic resistance or a free weight is used, have the patient lift the weight or lengthen the elastic band with the sound hand when returning to the starting position of wrist extension.<sup>65</sup>
  - **Progressions.** Progress to faster speeds before increasing the resistance. When resistance is increased, return to a slow speed and then again work up to a faster speed before increasing the resistance and so on. Gradually perform the eccentric contractions through a full, pain-free ROM.

### FOCUS ON EVIDENCE

There is emerging evidence and moderate research support that suggests eccentric resistance training (typically combined with a program of static stretching) is effective in the treatment of lateral epicondylitis and weak evidence for the use of isokinetic and isometric exercise.<sup>92</sup>

Theoretical rationale suggests that progressive loading is indicated for increasing tensile strength and muscle

endurance. A treatment approach that includes eccentric exercise performed in the range of 6 to 12 weeks with 3 sets of exercises consisting of 10 to 15 repetitions is effective in treating lateral epicondylitis and has the best current supporting evidence.<sup>40,64,65,92,103</sup>

- **Functional patterns.** As flexibility and strength improve and the pain is brought under control, incorporate functional training, utilizing functional patterns into the exercises. Emphasize control of the resistance through the pattern. If pain or deviation of the pattern with substitute motions occurs, have the patient rest before resuming additional repetitions. Exercises simulating the desired activity are progressed from slow, controlled motions to high speeds with low resistance to improve timing (see Fig. 18.22).
- **General strengthening and conditioning.** Incorporate any unused or underused part of the extremity or trunk into the training program prior to returning to the stressful activity.<sup>38</sup>
- **Plyometric exercises.** Add plyometrics to the program if the patient's goals include returning to sports or occupational activities that require elbow and forearm power. Suggestions include the following and are described and shown in Chapter 23.<sup>38</sup>
  - Dribbling a weighted ball against the wall or the floor
  - Flipping and catching a weighted ball
  - Bouncing a tennis ball on a short-handled racquet, progressing to a long-handled racquet
  - Rapid eccentric/concentric elbow and forearm motions against elastic resistance
  - Rapid chest passes or overhead passes using a weighted plyometric ball
- **Activity modification.** It may be necessary to modify the patient's activity or technique before he or she returns to the repetitive or stressful activity. For example, it may require taking tennis lessons to correct improper tennis techniques, adapting the use of a hammer or other equipment, or making ergonomic modifications of a computer workstation.<sup>38,39,109</sup>

**NOTE:** Information on ergonomic recommendations for computer workstations are described in Chapter 14.

### Patient Education

- Education includes advice and techniques on prevention, recognition of provoking factors, and identification of warning symptoms.
- Teach the patient how to reduce the overload forces that caused the problem and retrain the patient in proper techniques.<sup>38,39</sup>
- In addition to exercises, include home instructions on the application of cross-friction massage and stretching the involved muscle prior to activity.

### FOCUS ON EVIDENCE

In a descriptive study of 60 subjects with lateral epicondylalgia who were followed for 6 months after initiating physical therapy intervention, Waugh and associates<sup>109</sup> reported that 80% of the participants continued to improve, but only 33% had complete resolution of symptoms. The therapy intervention consisted of 8 weeks of ultrasound, deep transverse friction massage, and a stretching/strengthening program for the wrist extensor muscles; 37% of the participants also received treatment for the cervical spine or shoulder. Altogether, 50% continued with some form of therapeutic intervention after the initial 8 weeks. Those with poorer outcomes had repetitive work duties, with 92% of the repetitive duties involving computer work.

This study also reported that women who have positive cervical signs as well as repetitive job duties involving computer usage had a poorer prognosis. This was observed at both 8 weeks and 6 months. Ergonomic recommendations for postural adaptations when using a computer included having forearm support, smooth movements, and relaxed shoulders.<sup>109</sup>

## Exercise Interventions for the Elbow and Forearm

### Exercise Techniques to Increase Flexibility and Range of Motion

Prior to initiating a muscle stretching program, be sure the joint capsule is not restricting motion. Techniques to increase joint play in the elbow and forearm articulations are discussed earlier in the chapter. Principles and techniques for applying joint mobilization techniques are presented in Chapter 5.

In addition to the description of principles and techniques of stretching presented in Chapter 4, manual, mechanical, and self-stretching techniques directed to the elbow are described in this section. When teaching the patient self-stretching, emphasize the importance of maintaining a low-intensity, prolonged

stretch and not applying a ballistic stretch force (bouncing at the end of the range).

## Manual, Mechanical, and Self-Stretching Techniques

### To Increase Elbow Extension

#### Mechanical Stretch: Mild Flexion Contracture

**Patient position and procedure:** Supine with the arm supported on the treatment table and a folded towel under the distal humerus as a fulcrum. Place a light cuff weight around the distal forearm. Position the forearm in pronation, midposition, and then supination to affect each of the three flexor muscles. Have the patient stabilize the proximal humerus with the other hand or place a sandbag or belt across the proximal humerus to stabilize it. Instruct the patient to maintain the stretch for an extended period of time.<sup>10</sup>

### CLINICAL TIP

Of the three muscles that flex the elbow, only the biceps brachii crosses the shoulder; it also rotates the forearm. Therefore, to fully elongate the biceps brachii, the shoulder must be extended and forearm pronated in addition to extending the elbow.

#### Self-Stretch: Mild Flexion Contracture

**Patient position and procedure:** Sitting with arm supported on the treatment table and a folded towel under the distal humerus as a fulcrum. Using the opposite hand, have the patient apply the stretch force against the distal forearm positioned in pronation, midposition, and then supination to affect each of the flexor muscles.

#### Mechanical Stretch: Static Progressive Orthotic Intervention

Apply a low-intensity, long-duration mechanical stretch force with a static progressive orthosis to reduce a long-standing elbow flexion contracture by affecting the soft tissue properties of creep and stress-relaxation.<sup>36,104</sup>

### FOCUS ON EVIDENCE

Ulrich and colleagues<sup>104</sup> carried out a prospective study to investigate the effectiveness of a patient-directed stretching program based on the principles of static progressive stretch and stress-relaxation (see Fig. 4.7 B) with 37 patients (37 elbows) with posttraumatic contractures of the elbow. Patients with any degree of heterotopic bone formation were excluded from the study. Patients performed a 30-minute stretching protocol one to three times per day in a static progressive elbow orthosis over a period of time (mean, 10 weeks; range, 2 to 25 weeks). The intensity of the stretch was controlled by the patient.

At the conclusion of the study, the mean gain in overall elbow ROM was significant (26°, range 2° to 60°), as were gains in range of elbow flexion and extension individually. Prior to the

orthotic intervention program, overall elbow ROM was 81°, and it was 107° at the conclusion of the program. During the course of the study, overall patient satisfaction was good, and no patients required anti-inflammatory medication. The authors concluded that daily use of a static progressive orthosis and applying the principles of stress-relaxation over a relatively short period of time was an effective means of increasing elbow ROM.

### Manual Stretch: Biceps Brachii

**Patient position and procedure:** Prone with the elbow in end-range but comfortable extension and forearm in pronation. Stabilize the scapula and passively extend the shoulder.

### Mechanical Stretch: Biceps Brachii

**Patient position and procedure:** Supine with a light cuff weight around the distal forearm and the elbow in extension and forearm in pronation. Have the patient stabilize the proximal humerus with the opposite hand and then place the arm over the side of the table. Allow the elbow and shoulder to extend as far as possible and sustain the stretch position for an extended period of time (Fig. 18.7 A).

### Self-Stretch: Biceps Brachii

**Patient position and procedure:** Standing at the side of a table. Have the patient grasp the edge of the table and walk forward, causing shoulder extension with elbow extension

**FIGURE 18.7** Self-stretching the biceps brachii musculotendinous unit includes stretching the long head across the shoulder joint (A) supine and (B) standing.

(Fig. 18.7 B). It is important to note that this stretching position does not include forearm pronation.

## To Increase Elbow Flexion

### Self-Stretch: Mild Extension Contracture

- **Patient position and procedure:** Prone-lying and propped up on elbows with forearms resting on the exercise mat. Have the patient lower the chest as far as elbow flexion allows and maintain the position as long as tolerated.
- **Patient position and procedure:** Sitting with elbow flexed as far as possible. Have the patient press against the distal forearm with the opposite hand to provide the stretch force into flexion. Alternatively, with the forearm supported on a table or arm rest of a chair, have the patient lean forward flexing the humerus against the stabilized forearm and maintaining the position as long as tolerated.

### Self-Stretch: Long Head of Triceps

**Patient position and procedure:** Sitting or standing. Have the patient flex the elbow and shoulder as far as possible. The other hand can either push on the forearm to flex the elbow, or push the shoulder into more flexion (Fig. 18.8). Hold the stretch position as long as tolerated.

**FIGURE 18.8** Self-stretching the triceps brachii musculotendinous unit includes stretching the long head across the shoulder joint.

## To Increase Forearm Pronation and Supination

**Patient position and procedure:** Sitting with the elbow flexed to 90° stabilized against the side of the trunk or supported on a table. It is important to maintain the elbow position to prevent shoulder rotation.

### Self-Stretch to Increase Pronation

Have the patient grasp the dorsal surface of the involved forearm so the heel of the uninvolved hand is against the dorsal aspect of the radius just proximal to the wrist and wrap the fingers around the ulna. Have the patient passively pronate the forearm and sustain the stretch as long as tolerated. The force is applied against the distal radius and not the carpals to avoid trauma to the wrist.

### Self-Stretch to Increase Supination

Have the patient place the heel of the uninvolved hand against the volar aspect of the involved radius just proximal to the wrist, passively supinate the forearm, and sustain the stretch as long as tolerated. Be sure the force is applied against the radius, not the carpals to avoid trauma to the wrist (Fig. 18.9).

**FIGURE 18.9** Self-stretching the forearm into supination. The forearm may be stabilized on a table (as pictured) or at the patient's side. It is important to maintain elbow flexion to prevent shoulder rotation and to apply the stretch force against the radius, not the hand.

## Self-Stretching Techniques: Muscles of the Medial and Lateral Epicondyles

### To Stretch the Wrist Extensor Muscles (From the Lateral Epicondyle)

- *Patient position and procedure:* Sitting or standing with the elbow extended and forearm pronated. While holding this position have the patient ulnarly deviate the wrist and flex the wrist and fingers; then apply a gentle stretch force against the dorsum of the hand. The patient should feel a stretching sensation along the dorsal surface of the forearm.
- *Patient position and procedure:* Standing with elbow extended, forearm pronated, and back of the hand against a wall (fingers pointing down). Have the patient then slide the back of the hand up the wall until a stretch is felt in the forearm (Fig. 18.10). For additional stretch, have the patient flex the fingers.

**FIGURE 18.10** Self-stretching the wrist extensor muscles.

### To Stretch the Wrist Flexor Muscles (From the Medial Epicondyle)

- *Patient position and procedure:* Sitting or standing with the elbow extended and forearm supinated. While holding this position, have the patient radially deviate and extend the wrist and apply a gentle stretch force with the other hand against the palm of the hand. A stretch sensation should be felt along the volar surface of the forearm.
- *Patient position and procedure:* Standing with the elbow extended and forearm supinated. Have the patient place the palm of the hand against a wall, fingers pointing down, and then move the hand up the wall until a stretch sensation is felt in the wrist flexor muscles.

## Exercises to Develop and Improve Muscle Performance and Functional Control

In addition to the conditions already described in this chapter, imbalances in length and strength of muscles crossing the elbow and forearm can be the result of a variety of causes, such as nerve injury or after surgery, trauma, disuse, or immobilization. Appropriate exercises to develop neuromuscular control, increase strength, and improve muscular endurance for return to functional activities can be selected from the following exercises as well as the techniques described in Chapters 6 and 23.

For patients with elbow impairments, exercises for the regions above (shoulder girdle) and below (wrist and hand) also should be incorporated into the therapeutic exercise program to prevent complications and restore proper function of the entire upper quarter. The general principles of managing acute soft tissue lesions are discussed in Chapter 10. The exercises described in this section are for use during the controlled motion and return to function phases of intervention when tissues are in the subacute and chronic stages of healing and require only moderate to minimum protection.

## Isometric Exercises

### Multiple-Angle Isometric Exercises

Use manual or mechanical resistance at various positions throughout the available ROM of elbow flexion and extension and forearm rotation. Isolate the key musculature. Apply resistance at the distal forearm, not at the hand, to avoid forces across the wrist joints.

### Angle-Specific Training

During isometric exercises, emphasize joint positions that simulate use of the elbow for anticipated functional activities. For example, to simulate carrying large boxes close to the chest, strengthen the elbow flexors in a 70° to 90° position

with the forearm in neutral and supination. Emphasize holding objects for extended periods of time to increase muscular endurance for sustained control.

## Alternating Isometrics and Rhythmic Stabilization

### Open-Chain Exercises

Apply manual resistance to alternating isometric contractions of antagonists at multiple angles of elbow flexion/extension and forearm pronation/supination. Stabilize the humerus and apply the resistance against the forearm.

When the patient is able to respond to the alternating resistance at various elbow and forearm positions and at varying speeds, progress to alternating isometrics using total upper extremity patterns. To further develop stability superimposed on movement (dynamic stability), have the patient hold a vibrating BodyBlade® in various positions of the elbow, forearm, and the entire upper extremity and then during a variety of movements.

### Closed-Chain Exercises

Patient positions include standing with hands against a wall or table, in the quadruped position, or in the prone push-up position (with knees or toes as a fulcrum). Have the patient hold the desired elbow position and apply alternating isometrics and rhythmic stabilization by means of manual resistance against the shoulders and trunk.

## Dynamic Strengthening and Endurance Exercises

Many muscles that cross the elbow joint are multijoint muscles, such as the biceps, long head of the triceps, and wrist flexors and extensors. It is particularly important to consider the position of the shoulder and forearm during resistance training at the elbow. Dynamic strengthening and endurance activities for the *prime movers* of the elbow, forearm, and wrist using manual or mechanical resistance are noted in this section. Combined patterns of motion during open- and closed-chain activities are described in the final section describing a functional progression for the elbow and forearm.

### Elbow Flexion

Muscles include the biceps brachii, brachialis, and brachioradialis.

- *Patient position and procedure:* Sitting or standing, with the humerus at the side of the chest (arm perpendicular to the floor). Have the patient hold a weight or grasp a piece of elastic band or tubing (secured under the foot or to the floor) and flex and extend the elbow. This strengthens the elbow flexors concentrically and eccentrically throughout the available ROM to simulate functional lifting and lowering. Perform this motion with the forearm supinated, pronated, and in neutral.

- *Patient position and procedure:* Supine with the humerus supported on a treatment table. When the patient is supine, the resistive force from a free weight or gravity has a greater effect on the muscles near end-range extension and has little to no effect as the elbow reaches 90°.
- *Patient position and procedure:* Standing or sitting while holding a weight with the forearm supinated. Have the patient extend the shoulder as the elbow flexes (Fig. 18.11). This combined motion elongates the biceps brachii over the shoulder as the muscle is shortening to move the elbow and thus most efficiently maintains optimal length for development of maximum tension in the *biceps*. This combined motion develops control for carrying objects at the side.

**FIGURE 18.11** Resisting elbow flexion with emphasis on the biceps brachii. The shoulder extends as the elbow flexes with the forearm in supination. This combined action lengthens the proximal portion of the musculotendinous unit across the shoulder while it contracts to move the elbow, thus maintaining a more optimal length-tension relationship through a greater ROM.

### Elbow Extension

Muscles include the triceps and anconeus.

- *Patient position and procedure:* Prone, humerus abducted to 90° and supported on a rolled towel on a treatment table. Have the patient extend the elbow while holding a weight. This position strengthens the elbow extensors from 90° of flexion to terminal extension.
- *Patient position and procedure:* Supine with the shoulder flexed to 90°, holding a weight in the hand. Have the patient begin with the elbow flexed and the weight either at the ipsilateral or contralateral shoulder (external or internal rotation of the shoulder); then extend and flex the elbow (lift and slowly lower the weight) to strengthen the elbow extensors concentrically and eccentrically. To help

maintain the shoulder in a stable position, have the patient stabilize the humerus in the 90° position with the opposite hand.

### Long Head of Triceps With Elbow Extension

**Patient position and procedure:** Sitting or standing with the arm held overhead (shoulder fully flexed) and elbow flexed so the weight is near the shoulder (Fig. 18.12). Have

**FIGURE 18.12** Resisting elbow extension, beginning with the long head of the triceps brachii on a stretch.

the patient lift the weight overhead and then slowly lower the weight for concentric and eccentric strengthening. The patient may support the humerus with the opposite hand. Perform this exercise only if the patient has sufficient control of the shoulder.

### Pronation and Supination

Primary muscles of pronation are the pronator teres and pronator quadratus; primary muscles of supination are the supinator and biceps brachii.

**Patient position:** Sitting or standing with the elbow flexed to 90° and held close to the trunk. When sitting, the forearm may be on a table for support held next to the trunk.

- **Free weights.** When using a free weight to strengthen the pronators and supinators, the weight must be placed on one side or the other of the hand (Fig. 18.13). As the patient rotates the bar be sure that they keep the wrist in a neutral position so as not to stress the wrist especially at end ranges. The weight can also be turned through a downward arc by placing the resistance on the ulnar side of the hand.
- **Elastic resistance.** Have the patient grasp one end of the elastic resistance with the sound hand or by tying it to a doorknob (be sure that the elastic is secure). Have the patient grasp the other end with the involved extremity and rotate the forearm against the resistance. For greater resistance, secure the elastic resistance around the end of a short rod and have the patient pull against the resistance force.
- **Functional activity.** Have the patient stand, facing a doorknob with the arm kept at the side and the elbow flexed to 90° to avoid substituting with shoulder rotation. Have the patient turn the knob.

**FIGURE 18.13** Mechanical resistance exercise using a small bar with an asymmetrically placed weight for strengthening (A) forearm pronators and (B) supinators. The bar also can be rotated through a downward arc to affect the other half of the range for each muscle by placing the weight on the ulnar side of the hand.

## Wrist Flexion and Extension

Wrist flexion involves muscles attached to the medial epicondyle; extension involves muscles attached to the lateral epicondyle.

**NOTE:** In the following exercises, when the forearm is pronated, resistance is applied to the wrist extensors; when supinated, resistance is applied to the wrist flexors.

- **Elastic resistance.** Tie the ends of an elastic band or tubing together. While sitting, have the patient place one end of the loop under one foot. Stabilize the forearm on the thigh and place the other end of the loop across the dorsum (Fig. 18.14) or palm of the hand to resist the wrist extensors or flexors, respectively.
- **Free weights.** Have the patient sit, with forearm resting on a table and hand over the edge of the table holding a small weight (Fig. 18.15). Extend and flex the wrist against the resistance.
- **Wrist roller.** Have the patient sit or stand, with the elbows flexed or extended and the forearms pronated or supinated. Tie a 2- to 4-ft cord to the middle of a short rod and a weight to the other end of the cord. Have the patient hold each end of the rod and with an alternating wrist action, turn the rod causing the cord to wind around the rod and elevate the weight. The weight is then slowly lowered with a reverse motion (Fig. 18.16).

## Functional Progression for the Elbow and Forearm

A comprehensive rehabilitation program for the elbow and forearm designed to achieve an individual's functional goals involves a sequence of carefully progressed exercise interventions designed to develop or restore sufficient mobility, strength, stability, muscular endurance, and power. The final section of this chapter identifies integral components and

**FIGURE 18.14** Strengthening the wrist extensors using elastic resistance without the use of grasp.

**FIGURE 18.15** Strengthening the wrist extensors while grasping a handheld weight for resistance.

**FIGURE 18.16** Wrist roller exercise to strengthen grip and develop the wrist extensors. This exercise requires stabilization in the shoulder girdle and elbow muscles. The elbows may be flexed or the forearms supinated to emphasize the elbow flexors or muscles of the medial epicondyle, respectively.

examples of exercise interventions and simulated functional activities that often are included in a functional progression for the elbow and forearm. Refer to Chapters 17 and 23 for additional exercises and activities.

**NOTE:** Because the elbow primarily functions during activities that also involve the shoulder and hand, combined patterns of exercise that develop mobility and control the entire upper extremity should be implemented especially as it relates to

proximal stabilization. Be careful that substitute motions do not occur to compensate for a weak link in the chain.

### Diagonal Patterns

#### **PNF patterns against manual or mechanical resistance.**

Use unilateral or bilateral diagonal patterns as described in Chapter 6. Use manual resistance, free weights, elastic resistance, a weight-pulley system, or an isokinetic dynamometer to provide the resistance as the patient moves through the diagonal patterns. Gradually increase resistance, speed (if appropriate with the choice of equipment), and repetitions.

### Combined Pulling Motions

**Elbow flexors are used in pulling,** lifting, and carrying activities in open- and closed-chain activities. These upper extremity actions also require strength of the scapular retractors, shoulder extensors, and wrist and hand musculature. Many of the exercises that are described for the shoulder in Chapter 17 also involve resisted elbow flexion and therefore can be used to strengthen muscle groups during pulling motions. Suggestions include:

- Bilateral pull-ups against elastic resistance (Fig. 18.17).
- Closed-chain chin-ups or modified pull-ups on an overhead bar (Fig. 18.18).
- Unilateral combined pulling pattern simulating starting a lawn mower (Fig. 18.19) or bilateral or unilateral rowing motions, such as using a rowing machine.
- Pulling a variety of weighted objects with one or both arms, emphasizing elbow flexion and proper body mechanics.

**FIGURE 18.17** Bilateral pull-up against elastic resistance.

**FIGURE 18.18** Closed-chain, modified chin-up using top half of body weight for resistance to strengthen the elbow flexors. This exercise may be performed in a bed with an overhead trapeze.

**FIGURE 18.19** Simulation of a “lawn mower pull” for functional strengthening of the upper extremity.

### Combined Pushing Motions

The triceps muscle is involved in pushing motions. Pushing also involves variations of shoulder flexion and scapular protraction or depression so that muscles controlling these motions are functioning with the triceps. Many of the exercises described in Chapter 17 for the shoulder and Chapter 23 also involve resisted elbow extension and may be used to strengthen muscle groups involved in pushing patterns. Suggestions include:

- Military press-up (see Fig. 17.55)
- Bench press
- Upper extremity ergometry (see Fig. 6.55)

- Wall push-ups, semi-prone or prone push-ups (Fig. 18.20 A)
- Push-ups from a chair or on parallel bars (Fig. 18.20 B)
- Stepping/stair-climbing machine with hands on the “steps” (emphasize elbow extension)
- Pushing a variety of weighted objects with one or both arms using dynamic elbow extension (Fig. 18.21)

**FIGURE 18.20** Closed-chain strengthening of the triceps. (A) Modified push-up. (B) Seated push-up.

**FIGURE 18.21** Strengthening the triceps with pushing activities. (A) Pushing weighted objects across a table. (B) Depressing a door handle and pushing open a door.

### Plyometric Training (Stretch-Shortening Drills)

The following are suggestions for increasing power of the elbow musculature using plyometric exercises.<sup>10,38</sup> Advanced training activities are described in Chapter 23.

- Perform elbow flexion and extension exercises against elastic resistance, emphasizing rapid reversal between eccentric and concentric motions.
- Using a weighted ball, have the patient catch the ball and then quickly throw it back. Emphasize elbow motions with overhead passes, chest passes, and lateral passes.
- Bounce a ball against a wall or a tennis ball on a racquet with the forearm pronated and supinated.

### Simulated Functional Tasks and Activities

Determine the component motions of the patient's desired functional activities as well as occupational or recreational tasks. Have the patient simulate these motions and practice the entire task. Activities could involve lifting, lowering, carrying, pushing, pulling, twisting, turning, catching, throwing, or swinging. For example, if the patient is recovering from repetitive trauma to the muscles of the lateral epicondyle when playing tennis, have the patient practice the various racquet strokes using a wall-pulley system (Fig. 18.22). Impose controlled forces to challenge the patient by increasing the time or repetitions, speed, or resistance.<sup>38</sup>

**FIGURE 18.22** Mechanical resistance exercise using wall pulleys to simulate tennis swings. (A) Backhand stroke. (B) Forehand stroke. (C) Serve.

## Independent Learning Activities

### Critical Thinking and Discussion

1. Differentiate between the etiology, signs and symptoms, and management of lateral and medial epicondylalgia. Note the similarities and differences.
2. Develop, compare, and contrast the postoperative management (including an exercise progression and precautions) after two types of TEA: (1) a semiconstrained implant/triceps-reflecting approach and (2) a resurfacing implant/triceps-splitting approach.
3. The goal is to increase muscle performance and function of the elbow flexors that are currently functioning at a 3/5 strength level and endurance of four repetitions. Identify exercises that could be used at each increment of strength, including exercises for strength, endurance, power, control, stability, and function. Identify parameters for progression of each exercise and any precautions.
4. Do the same sequence of analysis and identification to increase muscle performance and function of the elbow extensors.
5. Analyze the following household, occupational, or sports-related activities. Identify the components and sequence of motions related to each of these motor tasks; pay particular attention to elbow and forearm motions during these tasks. Design a sequence of upper extremity exercises and simulated activities that could be incorporated into a late-stage rehabilitation program to prepare a patient to return to the desired task after an elbow injury.
  - Housecleaning
  - Gardening
  - Grocery store stocking
  - Carpentry
  - Volleyball
  - Tennis
  - Throwing sports

2. Demonstrate passive stretching and hold-relax techniques to elongate the following muscles that cross the elbow: brachialis, brachioradialis, biceps, long head of the triceps, extensor digitorum, flexor carpi ulnaris, and flexor carpi radialis.
3. Using the following pieces of resistance equipment demonstrate at least two methods (set-ups) to strengthen the elbow flexors/extensors and forearm rotators: free weights, weight-pulley system, and elastic resistance. Then demonstrate a progressive sequence of resistance exercise to strengthen the same muscle groups using self-resistance (body weight or manual resistance).

### Case Studies

1. Describe the mechanical problem causing impairments in the elbow and forearm in the following scenario and what techniques could be used for intervention. A patient is referred to you 4 weeks after sustaining a fracture of the distal radius with immobilization in a long arm cast following a fall on an outstretched arm and hand. She has limited elbow, forearm, and wrist motions. On palpation, you note a decreased space between the lateral aspect of the head of the radius and capitulum as well as decreased joint play at all articulations of the elbow, forearm, and wrist.
2. A 15-year-old patient with a 5-year history of polyarticular JRA just underwent open synovectomy and excision of the head of the radius with implant for late-stage joint disease of the elbow. Prior to surgery, the patient had severe pain in the elbow region, lacked full elbow flexion/extension and forearm rotation, and had limited use of the arm for functional activities. Continuous passive motion was implemented during the patient's hospitalization (3 days). A day prior to discharge, the patient was referred to physical therapy for a home program. Design an exercise program for this teenager. Prioritize and describe each exercise you want the patient to do for the first week at home. Outline a program of exercises for later use in the rehabilitation process. The patient plans to return to school within a week of discharge from the hospital. Indicate whether you recommend outpatient therapy; if so, indicate the frequency and duration; justify the need for this recommendation.

### Laboratory Practice

1. Apply mobilization techniques to a laboratory partner to increase the following elbow and forearm motions: mid- and end-range elbow flexion; mid- and end-range elbow extension; and forearm pronation and supination (proximal and distal articulations).

 Dexterity and Functional Activities 708

### Independent Learning Activities 709

The wrist is the final link of joints that positions the hand for functional activities. It functions to control the length-tension relationship of the multiarticular muscles of the hand as they adjust to various activities. The wrist is often considered the most complex joint of the body, both from an anatomical and physiological perspective. However, there are two points of consensus regarding the wrist: (1) the structure and biomechanics of the wrist as well as the hand vary significantly from person to person and (2) even subtle variations can produce differences in the way a particular functional activity occurs.<sup>9</sup> The hand is a valuable tool through which we control and manipulate our environment

and express ideas and talents. It also has an important function of providing sensory feedback to the central nervous system.

This chapter is divided into three major sections. The first section briefly reviews the rather complex structure and function of the wrist and hand—information that is important to know in order to effectively treat patients with wrist and hand pathology. The second section describes common disorders and guidelines for conservative and postoperative management. The last section describes exercise techniques commonly used to meet the goals of treatment during the stages of tissue healing and phases of rehabilitation.

## Structure and Function of the Wrist and Hand

The bones of the wrist include the distal radius and ulna. The scaphoid (S), lunate (L), triquetrum (Tri), and pisiform (P) make up the proximal carpal row; the trapezium (Tm), trapezoid (Tz), capitate (C), and hamate (H) make up the distal carpal row. Five metacarpals and 14 phalanges make up the hand and the five digits (Fig. 19.1).

**FIGURE 19.1** Bones of the wrist and hand complex.

## Joints of the Wrist and Hand

### Wrist Joint: Characteristics and Arthrokinematics

The distal radioulnar (RU) joint is not considered part of the wrist joint, although pain and impairments in this forearm articulation are often described by the patient as wrist pain. Structure and function of the RU joints are described in Chapter 18.

The wrist joint is multiarticular and is made up of two compound joints, the radiocarpal/ulnocarpal and midcarpal joints. It is biaxial, allowing flexion, extension, radial deviation, and ulnar deviation. However, due to an oblique axis of rotation, most activities are carried out with an oblique wrist motion from extension with radial deviation to flexion with ulnar deviation. This oblique plane of motions is referred to as the “dart thrower’s motion” (DRT) and is an important concept when developing treatment plans for individuals with wrist pathology.<sup>24,53</sup> Stability is provided by numerous extrinsic ligaments: the ulnar and radial collateral, the dorsal and

volar (palmar) radiocarpal, the ulnocarpal and the triangular fibrocartilage complex, as well as a multitude of intrinsic intercarpal ligaments.<sup>9,102</sup>

The pisiform is categorized as a carpal bone and aligned volar to the triquetrum in the proximal carpal row. It is not part of the wrist joint per se but functions as a sesamoid bone in the flexor carpi ulnaris tendon.

### Radiocarpal Joint

**Characteristics.** The radiocarpal (RC) and ulnocarpal (UC) joints are enclosed in a loose but strong capsule that is reinforced by the ligaments shared with the midcarpal joint. The biconcave articulating surface is made up of the distal end of the radius and articular disc (an integral part of the triangular fibrocartilage complex) and is angled slightly volarly and ulnarly.<sup>9,102</sup> The biconvex articulating surface of the proximal carpal row includes the scaphoid, lunate, and triquetrum. The triquetrum primarily articulates with the disc. These three carpals are bound together with numerous interosseous ligaments.

**Arthrokinematics.** With motions of the wrist, the convex proximal row of carpals slides on the concave distal radius and articular disc in the direction opposite the physiological motion of the hand. The arthrokinematics are summarized in ONLINE Box 19.1 available on the FA Davis website related to this textbook.

### Midcarpal Joint

**Characteristics.** The midcarpal joint is a compound joint between the proximal and distal carpal rows. It has a capsule that is also continuous with the intercarpal articulations. The combined distal surfaces of the distal carpal row (scaphoid, lunate, and triquetrum) articulate with the proximal carpal row (trapezium, trapezoid, capitate, and hamate).

**Arthrokinematics.** The midcarpal joint is divided into radial and ulnar compartments.

- The *ulnar compartment* consists of the articulating surfaces of the capitate and hamate and is, in essence, convex, which slides on the concave articulating surfaces of a portion of the scaphoid, lunate, and triquetrum. Therefore, with flexion and extension, as well as radial and ulnar deviation, the distal component of the ulnar compartment (capitate and hamate) slides opposite the physiological motion.
- The *radial compartment* of the midcarpal joint consists of the articulating concave surfaces of the trapezium and trapezoid, which slide on the convex distal surface of the scaphoid. With flexion and extension, the distal component of the radial compartment (trapezium and trapezoid) slides in the same direction as the physiological motion. However, during radial and ulnar deviation, it has been shown through cineradiography (three-dimensional CT scan) that the proximal row of carpal bones “rock” slightly either volarly or dorsally and, to a lesser extent, “twist.” The

rocking motion is most pronounced in the scaphoid, which moves volarly (flexes) during radial deviation and slightly dorsally (extends) during ulnar deviation.

### FOCUS ON EVIDENCE

According to Moojen, at 20° of ulnar deviation, the scaphoid rotates dorsally about 20° relative to the radius, and at 20° of radial deviation, the scaphoid moves volarly about 15°, which allows for a few more degrees of radial deviation.<sup>9,96,97,102</sup> The exact mechanism that produces this motion is not well understood; however, it is theorized that it occurs because of the passive forces of the ligaments and compression between the adjacent carpals.<sup>102</sup>

## Hand Joints: Characteristics and Arthrokinematics

### Carpometacarpal Joints of Digits 2 through 5

**Characteristics.** The carpometacarpal (CMC) joints are enclosed in a common joint cavity and include the articulations of each metacarpal with the distal row of carpals and the articulations between the bases of each metacarpal.

The joints of digits 2 and 3 are difficult to classify due to their jagged interlocking articular surfaces; however, they are most often considered to be planar joints. These interlocking surfaces, combined with strong ligaments, allow for very little motion as stability at these joints is paramount to the overall stability of the hand and forms the central pillar. The slightly convex bases of the fourth and fifth metacarpals articulate with the slightly concave surface of the hamate and allow for important mobility to the hand. The fourth and fifth metacarpal joints are able to “fold” or rotate toward the center of the hand, deepening the palmar concavity. This motion occurs by flexion and internal rotation of the fourth and fifth metacarpals moving toward the third digit and is often referred to as “cupping” of the hand.<sup>9,103</sup> This motion improves the ability of the hand to grasp objects of various sizes. Extension of the metacarpals contributes to flattening of the hand, which improves the ability to release objects.

**Arthrokinematics.** The slightly concave proximal surfaces of the metacarpals slide in a volar direction on the relatively convex surfaces of the distal carpal row with flexion and in a dorsal direction with extension motions in the hand (see ONLINE Box 19.1).

### Carpometacarpal Joint of the Thumb (Digit 1)

**Characteristics.** The CMC joint of the thumb is a saddle-shaped (sellar) joint between the trapezium and base of the first metacarpal. The longitudinal diameter of the articular surface of the trapezium is concave in the dorsal to volar direction, while the transverse diameter of the articular surface is convex in the radial to ulnar direction. The proximal articular surface of the thumb metacarpal joint is convex in

the dorsal to volar direction and concave in the radial to ulnar direction, thus opposite to the surface of the trapezium. The thumb CMC joint has a lax capsule and wide range of motion (ROM) that allows the thumb to fully oppose the other digits, which greatly enhances prehension activities.<sup>9,103</sup>

**Arthrokinematics.** A change in terminology relative to thumb CMC joint motion was adopted by the American Academy of Orthopaedic Surgeons (AAOS), the American Society for Surgery of the Hand (ASSH), the International Federation of Societies for Surgery of the Hand (IFSSH), and the American Society of Hand Therapists (ASHT) in the early 1990s. Many publications in the United States and internationally have since incorporated this terminology when discussing the thumb CMC joint.<sup>13,72,84,100,114</sup>

- The motions previously known as CMC abduction and adduction are termed *palmar abduction* and *adduction* (moving away from or toward the palm); in this plane the distal surface of the metacarpal is convex and the proximal surface of the trapezium is concave. Since the distal segment moves on the proximal segment, the motion is convex on concave; therefore, the metacarpal slides in the opposite direction of the physiological motion.
- The motions previously known as CMC flexion and extension are termed *radial abduction* and *adduction* (moving away or toward the radius). In this plane, the distal surface of the metacarpal is concave, and the proximal surface of the trapezium is convex; therefore, the motion is concave on convex and the metacarpal slides in the same direction as the physiological motion (see ONLINE Box 19.1).

### Metacarpophalangeal Joints of Digits 2–5

**Characteristics.** The metacarpophalangeal (MP) joints are condyloid joints, which allows for flexion/extension and abduction/adduction. The MP joints of the fingers are surrounded by a relatively lax articular capsule, allowing for significant accessory motion and axial rotation of the proximal phalanx. This mobility enables the fingers to better conform to the shapes of objects and increases the control of grasp. Each joint is supported by a volar plate and two collateral ligaments. The collaterals become taut in full flexion and prevent abduction and adduction in this position.<sup>9,103</sup>

**Arthrokinematics.** The distal end of each metacarpal is convex, and the proximal phalanx is concave. The proximal surface of the proximal phalanx rolls and slides in the same direction as the physiological motion (see ONLINE Box 19.1).

### Interphalangeal Joints and MP Joint of the Thumb

**Characteristics.** There is a proximal interphalangeal (PIP) joint and a distal interphalangeal (DIP) joint for each digit, 2 through 5. The thumb has only one IP joint, although the MP joint of the thumb is uniaxial and therefore functions similarly to the IP joints. The MP joint of the thumb differs in that it is reinforced by two sesamoid bones on the volar

surface, which improves the leverage of the flexor pollicis brevis muscle. Each of these joints is a uniaxial hinge joint.

The capsule of each joint is reinforced with collateral ligaments. Unlike the MP joints, the collateral ligaments of the IP joints remains relatively constant throughout the ROM. There is increasing flexion/extension ROM in the MP joints as you move from radial to ulnar digits of 2 through 5. This allows for greater opposition of the ulnar fingers to the thumb and also causes a potentially tighter grip on the ulnar side of the hand.

**Arthrokinematics.** The articulating surface at the distal end of each phalanx is convex; the articulating surface at the proximal end of each phalanx is concave. Therefore, the proximal

surface of each phalanx rolls and slides in the same direction as the physiological motion (see ONLINE Box 19.1).

## Hand Function

### Muscles of the Wrist and Hand

The complex function of the hand occurs as a result of an intricate balance and control of forces between the extrinsic and intrinsic muscles of the wrist and hand. The primary and secondary actions of the wrist and hand muscles are summarized in Table 19.1 and depicted in Figure 19.2.

**TABLE 19.1** Muscles of the Wrist and Hand

Action	Prime Movers	Secondary Movers
<b>Wrist</b>		
Flexion	Flexor carpi radialis Flexor carpi ulnaris Palmaris longus	Flexor digitorum superficialis Flexor digitorum profundus Flexor pollicis longus
Extension	Extensor carpi radialis longus Extensor carpi radialis brevis Extensor carpi ulnaris Extensor digitorum	Extensor indicis Extensor digiti minimi Extensor pollicis brevis Abductor pollicis longus
Radial deviation	Flexor carpi radialis longus Extensor carpi radialis longus Extensor carpi radialis brevis	Flexor pollicis longus Extensor pollicis brevis Abductor pollicis longus
Ulnar deviation	Flexor carpi ulnaris Extensor carpi ulnaris	
<b>Thumb (Digit 1)</b>		
CMC opposition	Opponens pollicis	
CMC radial adduction	Opponens pollicis	
CMC radial abduction	Abductor pollicis longus	Extensor pollicis longus
CMC palmar abduction	Opponens pollicis Abductor pollicis longus Abductor pollicis brevis Extensor pollicis brevis	Flexor pollicis brevis (superficial head)
CMC palmar adduction	Adductor pollicis (first volar interossei)	Flexor pollicis brevis (deep head) Extensor pollicis longus
MP flexion	Flexor pollicis brevis	Flexor pollicis longus
MP extension	Extensor pollicis brevis Extensor pollicis longus	Extensor pollicis longus
IP flexion	Flexor pollicis longus	
IP extension	Extensor pollicis longus	

**TABLE 19.1** Muscles of the Wrist and Hand—cont'd

Action	Prime Movers	Secondary Movers
<b>Digits 2 through 5 (function of these muscles varies with joint positions/motions)</b>		
MP flexion	Lumbricals Volar and dorsal interossei Flexor digitorum superficialis Flexor digitorum profundus	
MP extension	Extensor digitorum Extensor digiti minimi Extensor indices	
MP abduction	Dorsal interossei Abductor digiti minimi	(Note: Proximal wing tendons of the interossei have more influence on the MP joint) <sup>9</sup>
MP adduction	Volar interossei	
IP flexion	Flexor digitorum superficialis (PIP only) Flexor digitorum profundus (PIP and DIP)	
IP extension	Lumbricals, dorsal and volar interossei, and extensor digitorum via extensor mechanism	(Note: Distal wing tendons of the interossei have more influence on the IP joints) <sup>9</sup>

**FIGURE 19.2** The extrinsic and intrinsic muscles of the wrist and hand create a balance of forces that affect hand function.

### Length-Tension Relationships

The position of the wrist controls the length of the extrinsic muscles of the digits. As the fingers or thumb flex, the wrist extensor muscles must stabilize the wrist to prevent the flexor digitorum profundus and flexor digitorum superficialis or the flexor pollicis longus from simultaneously flexing the wrist. As the grip becomes stronger, synchronous wrist extension lengthens the extrinsic flexor tendons across the wrist and maintains a more favorable overall length of the musculotendinous unit for a stronger contraction.

For strong finger or thumb extension, the wrist flexor muscles stabilize the wrist so the extensor digitorum, extensor indicis, extensor digiti minimi, or extensor pollicis longus muscles can function more efficiently.

### Extensor Mechanism

Structurally, the foundation of the extensor mechanism is made up of the extensor digitorum tendon (with the extensor indicis and extensor digiti minimi), the extensor hood, the central tendon, and the lateral bands (stabilized by the

triangular ligament) that merge into the terminal tendon. The passive components of the extensor mechanism include the triangular ligament and the sagittal bands (which prevent bowstringing of the extensor mechanism and centralize the extensor tendons at the MP joints). The active components of the extensor mechanism include the dorsal interossei, the volar interossei, and the lumbrical muscles (collectively referred to as the intrinsic muscles) (Fig. 19.3).<sup>9,103</sup>

- The extensor digitorum tendon passes dorsal to the MP joint axis, and an active contraction of the extensor digitorum creates tension in the sagittal bands, pulling the bands proximally resulting in extension of the proximal phalanx.
- An isolated contraction of the extensor digitorum produces MP joint hyperextension with IP joint flexion. The IP joint flexion is produced from passive pull of the extrinsic flexor tendons. This position is called clawing or the hook position.
- PIP and DIP extension is interdependent, meaning when the PIP joint extends, the DIP joint will extend as well and is produced by the interossei and lumbrical muscles through their pull on the extensor hood.
- There must also be tension in the extensor digitorum tendon for there to be IP extension. This occurs either by active contraction of the muscle, causing MP extension concurrently as the intrinsic muscles contract, or by passive tension of the extensor digitorum tendon, which occurs with MP flexion.<sup>9</sup>
- The dorsal interossei, the volar interossei, and the lumbricals pass volar to the joint axis of the MP joint and insert

into the extensor mechanism proximal to the PIP joint. Therefore, when the extensor digitorum, the interossei, and the lumbricals all contract simultaneously, the MP joint and the IP joints will all extend. Although when the interossei and the lumbricals contract in the absence of active contraction of the extensor digitorum, the MP joints will flex and the IP joints will extend.

### Control of the Unloaded (Free) Hand

Anatomical factors, muscular contraction, and viscoelastic properties of the muscles influence finger motion.<sup>9,103</sup>

- When only the extrinsic extensor and flexor muscles contract, clawing motions occur in the digits.
- Closing motions occur with extrinsic flexor muscle contractions but also require the viscoelastic force of the interossei and, to a lesser extent, the lumbricals. In addition, the extensor digitorum muscle acts as a “brake” at the MP joints, allowing for more refined and controlled motion at the IP joints.
- Opening motions require synergistic contraction of the extrinsic extensor, as well as the intrinsic muscles accompanied by viscoelastic resistance of the flexor digitorum profundus.
- Reciprocal motion of MP flexion and IP extension is caused by the intrinsic muscles. The lumbrical removes the viscoelastic tension from the profundus tendon and, along with the interossei, acts as a strong IP extensor.

**FIGURE 19.3** Anatomical structures of the extensor mechanism: (A) lateral view and (B) dorsal view. See text for description of functional relationships.

## Grips and Prehension Patterns

The nature of the intended activity dictates the type of grip used.<sup>6,9,103</sup>

### Power Grips (Full Hand Prehension)

**Description.** Power grips involve clamping an object with partially flexed fingers against the palm of the hand and with counter pressure from the palmarly adducted thumb. Power grips are primarily isometric functions. The fingers assume a position of sustained flexion, which varies in degree with the size, shape, and weight of an object. The thumb reinforces the fingers and helps make small adjustments to control the direction of the force. Varieties include cylindrical grip, spherical grip, hook grip, and lateral prehension.<sup>9,102</sup>

**Muscle control.** The muscles primarily function with isometric contractions.<sup>6,9,101,102</sup>

- Maximum grip force occurs with the wrist positioned in slight extension and slight ulnar deviation stabilized by the extrinsic wrist extensors.
- Extrinsic finger flexors, especially the flexor digitorum profundus muscles of the fourth and fifth digits, provide the major gripping force.
- The extensor digitorum provides a compressive force to the MP joints, which increases stability and also provides a balancing force for the flexors.
- Interossei rotate and radially abduct the first phalanx for positioning to compress the external object and flex the MP joint.
- With the exception of the fourth lumbrical, lumbricals do not participate in the power grip.
- The thenar muscles and adductor pollicis provide compressive forces against the object being gripped.

### Precision Patterns

**Description.** Prehension patterns involve manipulating an object that is not in contact with the palm of the hand between the opposing thumb and fingers. The muscles primarily function isotonically. The sensory surfaces of the digits are used for maximum sensory input to influence delicate adjustments. With small objects, precise handling occurs primarily between the thumb and index finger. Varieties include pad-to-pad, tip-to-tip, and pad-to-side prehension.

**Muscle control.** The primary dynamic function of the muscles includes the following:<sup>9,85,103</sup>

- Extrinsic muscles provide the compressive force to hold the objects between the fingers and thumb.
- For manipulation of an object, the interossei abduct and adduct the fingers; the thenar muscles control movement of the thumb; and the lumbricals help move the object away from the palm of the hand. The amount of participation of each muscle varies with the amount and direction of motion.

### Combined Grips

**Description.** Combined grips involve digits 1 and 2 (and sometimes 3) performing precision activities, whereas digits 3 through 5 supplement with power.

**Pinch.** Pinch requires holding an object between the thumb and index or middle finger, as in precision handling, but may require primarily an isometric hold. The thenar eminence muscles, the adductor pollicis, the interossei, and the extrinsic flexors provide compression between the thumb and fingers. The lumbricals also participate.

## Major Nerves Subject to Pressure and Trauma at the Wrist and Hand

For a detailed description of peripheral nerve injuries and entrapments in the wrist and hand region, as well as complex regional pain syndromes and their management, see Chapter 13.

### Nerve Disorders in the Wrist

**Median nerve.** The most common site for compression of the median nerve is in the carpal tunnel.

**Ulnar nerve.** The most common site for compression of the ulnar nerve is in the ulnar tunnel (also called Guyon's canal).

### Referred Pain and Sensory Patterns

The hand is the terminal point for the C6, C7, C8, and T1 nerve roots coursing through the median, ulnar, and radial nerves (see Figs. 13.5, 13.6, and 13.7). Injury or entrapment of these nerves may occur anywhere along their course, from the cervical spine to their termination. What the patient perceives as pain or a sensory disturbance in the hand may be from injury of the nerve anywhere along its course, or the pain may derive from irritation of tissue of common segmental origin, such as the zygapophyseal facet joints of the spine. For treatment to be effective, it must be directed to the source of the problem, not to the site where the patient perceives the pain or sensory changes. Therefore, a thorough history is taken and examination of the entire upper quarter must be done, including the cervical spine when referred pain patterns or sensory changes are reported by the patient.<sup>86,92</sup>

## Management of Wrist and Hand Disorders and Surgeries

To make sound clinical decisions when treating patients with wrist and hand disorders, it is necessary to understand the various pathologies, surgical procedures, and associated

precautions and to identify presenting structural impairments, activity limitations, and participation restrictions. In this section, common pathologies and surgeries and conservative and postoperative management are presented.

## Joint Hypomobility: Nonoperative Management

Pathologies, such as rheumatoid arthritis (RA) and degenerative joint disease (DJD), affect the joints of the wrist and hand and may have a significant effect on participation and functional abilities of an individual as a result of pain, impaired mobility, and potential joint deformities. Impaired joint, tendon, and muscle mobility also occurs any time joints are immobilized due to fractures, trauma, or surgery. Chapter 11 describes the etiology and general guidelines for management of impairments due to these joint pathologies. This section focuses on specific interventions for the wrist and hand.

### Common Joint Pathologies and Associated Impairments

#### Rheumatoid Arthritis

The following is a summary of signs, symptoms, and resulting impairments typically seen in the wrist and hand with RA.<sup>2,18,104,134</sup>

**Acute stage.** There is pain, swelling, warmth, and limited motion from synovial inflammation (synovitis) and tissue proliferation, most commonly in the MP, PIP, and wrist joints bilaterally. There is also inflammation (tenosynovitis) and synovial proliferation in the extrinsic tendons and tendon sheaths. In addition, an individual with RA may experience:

- Progressive muscle weakness and imbalances in length and strength between agonists and antagonists and between intrinsic and extrinsic muscles.
- Carpal tunnel syndrome in conjunction with tenosynovitis due to compression of the median nerve from the swollen tissue.
- General systemic as well as muscular fatigue.

**Advanced stages.** Joint capsule weakening, cartilage destruction, bone erosion, and tendon rupture, as well as imbalances in musculotendinous forces leading to joint instabilities, subluxations, and deformities (Fig. 19.4). Typical deformities and the pathomechanics in the hand include:<sup>2,18</sup>

- *Volar subluxation of the triquetrum on the articular disk and ulna.* The extensor carpi ulnaris tendon displaces volarly and causes a flexor force at the wrist joint.
- *Ulnar subluxation of the carpals.* This causes radial deviation of the wrist.

**FIGURE 19.4** Joint deformities seen in the hand of a patient with rheumatoid arthritis. Note the hypertrophy of the IP joints, rheumatoid nodules, and volar subluxation of the triquetrum. This patient had fusion of the wrist joints due to pain and complete destruction of the joints, which has helped prevent the deforming, bowstringing effect of the extrinsic tendons on the MP joints. (Courtesy of Turtle Services Limited, [www.turtleserviceslimited.org/](http://www.turtleserviceslimited.org/))

- *Ulnar drift of the fingers and volar subluxation of the proximal phalanx.* There is stretching or rupture of the collateral ligaments at the MP joints and a bowstringing effect from the extrinsic tendons.<sup>2,18</sup>
- *Swan-neck deformity.* Laxity of the PIP joint with an overstretched volar (palmar) plate and bowstringing of the lateral bands of the extensor hood result in hyperextension of the PIP and flexion of the DIP joints (Fig. 19.5A). Tight or overactive interossei muscles pulling on the extensor tendon reinforces the hyperextension of the hypermobile PIP joints, and increased passive tension in the flexor digitorum profundus tendon causes flexion of the DIP joint.
- *Boutonnière deformity.* Stretching or rupture of the central band (central slip) of the extensor hood results in the lateral bands of the extensor mechanism migrating volarly to the PIP joint, causing PIP flexion and DIP extension (Fig. 19.5B).

**FIGURE 19.5** (A) Swan-neck and (B) boutonnière deformities. See text for description of the pathomechanics.

- *Zigzag deformity of the thumb.* Muscle imbalances and ligamentous laxity lead to metacarpal dislocation of the thumb and deformities similar to a swan-neck or boutonnière deformity. Tightness in the adductor pollicis contributes to deformities in the thumb.<sup>2,104</sup>

### Degenerative Joint Disease/Osteoarthritis and Posttraumatic Arthritis

Age and repetitive joint trauma lead to degenerative cartilaginous and bony changes in susceptible joints. DJD, or osteoarthritis (OA), most commonly involves the CMC joint of the thumb, and DIP joints of the digits, although the effects of trauma can occur in any joint.

Posttraumatic arthritis can develop in any joint of the wrist or hand as the result of a severe intra-articular fracture or fracture-dislocation. For example, at the wrist, deficiency of the scapholunate interosseous ligament as the result of a severe wrist sprain can alter joint alignment, which can cause articular degeneration over time. In the fingers, the PIP joint is a common site of articular fracture and subsequent joint degeneration.

The following is a summary of signs, symptoms, and resulting impairments commonly seen in DJD or posttraumatic arthritis.<sup>15</sup>

**Acute stage.** During the early stages of DJD, symptoms include achiness and feelings of stiffness, which abate with movement. Following stressful activities or trauma, joint swelling, warmth, and restricted and painful motion occur.

**Advanced stages.** With degeneration, there is capsular laxity resulting in hypermobility or instability; with progression, contractures and limited motion develop. Affected joints may become enlarged or sublux (Fig. 19.6). Limitation of both flexion and extension with a firm capsular end-feel develops in the affected joints. There is general muscle weakness, weak grip strength, and poor muscular endurance. Pain may also be a limiting factor in pinch and gripping activities.

**FIGURE 19.6** Advanced-stage osteoarthritis of the hands of an 86-year-old pianist. Note the carpometacarpal (CMC) joint subluxation at the base of each thumb. Atrophy of the first dorsal interossei, nodules, and joint enlargements are apparent, but the individual is still functional.

**PRECAUTION:** After trauma, the therapist must be alert to signs of a fracture in the wrist or hand because small bone fractures may not show on radiographs for as many as 2 weeks. Signs include swelling, muscle spasm when passive motion is attempted, increased pain when the involved bone is stressed (e.g., deviation toward the involved bone), and tenderness on palpation over the fracture site.<sup>64</sup>

### Postimmobilization Hypomobility

Immobilization may be necessary following a fracture, surgery, or trauma, or it may be used to rest a part when an individual sustains repetitive stress. Structural impairments may occur from the lack of motion and muscle contraction, including:

- Decreased ROM and decreased joint play with firm end-feel and pain on overpressure.
- Tendon adhesions as the result of inflammation in a tendon or its sheath.
- Decreased muscle performance including muscle weakness, weak grip strength, decreased flexibility, and decreased muscle endurance.

### Common Impairments of Function, Activity Limitations, and Participation Restrictions

When joint pathology is acute, many prehension activities are painful, interfering with activities of daily living (ADLs and IADLs), such as dressing, eating, grooming, and toileting, or almost any functional activity that requires pinching, gripping, and fine-finger dexterity, including writing and typing.

Functional loss may be minor or significant depending on which joints are involved; the amount of restricted movement and residual weakness, fatigue, or dexterity loss; and the type of grip or amount of precision handling required.

### Joint Hypomobility: Management—Protection Phase

General guidelines for managing acute joint lesions are described in Chapter 11, with special concerns for patients with RA and OA summarized in Boxes 11.2 and 11.4, respectively.

#### Control Pain and Protect Joints <sup>15,111</sup>

**Patient education.** Teach the patient how to protect involved joints and control pain with activity modification, ROM exercises, and appropriate use of an orthosis.<sup>15,108,111</sup>

**Pain management.** In addition to physician-prescribed medications or nonsteroidal anti-inflammatory medications and modalities, gentle grade I or II distraction and oscillation techniques may inhibit pain and move synovial fluid for nutrition in the involved joints.

**Orthoses.** Use an orthosis to rest and protect the involved joints. Instruct the patient to remove the orthosis for brief periods of nonstressful motion throughout the day.

**Activity modification.** Analyze the patient's daily activities and recommend adaptations or assistive devices to minimize repetitive or excessive stresses on the joints. This is particularly important for patients with chronic arthritic disorders to prevent repetitive trauma and to minimize joint-deforming forces.<sup>15,108</sup> Examples are summarized in Box 19.1.

## Maintain Joint and Tendon Mobility and Muscle Integrity

**Passive, assistive, or active ROM.** It is important to move the joints as tolerated, because immobility of the hand quickly

leads to muscle imbalance and contracture formation or further articular deterioration. Warm water aquatic therapy is an effective method of combining nonstressful, nonweight-bearing exercises with therapeutic heat.

**Tendon-gliding exercises.** Have the patient perform full motion in the uninvolved joints and as much motion as possible in the involved joints to prevent adhesions between the long tendons or between the tendons and their synovial sheaths.<sup>59</sup> Tendon-gliding exercises are described in the exercise section of this chapter.

**Multiple-angle muscle setting exercises.** Perform gentle, pain-free, isometrics of all wrist and hand musculature. Resistive ROM exercises usually are not tolerated if there is joint effusion or inflammation; therefore, isometric resistance within the tolerance of pain is performed.

### BOX 19.1 Joint Protection in the Wrist and Hand

**Purpose.** Performance of daily activities with minimal pain, stress to joints, and energy expenditure. Most of these principles are applicable to any arthritic problem in the hand but are especially important in the hand affected by rheumatoid arthritis.<sup>15</sup>

**Respect pain.** Monitor activities; stop when fatigue or discomfort begins to develop. Modify or discontinue any activity or exercise that causes pain that lasts longer than 1 hour after stopping the activity.

**Maintain strength and ROM.** Integrate exercises into daily activities.

- Look for early signs of muscle tightness in the intrinsic muscles. If tight, initiate stretching. One cause of swan-neck deformity is tight interossei muscles pulling on the extensor tendon, leading to hyperextension of hypermobile PIP joints.
- Strengthen radial deviation of the MP joints of the fingers to counter the ulnar drifting of the fingers that occurs in many functional activities.

**Balance activity level and rest.** More rest than normal is required during the active phases of RA. Conserve energy and perform activities in the most economical way or do the most important activities first.

**Avoid deforming positions or one position for prolonged periods.**

**Avoid using strong grasping activities that facilitate the deforming force.** Typical joint deformities with RA include radial deviation and extension of the wrist and ulnar deviation and volar subluxation of the MP joints. Adaptive suggestions include:

- Open jars with the left hand or with an assistive device.
- Cut food with the blade of the knife protruding from the ulnar side of the hand.
- Stir food with spoon on the ulnar side of the hand.
- Build up the handles of eating utensils.
- Use stronger, larger joints whenever feasible. For example, carry items in a shoulder bag or over the forearm or with two hands rather than with one hand.
- Avoid twisting or wringing motions with the fingers. Press water out of a rag by opposing the palms of both hands together.

## Joint Hypomobility: Management—Controlled Motion and Return to Function Phases

With joint pathology, increase ROM by utilizing joint mobilization techniques to stretch the capsule as well as passive stretching and muscle inhibition techniques to elongate the periarticular connective tissue and musculotendinous units following the principles described in Chapters 4 and 5. It is also critical to determine if scar tissue has formed in the long tendon sheaths in the hand and, if so, to attempt to re-establish smooth tendon gliding.

### Increase Joint Play and Accessory Motions

**Joint mobilization techniques.** Determine which of the articulations of the distal RU, wrist, hand, or digits are restricted because of decreased joint play and apply grade III sustained or grade IV oscillation techniques to stretch the capsules. See Figures 5.33 through 5.43 for mobilizing restricted joints of the distal forearm, wrist, hand, and digits.

**PRECAUTIONS:** For patients with RA, joint mobilization techniques are often contraindicated, especially in the inflammatory phase. The therapist must modify the intensity of joint mobilization and stretching techniques that are used to counter any restrictions. This is necessary because the disease process and steroid therapy weaken the tensile quality of the connective tissue, and consequently the tissue is more easily torn.

### Improve Joint Tracking and Pain-Free Motion

Mobilization with movement (MWM) techniques may be applied to increase ROM and/or decrease the pain associated with movement.<sup>99</sup> (The principles of MWM are described in Chapter 5.)

**MWM of the wrist.** Have the patient seated with the elbow flexed and forearm supinated (patient's palm facing toward his or her face); stabilize the distal radius and ulna with one

hand, and place the other hand on the ulnar aspect of the proximal carpal row.

- Apply a gentle pain-free radial glide to the proximal row of carpals, utilizing the web space of your hand. Have the patient then perform active wrist extension or flexion to the end of the available range and, with his or her free hand, apply gentle overpressure at the end of the pain-free range (Fig. 19.7).

**FIGURE 19.7** Mobilization with movement (MWM) to increase wrist flexion or extension. Apply a very gentle lateral glide while the patient actively flexes or extends the wrist and then applies a passive stretch force with his other hand at the end of the range.

- Rotation of the carpals, either dorsally or volarly, may need to be combined with the glide to achieve pain-free, end-range loading.

MWM can also be used with patients who experience pain over an individual carpal bone. In these cases, the MWM is really used to “reposition” a carpal bone in relation to an adjacent carpal (either proximal or distal). Provide a sustained gentle dorsal or volar glide to a specific carpal bone while the patient either performs pain-free wrist flexion, extension, radial or ulnar deviation 6-10 times or performs a pain-free gripping force. Repeat for 3 sets of 6-10 repetitions, ensuring that the technique remains pain free.<sup>99</sup>

**MWM of the MP and IP joints of the digits.** Gently radially or ulnarly glide the involved phalanx in a painless direction, then have the patient actively flex or extend the finger and apply a pain-free, end-range stretch. Rotation of the more distal phalanx may be required in conjunction with the medial or lateral glide to achieve painless end-range overpressure.<sup>99</sup>

### Improve Mobility, Strength, and Function

Carefully examine the multijoint and intrinsic muscles for restricted motion due to contractures or adhesions and poor movement patterns due to weakness or imbalances in strength.

Stretching, tendon gliding, and strengthening exercises are described in the exercise sections of this chapter. Utilize techniques that specifically address the impairments the patient demonstrates. Once range is gained, it is critical that the patient uses the new range with active ROM and functional activities.

### CLINICAL TIP

Strong muscles help protect the joints, but in the hand, imbalanced muscle forces lead to deformities. Teach isometric exercises in pain-free positions by showing the patient how to use one hand to resist the other in carefully controlled positions and directions. These exercises can be done throughout the day whenever the patient feels discomfort in his or her joints.

**Neuromuscular control and strength.** Progress exercises with controlled and nondestructive force to increase strength and muscle balance between antagonists and to progress endurance training. With pathological joints, use caution when applying weights so as not to stress the joints beyond the capability of the stabilizing tissues.

**Functional activities.** Develop exercises that prepare the patient for functional activities. Consider prehension patterns that are required for the patient’s job, recreational, and daily activities. Include exercises that require coordination and fine finger dexterity.

**Conditioning exercises.** Initiate physical conditioning exercises using activities that do not provoke joint symptoms, such as aquatic exercises or cycling.

**Joint protection.** Reinforce use of joint protection techniques as summarized in Box 19.1.

### FOCUS ON EVIDENCE

In a systematic literature review of randomized, controlled trials of adult patients with RA, the reviewers concluded that there is evidence to support the idea that low-intensity therapeutic exercise is beneficial for reducing pain and improving functional status (including hand grip strength) in patients with RA, whereas high-intensity exercise programs may exacerbate symptoms.<sup>109</sup>

## Joint Surgery and Postoperative Management

Long-standing RA, OA, or posttraumatic arthritis affecting the joints and soft tissues of the wrist and hand can lead to chronic pain, instability and deformity of joints, restricted ROM, loss of strength in the hand, and impaired function of the upper extremity. When nonoperative management is not sufficient, surgical intervention coupled with individually

designed and carefully supervised postoperative rehabilitation is indicated to improve and restore function.

Some of the more common surgical options for management of arthritis of the wrist and hand are listed in ONLINE Box 19.2 on the FA Davis website.

Soft tissue procedures, such as synovectomy, tenosynovectomy for chronic tenosynovitis of the extensor and flexor tendons of the wrist, repair of ruptured tendons, capsulotomy or release of other soft tissues for correcting a deformity, or muscle balancing of the wrist or finger joints, are employed independently or concomitantly when articular surfaces of the involved joints remain reasonably intact.<sup>21,35,59,7687,139</sup> If joint deterioration is significant, resection arthroplasty, such as resection of the distal ulna (Darrach procedure) or proximal row carpectomy; arthrodesis; or implant arthroplasty, performed in conjunction with soft tissue repair or reconstruction, is a surgical option for advanced joint deterioration.<sup>21,76,80,139</sup>

Some procedures are selected to relieve pain and others to minimize or delay further deformity. For example, if medical management of RA of the wrist does not adequately control synovitis, tenosynovectomy is performed to remove proliferated synovium from tendon sheaths and to prevent erosion or rupture of tendons before significant deformity and loss of active control of the wrist and fingers occur.<sup>32,35,76,139</sup> If rupture occurs, tendon repair or transfer can improve function of the hand and delay or prevent subluxation and dislocation of joints or fixed deformities.<sup>32,35,59,61</sup>

Partial or complete arthrodesis of the wrist and arthrodesis of an individual joint of a digit, such as the CMC joint of the thumb, yields predictable and durable results. Fusion corrects deformity and gives the patient stability and relief of pain with only some compromise of function despite the loss of joint motion.<sup>76,80</sup> If fusion is inappropriate and pain-free functional mobility is necessary, implant arthroplasty—either interposition arthroplasty or total joint replacement—is an option. In many instances, a combination of joint and soft tissue procedures is indicated.<sup>17,21,35,80</sup> For the most part, however, arthroplasty is reserved for the patient who requires only low-demand use of the hand.

**General goals.** The goals of surgery and postoperative management of advanced arthritis and associated deformities of the wrist and hand include<sup>17,21,32,59,80</sup> (1) relief of pain, (2) restoration of normal or sufficient function of the wrist and hand, (3) correction of instability or deformity, (4) restoration of ROM, and (5) improved strength of the wrist and fingers for functional grips and pinch.

A discussion of several types of arthroplasty and general guidelines for postoperative management follow. Information on surgical management and postoperative rehabilitation of tendon repairs and transfers associated with RA is then outlined. Given the complexity of hand rehabilitation, suggested phase-specific guidelines for exercise, founded on principles of tissue healing, must be individualized for each patient and determined by the patient's level of participation in the rehabilitation process and response to exercise.

Successful outcomes are contingent upon close communication among the surgeon, therapist, and patient or patient's

family. An effective postoperative rehabilitation program combines early, supervised therapy with patient education and progresses to long-term self-management by the patient.<sup>59,81</sup> Although rehabilitation is deemed essential after each of the surgical interventions covered in this section, postoperative protocols vary and have not been compared for each type of procedure, making it difficult to suggest that there is one best approach to postoperative management.

## Wrist Arthroplasty

Although arthrodesis of the wrist continues to be the most common surgical intervention for late-stage arthritis of the wrist, arthroplasty has become an acceptable alternative, particularly for patients with arthritis and impaired mobility of other joints of the extremities. Although wrist arthrodesis has not been shown to limit upper extremity function in daily living activities in patients with only posttraumatic arthritis of the wrist, it is thought that loss of wrist motion may adversely affect function, such as personal care, in patients with RA who also have impaired mobility of other upper extremity joints.<sup>32,80,130</sup> For these patients, wrist arthroplasty (total joint replacement) is an option that provides relief of symptoms while retaining some wrist mobility.<sup>32,35,130</sup>

### Indications for Surgery

The following are common indications for arthroplasty of the wrist:<sup>1,17,21,35,107,130</sup>

- Severe pain in the wrist region as the result of deterioration of the articular surfaces of the distal radius, carpals, and distal ulna from chronic arthritis (usually RA, but also OA and posttraumatic arthritis) that compromises hand and upper extremity function
- Deformity and marked limitation of wrist motion that cause muscle-tendon imbalances of the digits
- Subluxation or dislocation of the RC joint
- Appropriate procedure for *low-demand* upper extremity functional needs
- Appropriate procedure for patients with bilateral wrist involvement in which arthrodesis of both wrists would limit rather than improve overall function
- Also appropriate procedure for patients with significant stiffness of the ipsilateral shoulder, elbow, or finger joints in whom unilateral wrist arthrodesis would further limit, rather than improve, functional use of the upper extremity

**CONTRAINDICATIONS:** Box 19.2 identifies some absolute and relative contraindications to wrist arthroplasty and arthroplasty of the joints of the fingers and thumb.<sup>1,17,21,107</sup>

### Procedures

#### Implant Design, Materials, and Fixation

Numerous designs of total wrist replacement arthroplasty have been developed and consistently refined over the past few decades, making arthroplasty available not only to patients with late-stage joint disease, but also those with severe deformity and collapse of the wrist joint.<sup>17,32,107,130</sup>

### BOX 19.2 Contraindications to Arthroplasty of the Wrist or Digits

#### Absolute

- Active infection
- Expected high-demand use of the hand (e.g., manual labor) or high-impact sport activities (e.g., tennis and volleyball)
- Inadequate motor control of the wrist or hand as the result of neurological damage
- Rupture of the radial wrist extensors
- Limited ROM without pain

#### Relative

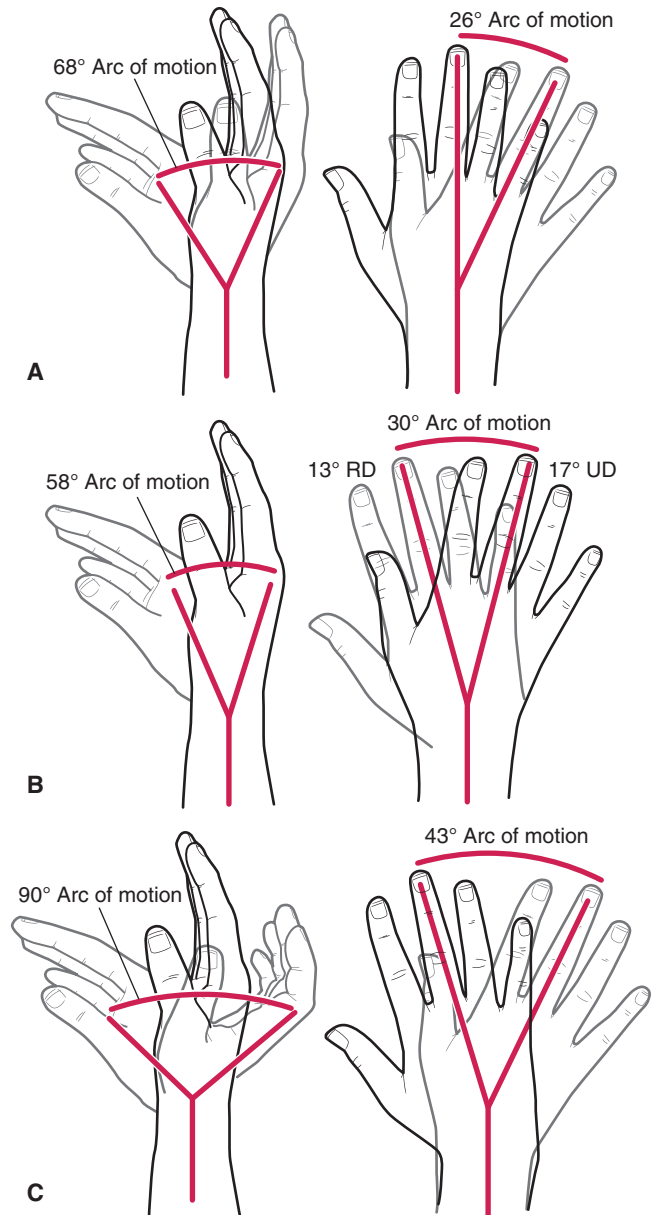

- Severe and irreparable deformity of the wrist or digits
- Rupture of multiple extensor tendons of the digits
- Inadequate, poor quality bone stock
- Need for ambulation aids (e.g., crutches or a walker) that place significant forces across the wrist and hand
- Compromised immune system

However, a total wrist arthroplasty is still contraindicated for individuals with a nonfunctional hand due to neurological dysfunction as well as in high-demand patients, laborers, and those with previous history of sepsis or deep local infection. It is also contraindicated for those patients who require the use of assistive devices for support during ambulation or transfers.

Implants used in total wrist arthroplasty have undergone considerable changes aimed at increasing implant survivorship. Currently there are three implant designs approved by the US Food and Drug Administration: the Universal 2 (which uses an ellipsoidal articulation with a beaded porous coating and radial and ulnar variable-angle screws), the ReMotion (designed to allow some degree of intercarpal rotation—the polyethylene ellipse snaps on a ball on the proximal side of the carpal plate), and the Maestro (which mimics a proximal row carpectomy and depends on replacement of the capitate head. The articulation is achieved with a polyethylene proximal component seated into the radius. Follow-up studies have demonstrated that the Universal 2 produces an average total arc of motion of 68° (42° of flexion and 26° of extension and an average of 1° of radial deviation and 26° of ulnar deviation) (Fig. 19.8A). The ReMotion produces a flexion-extension arc of 58°, and radial deviation/ulnar deviation of 30° (13° of radial deviation and 17° of ulnar deviation) (Fig. 19.8B). The Maestro, the newest of the implants, produces an average flexion-extension arc of 90° (43° of flexion and 47° of extension) and a radial/ulnar deviation arc of 43° (14° of radial deviation and 29° of ulnar deviation) (Fig. 19.8C) and is the only implant currently on the market that has achieved functional ROM.<sup>107,130,153</sup>

#### Operative Overview

Total wrist arthroplasty requires a longitudinal incision along the dorsal aspect of the wrist in line with the third

**FIGURE 19.8** Arc of motion achieved with (A) the Universal 2, (B) the ReMotion, and (C) the Maestro joint implants.

metacarpal.<sup>17,21,80,130</sup> Concomitant *dorsal clearance* (synovectomy of the wrist and tenosynovectomy of the extensor tendons) is often necessary. The retinaculum is incised and reflected, and the digital extensor tendons are retracted for access to the joint capsule.

The distal portions of the radius, the proximal row (scaphoid, lunate, and triquetrum), and the proximal half of the capitate are resected. The axis of rotation for the wrist lies at the proximal third of the capitate; therefore, the closer the center of the implant to the original, normal center, the better the balance of the implant and ultimately the better the functional outcome of the arthroplasty. An intercarpal fusion of the distal carpal row is performed to support the distal component of the implant, which is

subsequently secured to the distal carpal row. With instability and subluxation of the radiocarpal joint, capsule and ligament reconstruction typically is performed to improve wrist stability. Soft tissue balancing is critical for satisfactory results.<sup>80,130</sup>

After closure of the dorsal incision, the hand is placed in a long-arm or short-arm bulky compression dressing and elevated for several days postoperatively to control edema.

## Postoperative Management

### Immobilization

At 2 to 5 days' following surgery, the bulky dressing is removed and the wrist and forearm are placed in a short-arm volar wrist orthosis with the wrist positioned in 10° to 15° extension. The orthosis allows full, unrestricted finger ROM and opposition of the thumb. At this stage it is important to encourage finger and thumb mobility while in the orthosis. Early on, the patient may have difficulty with activation and glide of the finger extensor muscles because of the surgical approach; therefore, it is beneficial to have the patient perform place and hold exercises for the digital extensors to assist with tendon glide and muscle activation.<sup>26,80</sup>

Depending on the stability of the prosthesis, gentle active ROM of the wrist may begin as early as 2 weeks progressing to passive range stretching begun at approximately 4 weeks. During the first 4 to 6 weeks, the patient will wear the orthosis most of the time, only removing for bathing and exercises.<sup>26,80,130</sup>

### Exercise Progression

As with arthroplasty of other large or small joints, the goals and progression of exercise during each successive phase of rehabilitation after wrist arthroplasty are based on the stages of soft tissue healing. If concomitant extensor tendon repairs were also done, the guidelines and time frame for exercise are adjusted and special precautions are taken, as discussed in a later section of the chapter on repair of extensor tendon ruptures in RA.

### CLINICAL TIP

When implementing a postoperative exercise program after any type of wrist arthroplasty, stability of the wrist always takes precedence over restoration of wrist mobility. As a point of interest with regard to wrist ROM, the results of biomechanical studies of normal individuals performing a variety of functional activities have revealed that no more than 40° of wrist flexion or extension and a combined 40° of radial and ulnar deviation is used during most activities.<sup>102</sup>

For protection of the wrist after arthroplasty, precautions, identified in Box 19.3, must be incorporated into postoperative exercises and functional activities during and after rehabilitation.<sup>26,80,130,134</sup>

### BOX 19.3 Precautions After Wrist Arthroplasty

- Avoid weight bearing on the operated hand during transfers, ambulation with assistive devices, or other daily living activities.
- If ambulation aids are required because of lower extremity joint involvement, use forearm-support crutches or walker.
- Avoid functional activities that place more than 5- to 10-lb loads on the wrist.
- Wear a wrist orthosis for additional protection during functional activities.
- Permanently refrain from high-impact vocational or recreational activities, such as heavy labor or racquet sports.

### Exercise: Maximum and Moderate Protection Phases

The focus of rehabilitation during the maximum protection phase is to control pain and peripheral edema, protect the wrist, and prevent stiffness of the rest of the upper extremity. When the orthosis can be removed for wrist exercises, protection of the wrist is still essential.

The emphasis during the moderate protection (controlled motion) phase, which typically begins about 4 weeks postoperatively, is to gradually restore active control and mobility of the digits, wrist, and forearm motion without jeopardizing wrist stability.

**Goals and interventions.** The following goals and interventions should be considered before and after the wrist orthosis can be removed for exercise.<sup>26,80,130</sup>

- **Maintain and later improve mobility of uninvolved joints.**
  - Begin active ROM exercises of the digits, elbow, and shoulder while the wrist is immobilized and the use of the hand is restricted.
  - At 6 weeks postoperatively, if there was limited finger mobility preoperatively, initiate gentle passive stretching of the fingers with the wrist in a neutral position and selectively use a low-load, dynamic or static progressive finger orthosis during the day to increase mobility for a sufficient level of hand function.
  - Grade II and possibly grade III joint mobilization techniques are appropriate if the joints of the digits are not inflamed.
- **Restore control and mobility of the wrist.**
  - Edema control and scar management are an essential part of the program.
  - Include active ROM and tendon-gliding exercises with the wrist in neutral (see Fig. 19.16 A through E in the exercise section of this chapter).
- **Regain use of wrist, finger, and thumb musculature.**
  - Start with gentle setting (place and hold) exercises and progress to low-intensity, isometric resistance exercises of the wrist and finger musculature.
  - Begin to use the hand for light (minimum-load) functional activities around 6 to 8 weeks.<sup>118</sup>

### Exercise: Minimum Protection/Return to Function Phase

During the final phase of rehabilitation, which usually does not begin until 8 to 10 weeks postoperatively, regaining sufficient strength and muscular endurance of the entire upper extremity for functional activities is the priority.<sup>26,80</sup> Patient education focuses on incorporating joint protection during functional activities (refer to Box 19.1). Use of a resting orthosis is advisable at night, particularly if a wrist flexion contracture persists.

**Goals and interventions.** The following goals and interventions can be progressed as the extent of protection decreases:

- **Regain functional strength of the hand and wrist.**
  - Transition to low-intensity, dynamic resistance (about 1 lb) exercises of the hand and wrist.<sup>26,81</sup>
  - Emphasize simulated functional movement patterns, such as various types of grasping activities, being certain to reinforce principles of joint protection. If not previously initiated, begin to use the hand for light functional activities.<sup>130</sup>
  - Advise patients regarding avoidance of repetitive forceful activities (i.e., hammering), heavy manual labor, and contact sports.<sup>130</sup>

### Outcomes

A successful outcome after wrist arthroplasty gives the patient a stable, pain-free wrist with functional ROM. Postoperative outcomes typically measured are pain relief, use of the hand for functional activities, wrist and forearm ROM, and grip strength. Instruments, such as the Disabilities of the Arm, Shoulder, and Hand (DASH) questionnaire and the Patient-Rated Wrist Evaluation, are used to assess pain, function, and satisfaction.<sup>107</sup>

For the patient with late-stage arthritis in multiple joints, the sequencing of joint surgeries is critical for successful outcomes. For example, a hip or knee replacement should be done before wrist arthroplasty to avoid the need to place weight on the wrist replacement when using an assistive device for ambulation.<sup>1</sup>

**Pain relief.** Barring complications, short- and long-term relief of pain after total wrist arthroplasty<sup>17,21</sup> is a consistent finding.<sup>107,130</sup> For example, Ferreres and associates<sup>62</sup> reviewed midterm results using the Universal 2 implant in 22 wrists (22 patients) with an average follow up of 5.5 years (range 3 to 9 years). Fifteen of the 22 patients had RA, 2 had wrist destruction from advanced Kienbocks disease, and the remaining 5 patients had nonrheumatoid inflammatory arthritis. Following the procedure, 10 patients reported being very satisfied and 10 patients were satisfied. Pain during ADLs was absent or slight in 17 patients, and when discomfort was present, it was attributed to neighboring diseased joints. Similar results have been found with the ReMotion and Maestro implants.<sup>107</sup>

**Wrist and forearm ROM, strength, and function.** Improvement in ROM is less predictable than pain relief. ROM

of the wrist achieved postoperatively is usually about 25° to 35° of extension and 30° to 40° of flexion; 10° of radial deviation and 15° of ulnar deviation, however, these ranges can be highly variable.<sup>130</sup> A functional level of active wrist ROM appears to be retained over an extended number of years.

Grip strength and use of the operated hand for functional activities routinely improve after wrist arthroplasty. Relief of pain has an obvious impact on hand function. Concomitant soft tissue repair, such as repair of ruptured tendons, also contributes to improved function.<sup>107</sup> Furthermore, arthroplasty provides some additional length to the wrist, which in turn improves the length-tension relationship of the muscle-tendon units that cross the wrist.<sup>17</sup>

**Complications.** Potential complications, any of which can compromise outcomes following wrist arthroplasty, fall into two broad categories: intraoperative and postoperative.<sup>1,63</sup>

During surgery, there is a risk of fracture of the radius or carpal bone during component implantation, particularly if there is weakening of the cortical bone from long-standing synovitis. This complication requires use of a bone graft and an extended period of immobilization, which can result in postoperative tendon adhesions and stiffness of the wrist. There is also risk of intraoperative damage to an extensor tendon when exposing the joint, requiring repair of the tendon and modification of postoperative exercises so as not to place excessive stress on the repaired tendon.<sup>63</sup>

Postoperative complications include wound infection, dislocation or component loosening, and component wear and eventual breakage.<sup>1</sup> However, results of recent modifications to implant designs that rely on the distal component fixed to the carpus with concomitant intercarpal fusion have significantly reduced the incidence of loosening when compared to older models fixed into the metacarpal shafts.<sup>63,130</sup> Complications may require an alternative procedure or revision arthroplasty. If a silicone implant arthroplasty fails, total wrist arthroplasty is still possible; if a total wrist arthroplasty fails because of mechanical loosening or component failure, revision arthroplasty and wrist arthrodesis are still viable alternatives.<sup>1,17,63,130</sup>

## Metacarpophalangeal Implant Arthroplasty

Arthroplasty of the MP joints of fingers (digits 2 to 5), combined with necessary reconstruction of soft tissues, is the most common surgical procedure performed to manage impaired function and progressive deformity as the result of late-stage RA of the hand.<sup>32,40,128</sup> In patients with RA, hand function has been shown to improve over a 1-year period following MP arthroplasty when combined with ongoing medical management. In contrast, the level of hand function does not deteriorate but does not improve over the same time period with ongoing medical management alone.<sup>33</sup> Arthroplasty is also an option for patients with idiopathic OA and posttraumatic arthritis of the MP joints.<sup>40,89,115,130,132</sup>

For MP arthroplasty to be successful, a patient must have intact extensor digitorum tendons, or repair of these tendons must be performed. The two procedures may be staged, one prior to the other, or performed simultaneously as determined by the surgeon. Other procedures to balance soft tissues must accompany MP arthroplasty for improved hand function postoperatively.<sup>33,88,132</sup>

If joints other than the MP joints are involved, which is often the case in RA, surgeries are carefully sequenced. For example, if the wrist is involved, a radiolunate or total wrist arthrodesis for pain-free wrist stability in a functional position may be necessary prior to MP arthroplasty. In contrast, a swan-neck deformity of a finger is managed with PIP fusion in 30° to 40° of flexion, but typically it is done after—not before—MP arthroplasty.<sup>32,33,134</sup>

Similar to wrist arthroplasty, the overall goals of this surgery and postoperative management are to relieve pain, correct alignment of the fingers, improve active hand opening and grasp, and improve the cosmetic appearance of the hand.<sup>32,88,130</sup>

### Indications for Surgery

The following are common indications for arthroplasty of the MP joint(s):<sup>32,33,80,88,130</sup>

- Pain at the MP joint(s) of the hand and diminished hand function as the result of deterioration of the articular surfaces, usually because of RA but sometimes as the result of OA or posttraumatic arthritis
- Instability, often coupled with volar subluxation, and deformity (flexion and ulnar drift) of the MP joint(s) that cannot be corrected with soft tissue releases and reconstruction alone
- Stiffness and decreased active ROM of the MP joints, often associated with a deficient extensor mechanism, causing inability to open the hand to grasp large objects
- Poor appearance of the hand as the result of deformity

### Procedures

#### Implant Design, Materials, and Fixation

MP joint arthroplasty is designed to provide a balance of stability and mobility to the MP joints for patients with late-stage arthritis. Several designs using different materials and methods of fixation have been developed over the past few decades. Currently there are three types of implants available in the United States for MP arthroplasty: pyrolytic carbon (pyrocarbon) MP joint implants, silicone elastomer implants, and surface replacement implants. Both the pyrolytic carbon implant as well as the surface replacement implant attempt to recreate more normal anatomy and may offer patients improved function in the long term.<sup>5,49,80,128</sup> The silicone elastomer implant (Fig. 19.9) has been used since the 1960s and with its known material and long track record, is predictable and dependable in low-demand patients.<sup>5,32,80,130</sup> Silicone elastomer implants have traditionally been used for patients with RA and less commonly in traumatic or isolated degenerative arthritis.

**FIGURE 19.9** Lateral view of the three most common silicone-based implants: Neuflex (top), Avanta (middle), Swanson (bottom). Note that the Avanta and Swanson implants are of a 0° bend type. (From Manuel, JLM, and Weiss, APC: *Silicone metacarpophalangeal joint arthroplasty*. In Strickland, JW, and Graham, TJ [eds]: *Master Techniques in Orthopedic Surgery—The Hand*, ed. 2. Philadelphia: Lippincott Williams & Wilkins, 2005, p 393, with permission.)

### FOCUS ON EVIDENCE

Kevin Chung and colleagues<sup>37</sup> performed the largest collaborative multicenter prospective cohort study to date, comparing the silicone elastomer implant to a nonsurgical group. A total of 67 surgical patients and 95 nonsurgical patients with severe subluxation and/or ulnar drift of the fingers at the MP joints were recruited. Outcomes included the Michigan Hand Outcomes Questionnaire (MHQ), the Arthritis Impact Measurement Scales 2 (AIMS2), grip/pinch strength, the Jebsen-Taylor Test, ulnar deviation, extensor lag, and arc of motion at the MP joints. At 3 years, data was available on 42 surgical and 73 nonsurgical patients and demonstrated significant improvement in mean overall MHQ score and the MHQ function, ADLs, aesthetics, and satisfaction scores in the surgical group as compared to the nonsurgical group. Ulnar deviation (20°), extensor lag (30°), and arc of motion (99°) in the MP joints also improved significantly in the surgical group. The AIMS2 scores and grip/pinch did not show improvement. Complications were reported as minimal with a fracture rate of 9.5%.

As an alternative to silicone elastomer implants, two-component, convex-concave implants have been developed. The surface replacement (SRA) implant provides a medial-lateral stability in flexion, and the radius of the curvature of the articular surfaces allows for the potential of a near normal arc of motion. The components are designed to be cemented; however, noncemented components are being considered for the future.<sup>80,128</sup> The indications for SRA are the same for silicone implants; however, the need for functional collateral ligaments is critical in both the surface replacement and

pyrolytic designs.<sup>49,128</sup> The pyrolytic carbon implant has demonstrated properties similar to cortical bone, and wear models have demonstrated no evidence of wear or wear debris, no evidence of inflammation, and excellent bone-implant incorporation. The material properties of the pyrolytic carbon implant provide a good alternative for patients with degenerative or traumatic arthritis of the MP joint. For those patients with RA, where there are signs of instability, dislocation, and cortical bone loss, traditional silicone implants remain the most favorable option.<sup>32,37,49,80,128</sup>

### FOCUS ON EVIDENCE

Wagner and colleagues<sup>146</sup> performed a prospective study over 14 years (1998 to 2012) of 254 MP arthroplasties in 110 patients using the pyrocarbon implant design. Of those, 164 patients had inflammatory arthritis (51 required prednisone and 93 required methotrexate), 37 had posttraumatic arthritis, and 53 had osteoarthritis. Of the 254 arthroplasties over 14 years, 26 required revision surgery. The 2-, 5-, and 10-year survival rates were 96%, 89%, and 77%, respectively. The risk for revision surgery was greatest in smokers and those with inflammatory arthritis requiring either prednisone or methotrexate. The 5-year survival rate was not significantly different for inflammatory arthritis (90%), osteoarthritis (85%), and posttraumatic arthritis (85%). The authors concluded that patients overall experience provided predictable pain relief and improvements in ROM and pinch strength and that MP arthroplasties using a pyrocarbon implant demonstrated a nearly 90% 5-year survival rate with a relatively low rate of complications regardless of the diagnosis.

### Operative Overview

MP arthroplasty and related soft tissue balancing involve the following procedures.<sup>5,40,88,115,128</sup> The involved MP joints are approached by either a single, transverse incision over the dorsal aspect of the metacarpal heads or by double, longitudinal incisions made between the index and middle fingers and the ring and little fingers. The joint capsule is exposed by carefully separating the extensor tendons, which are often ulnarly displaced from the underlying capsule, and longitudinally incising the extensor hood. The tendons are retracted; the ulnar and possibly the radial collateral ligaments, if intact, are reflected from the head of each metacarpal; and the dorsal aspect of the capsule is incised (capsulotomy). Every effort is made to preserve the radial collateral ligaments. A synovectomy is performed if necessary. If a significant flexion contracture exists, the volar aspect of each capsule may also be incised to allow greater extension of the MP joints.

The heads (distal aspect) of the metacarpals and proximal aspect of the first phalanges of the involved joints are excised, and the intramedullary canals of the metacarpals and proximal phalanges are widened to accept the prosthetic implants. After insertion of the implants, the ROM of the replaced joints is checked. The joint capsule, radial collateral ligament

(if preserved), and extensor mechanism of each digit are repaired. The wound is then closed, and a bulky compression dressing and volar hand and forearm orthosis are placed on the hand. The hand is elevated to control edema.<sup>5,80,128</sup>

### Postoperative Management

As with arthroplasty of the wrist or other joints of the digits, the postoperative rehabilitation program is founded on the principles of soft tissue healing and includes phase-specific goals and interventions, including the use of dynamic and/or static orthoses and a supervised home exercise program.

General postoperative guidelines from a number of resources for a progression of exercises combined with the use of orthoses to maintain alignment and protect soft tissues as they heal are summarized in this section.<sup>28,40,80</sup> These guidelines must be individualized based on the type of arthroplasty and soft tissue procedures performed and each patient's response. Ongoing patient education and close communication with the surgeon are essential for effective outcomes. Postoperative rehabilitation continues for 3 to 6 months.

### Immobilization

Initially, the wrist and hand are continuously immobilized in the bulky compression dressing and volar orthosis applied at the end of surgery, with the wrist positioned in neutral, the MP joints in full extension and either neutral or slight radial deviation (opposite the position of deformity), and the distal joints (PIP and DIP) are free.<sup>5,32,40,80,115</sup>

Continuous immobilization is not lengthy but varies with the type of arthroplasty, the type and quality of the soft tissue repairs, and the stability of the reconstructed joints. If only an MP implant was performed, the hand remains immobilized for only a few days. If, in addition to the MP arthroplasty, ruptured extensor tendons were repaired or transferred, the hand remains immobilized longer to protect the tendons.<sup>61</sup>

**Dynamic orthoses.** When the compression dressing is removed, the hand is placed in a dynamic MP extension orthosis with an outrigger (Fig. 19.10). The orthosis is worn to protect

**FIGURE 19.10** A dynamic extension orthosis with rubber bands attached to a dorsal outrigger used after MP arthroplasty; permits active MP flexion; and, at rest, maintains the MP joints in extension and sometimes slight radial deviation. (Courtesy of Janet Bailey, OTR/L, CHT.)

healing structures, maintain alignment (to prevent recurrent flexion and ulnar drift deformities at the MP joints), and control and guide the range and plane of motion during exercises as soft tissues heal.<sup>20,33,80</sup>

The dynamic orthosis holds the wrist in about 10° to 15° of extension and the MP joints in neutral (at 0°) and slight radial deviation, but it does not control motion in the IP joints. Slings under the proximal phalanx of each finger with spring and fishing line, rubber bands, or elastic cord attached to the outrigger of the orthosis hold the MP joints in a neutral (0°) position when the hand is at rest but still allow active flexion of the MP joints within a functional range. The finger slings are placed around the proximal phalanges with a 90° angle of pull from the proximal phalanx to the outrigger. It is critical to maintain the MP joints in a neutral position of extension when at rest. The pull must also be in the radial direction to prevent recurrence of the ulnar drift and also to prevent radial and ulnar instability by decreasing stress on the radial aspect of the capsule. The patient wears the dynamic orthosis throughout the day for about 6 weeks.<sup>33,80,130</sup>

**Static orthoses.** A static orthosis is provided for the patient to wear while sleeping. The night orthosis is made with the wrist and MP joints in neutral extension with control of the alignment of the fingers. The night orthosis is worn for 3 to 6 months after surgery or longer as determined by joint alignment and/or the presence of an extensor lag.<sup>32,80</sup>

### Exercise Progression

Protected motion in a dynamic orthosis is initiated as early as 3 to 5 days or as late as 10 to 14 days postoperatively when the bulky compression dressing is removed and orthoses have been fabricated.<sup>20,32,40,80,128</sup> Within the first week, emphasis is placed on edema management and gentle active ROM and passive ROM for MP joint flexion and extension within the orthosis with careful monitoring of alignment and rotation.<sup>32,80</sup> Time frames may vary with the type of procedures performed, the underlying pathology, and the stability of the joint. Even after the bulky dressing is removed, exercise may be delayed for a patient with poor soft tissue quality and potential joint instability or delayed wound healing.

With OA or posttraumatic arthritis, the involved MP joints are usually stable postoperatively. Therefore, MP exercises typically are begun earlier and progressed more rapidly in these patients than is permissible for patients with RA, whose joints tend to be less stable as the result of long-standing tissue inflammation and deformities.<sup>115</sup>

Lubahn and associates<sup>80</sup> proposed general goals following MP joint arthroplasty: optimal wound healing, prevention of scar adhesion, management of postoperative edema, neutral alignment with a 35° to 45° arc of motion at the MP joints, and optimal performance of ADLs and vocation/avocational activities. Amadio and Shin<sup>5</sup> reported an expected outcome of a 30° to 40° arc of motion; however, Chung<sup>34</sup> and colleagues studied 162 patients with 180 arthroplasties, and their results demonstrated a 28° arc of motion for the index finger, 28° for the long finger, 32° for the ring finger, and 35° for the small finger, which

is slightly less than others have reported. Regardless, appropriate treatment leads to improved motion. The most effective treatment is one based on the individual's tissue response to the exercises and the orthotic positioning program. The most important outcome is for the patient to achieve functional motion in the fingers and satisfaction that their pain has been relieved and their deformity has been improved.<sup>33,37,80,128</sup>

### CLINICAL TIP

During the course of rehabilitation, active MP flexion usually plateaus before active MP extension, with flexion levelling off at about 3 to 4 months; however, extension often continues to improve for up to a year.<sup>46</sup>

### Exercise: Maximum Protection Phase

For the first 3 weeks, the emphasis is on edema management with active ROM and gentle passive stretching performed within the orthosis. The MP joint is flexed, with the shelf position (MP flexion with IP extension) emphasized, followed by the fingers slowly flexing into the palm. The focus is on the range of the MP joint. During the second week after surgery, collagen formation increases around the capsule and the implant and the joint become more stable. This may appear as increased stiffness of the MP joints; therefore, it is important to monitor the ROM to ensure that the motion is maintained during this time of scar production and maturation.<sup>80</sup>

### CLINICAL TIP

Extra attention must be given to the small finger, because the small finger may demonstrate weak flexor power due to chronic subluxation at the MP joint. Buddy taping the small finger to the ring finger at the proximal phalanx may assist with small finger MP joint flexion.<sup>80</sup>

**Goals and interventions.** The following goals and exercises are emphasized during the maximum protection phase:<sup>20,80,147</sup>

- **Maintain mobility of the shoulder, elbow, and forearm.**
  - Perform active shoulder, elbow, and forearm ROM. This is particularly important for patients whose RA is affecting multiple joints of the body.
- **Improve functional ROM of the fingers and maintain gliding of tendons within their sheaths.**
  - To facilitate ROM, edema management techniques including compression sleeves or compression wrapping is initiated.
  - Begin active and gentle passive stretching of the MP, PIP, and DIP joints into flexion and extension within the dynamic orthosis. Emphasize the shelf position of the MP joints followed by flexion of the PIP and DIP joints into the palm of the hand closely monitoring alignment and rotation.

**PRECAUTIONS:** Carefully observe the incision during MP flexion, being certain to avoid excessive tension on the skin and delay wound closure.

- **Prevent adhesions along the healed incision.**
  - Perform gentle mobilization of the scar when sutures have been removed.

### Exercise: Moderate and Minimum Protection Phases

The *moderate protection phase* begins at about 3 weeks when the implant is clinically stable. The emphasis at this time is to achieve full *active* extension of the MP joints to neutral (no extensor lag) and continue to increase active MP flexion for functional use of the hand. If MP joint flexion is not at the desired range, passive flexion cuffs or rubber band traction may be initiated at this time. The frequency and duration of orthotic positioning is determined by the patient's active and passive motion at this time.

At 4 weeks, in the late fibroblastic stage, coordination and muscle balancing exercises to maintain flexion and extension begin. Light strengthening exercises may also be initiated. It is important to review the joint protection principles and modify the behaviors as needed. At 5 weeks, light ADLs and functional activities are initiated utilizing the joint protection principles. The dynamic orthosis may be continued as needed to assist with alignment and to provide an extension assist if an extensor lag is present. By 6 weeks, the daytime dynamic extension orthosis is gradually discontinued; however, it may be helpful for some patients to use a hand-based dynamic orthosis to maintain the MP joints in extension, yet allow for flexion during functional activities.<sup>80,128</sup> Or, if additional support for alignment is needed, a soft hand-based or forearm-based ulnar drift orthosis may be beneficial. The static night orthosis is continued for an additional 3 to 6 months. During the *minimum protection phase*, which begins around 8 weeks postoperatively, scar maturation is underway; progressive strengthening of the wrist and hand musculature and increasing use of the hand for functional activities while reinforcing principles of joint protection are emphasized. In most instances, a patient is allowed full use of the hand for light to moderate functional tasks by 12 weeks postoperatively.

**Goals and interventions.** During the moderate and minimum protection phases, goals include the following:<sup>20,40,80</sup>

- **Continue to increase ROM and active control of the MP joints.**
  - Have the patient continue active flexion exercises in the dynamic orthosis until the daytime orthosis is discontinued. Continue passive stretching, one finger at a time, to increase flexion.
  - Emphasize active MP extension with the wrist in neutral and the IP joints flexed (the hook fist position of the hand) to reinforce the action of the extensor digitorum (ED) muscle and minimize influence of the intrinsic finger extensors. This movement also promotes gliding of the extrinsic extensors in the tendon sheaths.

- Reinforce MP extension by maintaining the extended position briefly with each repetition.
- Teach the patient to perform active radial deviation of the MP joints by placing the open hand palm-down on a table, stabilizing the dorsum of the hand with the opposite hand, and sliding (“walking”) the fingers toward the thumb.
- Include active composite finger flexion and opposition of the thumb to each digit, emphasizing pad-to-pad pinch rather than lateral pinch.
- **Restore ROM of the wrist.**
  - When the dynamic orthosis can be removed during exercise, initiate active ROM of the wrist, emphasizing wrist extension. Be sure the fingers are relaxed during wrist motions.
- **Improve functional strength of the hand and wrist.**
  - Have the patient begin isometric flexion and extension against submaximal manual resistance or a solid object at 4 weeks postoperatively. Then transition to resisted dynamic finger flexion and extension using a variety of exercise devices, such as a small spring-loaded hand exerciser or exercise putty beginning around 6 weeks.<sup>80</sup>
  - Include resisted radial deviation of the digits. For example, have the patient place the hand on a table palm-down and stabilize the dorsum of the involved hand with the opposite hand. Abduct the index finger against the resistance of a rubber band or push against a coffee cup and slide it across the table.<sup>20</sup>
- **Regain use of the hand for functional activities while protecting the operated joints to prevent recurrence of deformity.**
  - Reinforce principles of joint protection and energy conservation through patient education (see Box 19.1). Emphasize avoidance of stresses on the fingers in an ulnar direction.
  - Perform simulated functional grasping activities, beginning with light prehension activities. Use the hand for light to moderate functional activities by 5 to 6 weeks postoperatively.
  - Modify ADLs that could contribute to deforming stresses on the MP or other involved joints.<sup>80</sup> Consider use of a commercially fabricated, hand-based, digital alignment orthosis made of neoprene during heavier, more stressful activities.

### Outcomes

A successful outcome provides the patient with pain-free, stable, and properly aligned MP joints combined with improved active extension of the digits while retaining or improving MP flexion sufficient for functional grasp. Of these outcomes, pain relief and improved deformity is the primary value of MP arthroplasty.<sup>37</sup>

**Pain relief and patient satisfaction.** Pain relief is excellent or good for most patients, and correction of a flexion/ulnar drift deformity is consistently sufficient after MP arthroplasty. Both of these outcomes contribute to patient satisfaction

because they improve hand function and the cosmetic appearance of the hand.<sup>33,80,128</sup>

**ROM and hand function.** As previously noted, approximately 70° of active flexion of the MP joints with full active extension to neutral and correction of ulnar drift of the fingers are considered an ideal overall result.<sup>80</sup>

This degree of mobility enables a patient to open the hand far enough to grasp large objects, touch the fingertips of the ulnar digits to the palm (which is necessary for grasping small objects), and touch the tips of the index finger and thumb for pinch. Less MP flexion in the index and middle fingers is acceptable because limited motion of the MP joints enhances stability and allows dexterity and pinch without compromising functional grasp. In a review of a number of short- and long-term studies of patients with various types of arthritis undergoing MP arthroplasty, the postoperative range of MP flexion/extension varied considerably from study to study, with the mean arc of active motion for all fingers reported to be 40° to 45° and a mean extensor lag of 15°. When comparing pre- and postoperative mobility, the total range of flexion/extension may increase only to a small or moderate extent, but the arc of active motion postoperatively often is elevated and becomes more functional. Few studies have directly compared one type of prosthetic implant to another. However, Delaney and colleagues<sup>47</sup> performed a prospective, double-blind study of patients with RA, which followed patients for 2 years postoperatively, and compared the results of two types of silicone implants, the Swanson and the Neuflex® designs (see Fig. 19.9). The findings indicated a significantly greater improvement in MP flexion in patients who received the Neuflex® design than in patients who received the Swanson implant, but there was no significant difference in active MP extension, ulnar deviation, or grip strength between the two groups. Of interest in this study is that the Neuflex® implant, which is performed in 30° of flexion, did not adversely affect active MP extension, which had been a concern of the investigators.

Although satisfactory improvement of MP mobility and a significant correction of deformity (decreased ulnar drift of the fingers) are predictable outcomes after joint arthroplasty, grip and pinch strength do not seem to increase significantly or consistently or they improve only modestly. For example, results of a study by Chung and associates<sup>33</sup> demonstrated that grip and pinch strength had decreased at 6 months after surgery (compared to preoperative measurements) and then gradually increased to preoperative levels by 1 year.

**Complications.** As the result of a number of complications, approximately 70% of MP silicone implants survive 10 years before revision is necessary.<sup>40,80,123</sup> However, some postoperative complications affect outcomes but do not necessitate additional surgery. Delayed wound healing is a short-term complication that may have an adverse effect on re-establishing adequate MP flexion for functional grasp.<sup>134</sup>

As with the wrist, the most common long-term complication after silicone implant arthroplasty is breakage of the implant,<sup>32,49,123</sup> whereas subluxation or dislocation, mechanical

loosening, and implant fracture are common reasons for failure of the two-component metal-plastic and pyrocarbon designs.<sup>32,40,123</sup> It is believed that these long-term complications can be minimized if the patient adheres to joint protection principles by consistently avoiding heavy loads, high-impact activities and deforming forces on the reconstructed joints.

## Proximal Interphalangeal Implant Arthroplasty

There are a number of joint and soft tissue procedures for managing arthritis and associated deformities of the PIP joints. They include soft tissue release and reconstruction for swan-neck and boutonnière deformities<sup>32,134</sup> and implant arthroplasty or arthrodesis when there is significant destruction of the articular surfaces.<sup>1,136</sup> PIP arthroplasty is used more frequently for late-stage OA or posttraumatic arthritis than for RA but may or may not be preferable to arthrodesis to improve functional use of the hand.

In the ulnar digits, where mobility of the PIP joints is particularly important for functional grasp, arthroplasty may be the procedure of choice.<sup>136</sup> However, in the index finger, where stability of the PIP joint is a necessity for many functional tasks, arthrodesis is often preferable.<sup>4,73,128,145</sup> If the MP and PIP joints are involved, as is often the case in patients with RA, the MP joint is usually replaced, but the PIP joint deformity (usually a swan-neck deformity) is corrected by soft tissue reconstruction or fusion.<sup>4,59</sup>

### Indications for Surgery

In general, PIP implant arthroplasty is indicated for patients with isolated PIP involvement, particularly those who are free of MP joint disease. Implant arthroplasty of contiguous joints (both the MP and PIP joints) is not recommended.<sup>59</sup> The following are commonly accepted indications for PIP joint arthroplasty.<sup>4,59,60</sup>

- PIP joint pain and destruction of the articular surfaces (with or without joint subluxation) secondary to OA or posttraumatic arthritis (less frequently indicated for RA) when nonoperative management has been unsuccessful
- Loss of hand function as the result of joint stiffness, deformity, and decreased ROM that cannot be corrected with soft tissue reconstruction and/or nonoperative treatment
- Only occasionally for isolated boutonnière deformity or swan-neck deformity if fusion is not a viable option

**NOTE:** Necessary prerequisites for PIP arthroplasty include adequate bone stock, intact neurovascular system, and functioning flexor/extensor mechanisms.<sup>128</sup>

### Procedure

#### Implant Design, Materials, and Fixation

The type of arthroplasty of the PIP joint selected by the surgeon depends on the underlying pathology, the extent of associated impairments and deformities, and the experience

of the surgeon. The selection of PIP joint implants available for use today for patients without RA include the silicone elastomer one-piece flexible implant, such as the Swanson, Neuflex, or SBI devices, and surface replacement implants, including titanium-polyethylene (TI) and pyrocarbon (PY).<sup>5,23,44,80,136</sup>

The silicone implant, originally designed by Swanson during the 1960s, remains in use today.<sup>5,44,71,136</sup> A surface replacement design affords greater joint mobility than the one-piece silicone design but provides no inherent stability. Therefore, when PIP arthroplasty is deemed appropriate for patients with RA, who typically have compromised joint stability as the result of damage to periarticular soft tissues secondary to chronic synovitis, a one-piece silicone implant tends to be used to provide some stability to the joint. In contrast, surface replacement arthroplasty is used almost exclusively in patients with OA or posttraumatic arthritis because the collateral ligaments usually are intact or repairable.<sup>5,44,59,71</sup>

### Operative Overview

A curved, longitudinal incision is made along the dorsal aspect of the PIP joint. Occasionally, a volar (palmar) or lateral approach is used.<sup>23,59,80</sup> With a dorsal approach, either a *central slip-sparing technique* (which leaves the central tendon intact) or a *central slip-splitting technique* (where the central tendon is incised longitudinally) is used. The latter approach is selected when there is significant joint deformity. Table 19.2 provides an overview of which soft tissues are released, repaired, and require protection during the postoperative program and which structures remain intact during the operative procedure.<sup>4,5,16,59,60,80</sup>

### CLINICAL TIP

Although published resources provide descriptions of the various surgical approaches, it is important to review the operative report in a patient's medical record to learn what type of surgical approach was used and which soft tissue structures were incised or released, repaired prior to closure, and will require protection during rehabilitation.

Portions of the head of the proximal phalanx and the base of the middle phalanx are resected. The intramedullary canals of the proximal and middle phalanges are reamed and prepared for the prosthetic implant(s), which is then inserted.

If necessary, the volar plate is released for a flexion contracture, and the extensor tendon mechanism (if split during the approach) is repaired followed by repair of the joint capsule. The wound is closed and a supportive bulky compression dressing is applied holding the PIP joint in extension.

## Postoperative Management

### Immobilization

At approximately 3 to 5 days postoperatively the surgical dressing is removed and a custom forearm-based dynamic PIP extension orthosis is fabricated with the wrist in 15° of extension and the MP joints in 20° of flexion. This daytime orthosis allows for a passive PIP extension assist and active PIP flexion. A static forearm-based night orthosis is also fabricated with the wrist in 15° of extension, the MP joints in slight flexion, and the IP joints in near full extension.<sup>4,5,59,80,116</sup>

The duration of immobilization varies with the type of arthroplasty, whether extensor tendon or collateral ligament reconstruction of the fingers was part of the procedure, and the surgeon's philosophy; however, it is generally accepted that the dynamic orthosis is discontinued at around 4 weeks if the patient demonstrates full PIP extension and buddy taping is initiated during the day. The protective night orthosis may be continued for up to 3 months postoperatively for those patients having difficulty maintaining their extension and to protect the repaired joints.<sup>5,59,60,80,116</sup>

### Exercise Progression

The sequence of exercises after PIP arthroplasty emphasizes early but protected motion of the operated and adjacent joints. PIP exercises in the dynamic orthosis are initiated 3 to 5 days postoperatively with a limited arc of motion starting with 0° to 30°. At 2 weeks, PIP joint motion is increased to 45° if there is no extension lag. At 4 weeks, if the patient demonstrates full active extension, the arc of flexion is increased to 60°. By 6 weeks, a 0° to 75° arc of motion should be achieved and gentle stretching is initiated. By 3 months, the goal is 0° to 75° and activity as tolerated.<sup>5,80,116</sup>

**TABLE 19.2** Comparison of Surgical Approaches for PIP Joint Arthroplasty

Type of Approach	Structures Released, Repaired, and Protected Postoperatively	Structures Left Intact
Dorsal approach—central slip-sparing technique	Collateral ligaments incised/repaired; Volar plate disrupted	Central tendon/extensor mechanism intact; allows AROM immediately after surgery
Dorsal approach—central slip-splitting technique	Central tendon incised longitudinally and detached; delays AROM after surgery Volar plate may or may not be disrupted	Collateral ligaments intact; provides joint stability

The goals of exercise during each of the following phases of rehabilitation after PIP arthroplasty are similar to those already detailed in this chapter for rehabilitation after MP arthroplasty. Only guidelines and precautions unique to PIP arthroplasty or procedures for associated correction of specific soft tissue deformities of the PIP joints are addressed in this section.

### Exercise: Maximum and Moderate Protection Phases

The primary goals of the maximum and moderate protection phases of rehabilitation after PIP arthroplasty are to control peripheral edema and restore functional mobility of the operated joint(s) without compromising the repair or reconstruction of soft tissues.

In most instances, the emphasis is to regain full or nearly full active PIP extension while gradually increasing PIP flexion by 10° to 15° per week.<sup>5,60,80,116</sup>

### CLINICAL TIP

A balance of ROM exercises to regain flexion and extension must occur. Regaining PIP flexion should not be at the expense of attaining full or nearly full active PIP extension, so there is little to no extensor lag.<sup>80</sup>

**Goals and interventions.** The following goals and interventions are recommended as general guidelines during the first 6 to 8 weeks after surgery. Detailed protocols describing use of orthoses and progression of exercises following different types of PIP arthroplasty are described in several resources:<sup>5,60,80,116,148</sup>

- **Maintain mobility of the wrist, MP, and DIP joints.**
  - Immediately after surgery, initiate active ROM of all joints not restricted by the bulky dressing.
- **Restore ROM of the operated joints.**
  - Begin active PIP flexion in the dynamic orthosis 0° to 30° of each involved PIP joint for 2 weeks. At 2 weeks if there is no extension lag, increase the motion to 45°. At 4 weeks, if the PIP joint has full active extension, the arc of flexion is increased to 60°. By 6 weeks postoperatively, the goal is to achieve 0° to 75° of active PIP joint motion.<sup>5,60,80,116</sup> Stabilize the MP and DIP joints in neutral to direct motion to the PIP joint (promotes joint mobility and tendon gliding).
  - If a *boutonnière deformity* was corrected (which requires reconstruction of the extensor mechanism), follow the guidelines and precautions described in Box 19.4.<sup>134</sup>
  - If a *swan-neck deformity* was corrected, follow the guidelines and precautions noted in Box 19.5.<sup>59</sup> A central, slip-splitting approach is necessary for correcting a swan-neck deformity to allow the tension on the extensor mechanism to be adjusted and greater excursion of the PIP joint into flexion.

### BOX 19.4 Postoperative Guidelines and Precautions After Correction of a Boutonnière Deformity

#### Exercise

- Maintain as much extension as possible of the PIP joint through the use of an extension orthosis and exercise for 3 to 6 weeks postoperatively. Remove the orthosis only for exercise and wound care.
- Initiate early DIP flexion exercises with the PIP joint stabilized in extension to maintain the length of the oblique retinacular ligament.
- Begin active or assisted PIP flexion/extension exercises by 10 to 14 days or sooner postoperatively. Stabilize the MP joint in neutral (on a book or at the edge of a table) during PIP movements.
- Emphasize PIP extension and DIP flexion during exercise.

#### Precautions

- Avoid hyperextension of the DIP joint.
- Because correction of a boutonnière deformity requires a central slip-splitting approach and repair of the extensor mechanism, avoid resisted exercises and stretching of the extensor mechanism of the PIP joint for 6 to 8 weeks or as long as 12 weeks postoperatively.

### BOX 19.5 Postoperative Guidelines and Precautions after Correction of a Swan-Neck Deformity

#### Exercise

- Maintain the PIP joint(s) in 20° to 30° of flexion and the DIP joint(s) in full extension with the use of a static digital orthosis.<sup>59</sup>
- Initiate active ROM exercises at the PIP and DIP joints several days postoperatively.<sup>59</sup>
- Perform DIP extension exercises with the PIP joint stabilized in slight flexion.
- Stabilize the DIP joint in neutral during PIP ROM exercises.
- Emphasize PIP flexion and DIP extension.

#### Precautions

- Limit PIP extension to 10° of flexion during exercise to avoid excessive stretch to the volar aspect of the capsule.
- Avoid extreme flexion of the DIP joint.

**PRECAUTION:** During ROM exercises, it is essential to avoid lateral and rotational stresses to the operated joints that could compromise the integrity of the collateral ligaments and joint stability.

### Exercise: Minimum Protection/Return to Function Phase

The primary goal of the minimum protection phase shifts from restoration of functional ROM to improving strength

in the hand and wrist and gradually incorporating safe but progressive use of the hand into functional ADLs. This transition occurs around 6 to 8 weeks postoperatively. The status of the soft tissue repairs, particularly the extensor tendons, determines how early resisted exercises are initiated. For optimal results, rehabilitation may need to continue (through adherence to a home program) for 3 to 6 months or longer postoperatively.

As with MP arthroplasty, low-intensity strengthening exercises can be performed with equipment specifically designed for hand rehabilitation, such as exercise putty, or through graded functional activities that involve resisted movements. Principles of joint protection (see Box 19.2) are integrated into daily living through patient education, with attention to continued avoidance of lateral stresses to the PIP joints.

### Outcomes

After PIP joint arthroplasty, an optimal result provides the patient with a pain-free, mobile, but stable and well-aligned joint for functional use of the hand.<sup>16,59,80,128</sup> Pain relief is the most consistent outcome after PIP arthroplasty. Although patients typically report improvement in use of the hand for functional activities, improvements in ROM and grip strength tend to be marginal at best.<sup>49,148</sup>

Successful outcomes are dependent on proper balancing and repair of the collateral ligaments, adequate soft tissue coverage, and lack of infection following surgery. Outcomes usually are better in patients with OA than in those with posttraumatic arthritis or RA and in fingers without preoperative deformity,<sup>128</sup> but there is no conclusive evidence that one surgical approach or type of current-day arthroplasty is superior to another.<sup>49</sup>

Optimal ROM for functional use of the hand after arthroplasty of the PIP joint is 45° to 70° of active flexion and full or almost full active extension (no extensor lag). However, postoperative ROM reported in most studies is substantially less than optimal.<sup>5</sup>

If the extensor tendon mechanism is intact and a central slip-sparing approach is used, which allows early initiation of mobility exercises, approximately 10° more PIP flexion can be expected than if a central slip-splitting approach is used or repair of extensor tendons is required. If a swan-neck deformity was corrected, a slight (up to 10°) flexion contracture at the PIP joint is acceptable to protect the volar aspect of the joint capsule and possibly avoid recurrence of the deformity.

**Complications.** The potential complications that can arise following PIP arthroplasty are similar to those associated with MP arthroplasty. Sclerosis around the implant and eventual implant loosening or breakage are long-term complications seen with one-piece silicone implant arthroplasty; however, silicone synovitis is rare.<sup>49,123</sup> Joint instability, subluxation, and dislocation are complications seen with the two-component metal-plastic or pyrocarbon surface replacements because these designs have no inherent stability. Loosening is a long-term complication that may occur regardless

of whether cemented or noncemented fixation was used. A unique complication reported only in pyrocarbon designs is an audible squeaking of the implant during joint motion.<sup>49,123</sup>

Patients must continue to avoid forceful grasping and high-impact activities and must practice principles of joint protection for a lifetime to prevent common long-term complications, such as fracture of the implant.<sup>60</sup>

## Carpometacarpal Arthroplasty of the Thumb

The CMC joint of the thumb, also called the trapeziometacarpal or basal joint, is one of the most common sites for arthritis in the body. The constant multiplanar forces to which this joint is subjected to over the course of daily activities, work, and recreation can lead to arthritis in one of every three women and one of every eight men.<sup>12,14,19</sup> Pain is the primary reason for patients seeking treatment. Patients with CMC arthritis often describe a constant ache that becomes sharp in nature with activities such as gripping, pinching, or twisting motions. Difficulty and pain with writing is a common complaint. Additional difficulties with participation or activity limitations are specific to an individual's work or recreational pursuits.<sup>14,43</sup>

### Indications for Surgery

The following are common indications for CMC arthroplasty of the thumb:<sup>12,14,19,110,132</sup>

- Failure of conservative care including activity modification, hand therapy, orthosis support, anti-inflammatory medication, and intra-articular corticosteroid injections.
- Ongoing disabling pain at the base of the thumb, specifically the CMC joint, as the result of OA, posttraumatic arthritis, or RA. However, most CMC arthroplasties are performed for degenerative joint diseases and less often for synovium-based diseases.
- Dorsal-radial instability (subluxation or dislocation) of the first metacarpal on the trapezium, leading to a hyperextension deformity at the MP joint of the thumb.
- Stiffness and limited ROM (often an adduction contracture) of the thumb.
- Decreased pinch and grip strength because of CMC pain or subluxation.
- Arthrodesis of the CMC joint is inappropriate.

### Procedures

#### Background and Surgical Options

There are a myriad of surgical options from which to choose. The type of procedure selected depends on the degree of ligament laxity, the extent of destruction of the articular surfaces, the underlying pathology, the expected demands that will be placed on the hands postoperatively, and most frequently the surgeons' background and training during residency or fellowship.<sup>11,12,14,41,70</sup> Badia<sup>11</sup> described a classification and treatment system based on arthroscopic findings to assist surgeons in determining the most appropriate course of treatment

relative to the stage of arthritis. He defines arthroscopic stage I osteoarthritis as synovitis with intact articular cartilage, and the treatment of choice would be synovectomy. He defines arthroscopic stage II as loss of articular cartilage on the ulnar third of the thumb metacarpal and the central third of the trapezium with disruption of the dorsal radial ligament and attenuation of the anterior oblique ligament. For these patients, he recommends synovectomy, removal of loose bodies and arthroscopic thermal shrinkage (capsulorrhaphy), and metacarpal extension osteotomy when necessary. He defines arthroscopy stage III as loss of articular cartilage on the trapezium and metacarpal, for which he recommends hemitrapeziectomy with interposition arthroplasty.<sup>11,110</sup> Arthrodesis, rather than arthroplasty, is an option for patients who use the hand for high-demand occupational activities. However, for the patient whose activities place less stress on the hand, there are a number of soft tissue and bony procedures that relieve pain and restore joint stability but preserve functional mobility at the base of the thumb.<sup>12,19,41,70,104</sup> Retaining some CMC joint mobility is particularly important for the patient with RA, who typically has loss of mobility of other joints of the hand and wrist.<sup>138</sup>

Currently there are eight commonly used surgical procedures to treat CMC OA that have been presented in the literature: (1) volar ligament reconstruction, (2) metacarpal osteotomy, (3) CMC arthrodesis, (4) total joint replacement, (5) trapeziectomy, (6) trapeziectomy with tendon interposition, (7) trapeziectomy with ligament reconstruction, and (8) trapeziectomy with ligament reconstruction and tendon interposition (LRTI).<sup>12,14,143</sup> Among these procedures, ligament reconstruction alone is used when there is pain and instability but little to no loss of articular cartilage.<sup>41</sup> Trapezial resection with tendon interposition is by far the most widely used approach to treatment when there is joint subluxation and loss of the joint space due to deterioration of articular cartilage.<sup>14,19,22,59,70,110,132,138,143</sup> Trapezial resection, combined with ligament reconstruction but without tendon interposition, also has been shown to be an effective surgical approach to treatment.<sup>19,22,110,143</sup>

Surface replacement arthroplasty is an alternative to trapezial resection/tendon interposition arthroplasty for a select few patients with CMC OA. Surface replacement arthroplasty involves either resurfacing one articular surface or replacing the surfaces of the trapezium and metacarpal (also known as a total joint surface replacement) with a two-component, saddle-shaped rigid implant that is cemented in place.<sup>14,41,70,144</sup> A patient must have good quality bone stock to be a candidate for surface replacement arthroplasty. In the past decade, total joint arthroplasty using a semiconstrained cemented implant that allows freedom of motion while providing good stability has gained popularity. The main advantage of using a total joint arthroplasty is that if the implant fails or the patient is symptomatic, the implant can be removed and the trapezium resected, allowing for the standard LRTI procedure to be performed. However, the current indications for a total joint arthroplasty is for older

women with limited hand use due to reports of heterotopic ossification and implant loosening.<sup>12,14</sup> On the other hand, preliminary studies of the newer implants are showing promise by allowing for a minimally invasive procedure with minimal bone resection and providing sufficient stability while allowing for biologic ingrowth at the new joint location.<sup>12,69,143,144</sup>

### Operative Overview

**LRTI arthroplasty.** For an LRTI, a dorsal incision is made at the base of the thumb, with careful attention paid to protecting the branches of the superficial radial nerve. The trapezium is resected (trapeziectomy), the EPB tendon is reflected, and a hole is created in the base of the metacarpal perpendicular to the nail plate. A portion of the FCR tendon is harvested through a proximal transverse incision. The tendon is passed through the base of the metacarpal and between the thumb and index metacarpal. The remainder of the tendon is rolled into a ball and inserted into the trapezium space. The capsule is repaired, being sure to include the tendon reconstruction in the repair. Before wound closure, the MP joint is evaluated as indicated and treated with a capsulodesis or arthrodesis, along with possible transfer of the EBP tendon to the first metacarpal base. The capsule and adjacent soft tissues are then repaired, and the wound is subsequently closed.<sup>8,12,14,16,22,59,70</sup>

**Surface replacement arthroplasty.** For a partial trapeziectomy with interposition of a biologic implant, a dorsal approach is used. Approximately 2 mm of the distal trapezium articular surface is removed, and a shallow trough is made in the dorsal surfaces of the metacarpal base and the trapezium. The trough allows for the implant to lie flush to the bone. The implant is inserted into the space and secured to the bone. The capsule is closed over the implant, and the wound is closed.<sup>14,110,144</sup> With a two-component design, after the capsule has been split longitudinally, the distal portion of the trapezium and the base of the first metacarpal are resected. The trapezium and the intramedullary canal of the metacarpal are prepared, and the prosthetic components are inserted and cemented in place. The capsule is repaired, and as with soft tissue interposition arthroplasty, the abductor pollicis longus may be advanced to enhance joint stability. Joint stability and ROM are assessed prior to closure and application of a bulky compression dressing.

### Postoperative Management

The overall goal of rehabilitation following CMC arthroplasty is to attain sufficient pain-free mobility of the thumb for functional activities while maintaining joint stability for strong pinch and grasp. It may take up to a year after surgery for a patient to achieve optimal results.

### Immobilization

With all procedures, the thumb and hand are immobilized postoperatively in a bulky compression dressing and elevated for several days to a week to control edema.

After the postoperative dressing is removed, the hand is placed in a static, forearm-based thumb spica cast for the first 4 to 6 weeks. The cast is later replaced with a custom removable orthosis, with the CMC joint immobilized in palmar abduction (40° to 60°), the MP joint in slight flexion, and the wrist in neutral to slight extension.<sup>8,14,19,43,70</sup> The IP joint of the thumb and the fingers are left free.

The length of time the CMC joint is *continuously* immobilized depends on the surgery. The time frame varies from just 1 to 2 weeks after total surface replacement arthroplasty<sup>43</sup> to 3 to 5 weeks after ligament reconstruction/tendon interposition arthroplasty or resurfacing arthroplasty with prosthetic implants.<sup>19,41,43,59,104</sup>

After surgery, when ROM exercises are permitted, the orthosis is removed during the day for frequent exercise sessions. From 8 to 12 weeks, as the patient uses the hand for functional activities, the use of a daytime orthosis is gradually discontinued. Use of a night orthosis to stabilize the thumb continues for 8 to 12 weeks or until the joint is stable and essentially pain free.<sup>19</sup>

### Exercise Progression

Progression of exercises varies with the type of arthroplasty. Guidelines presented in this section are for *ligament reconstruction/tendon interposition arthroplasty*, still the most common form of CMC arthroplasty. Management guidelines unique to total surface replacement arthroplasty also are noted. Precautions after CMC arthroplasty are summarized in Box 19.6.<sup>8,14,19</sup>

### Exercise: Maximum Protection Phase

The focus of the first 6 weeks of rehabilitation is to control pain and edema, maintain ROM in nonimmobilized joints, and initiate protected motion of the CMC joint when it is permissible to remove the thumb spica orthosis for exercise.<sup>8,14,19,70</sup>

#### BOX 19.6 Precautions After CMC Arthroplasty of the Thumb

- Initially refrain from full CMC radial adduction (sliding the thumb across the palm to the base of the fifth finger) as this motion places excessive stress on the dorsal aspect of the capsule and ligament reconstruction. Be certain it is possible to oppose the thumb to each fingertip before attempting to touch the base of the fifth finger.
- When stretching to increase CMC palmar abduction, apply the stretch force to the metacarpal, not the first phalanx, to avoid hyperextension or compromising stability of the MP joint. Follow the same precaution during light resistance exercises.
- Avoid forceful pinch and grasp for at least 3 months after surgery.
- Modify ADLs to limit heavy lifting. If occasionally heavy lifting is necessary, advise the patient to wear a protective orthosis.

**Goals and interventions.** The following are suggested goals and exercise interventions for the first 6 weeks after surgery:

- **Maintain mobility of the fingers and IP joint of the thumb.**
  - During the period of continuous immobilization of the wrist and CMC and MP joints of the thumb, have the patient perform active ROM of the fingers, IP joint of the thumb, elbow, and shoulder.
- **Initiate protected mobility of the thumb and wrist.**
  - When permissible, begin active ROM of the wrist and controlled ROM of the thumb within protected ranges.
  - After *tendon interposition arthroplasty*, protected ROM is not initiated until about 4 to 6 weeks after surgery to allow time for the reconstructed soft tissues to adequately heal.<sup>8,41,43,70,110,138,147</sup>
  - After *total surface replacement arthroplasty*, ROM may be initiated at about 1 week postoperatively because of the inherent stability of the cemented implants.<sup>41</sup> When it is permissible to remove the orthosis for exercise, begin active wrist ROM in all directions and CMC ROM with active radial and palmar abduction, opposition, and circumduction. Also include active MP flexion and extension, being certain to stabilize the CMC joint.

### Exercise: Moderate and Minimum Protection Phases

While continuing to regain ROM, the focus of rehabilitation during the intermediate and final phases of rehabilitation gradually shifts to developing grip and pinch strength for functional tasks.

**Goals and interventions.** Consider the following goals and interventions:

- **Re-establish functional mobility of the hand and wrist.**
  - Continue active ROM exercises, gradually increasing the range.
  - At about 8 weeks, begin gentle self-stretching exercises.
- **Regain strength and functional use of the hand and wrist.**<sup>8,19,43,138,147</sup>
  - At about 8 weeks postoperatively, initiate isometric exercises against light resistance, emphasizing palmar abduction, radial abduction, opposition, and circumduction.
  - If the CMC joint is stable and pain free, progress to dynamic resistance exercises to regain pinch and grip strength.
  - Between 8 and 12 weeks, remove the orthosis when using the hand for light ADLs, such as buttoning and unbuttoning.
  - Incorporate principles of joint protection during strengthening exercises and ADLs.
  - Continue to increase use of the hand for light to moderate ADLs over the next 4 to 6 weeks. A patient typically can return to light-duty work by 3 to 4 months and can resume most functional activities by 4 to 6 months.

## Outcomes

Most of the studies reported in the literature have investigated outcomes of trapezial resection/tendon interposition arthroplasty with limited evidence reported on the results of surface replacement arthroplasty. Based on data from a variety of instruments that measure pain, ROM, hand function, patient satisfaction, and quality of life, pain-free ROM of the basal joint of the thumb and improved hand function, measured by patient's dexterity, pinch, and grasp, are considered successful overall outcomes following CMC arthroplasty.<sup>12,14,19,41,69</sup> The time required to achieve maximum benefit from the surgery is typically 6 to 12 months.<sup>14</sup>

Among the procedures available, trapezial resection/tendon interposition arthroplasty with or without ligament reconstruction yields the most predictable and successful outcomes.<sup>14,41,70</sup> In a review of tendon interposition arthroplasty, outcomes appear better when the procedure includes reconstruction of ligaments, possibly because the CMC joint is more stable with reconstruction.<sup>41</sup>

**Pain relief and patient satisfaction.** Regardless of the type of CMC arthroplasty, the most consistent and predictable benefit of these procedures is relief of pain.<sup>12,14,19,41,59,77,143</sup> For example, in a review of outcomes of a number of studies for patients with OA who had undergone tendon interposition arthroplasty with or without ligament reconstruction, 94% of patients reported long-term relief of pain.<sup>132</sup> Although tendon interposition is designed to resurface the deteriorated joint to make motion more comfortable, in a prospective, randomized study of patients with OA, investigators compared the results of trapezial resection and ligament reconstruction with and without the use of tendon interposition. They found that at a mean of 48 months after surgery, both groups had equally satisfactory pain relief.<sup>77</sup>

A patient's quality of life also improves after CMC arthroplasty. In a follow-up study of 103 patients with OA who had primary tendon interposition arthroplasty, participants completed several standardized self-assessment questionnaires at a mean of 6.2 years after surgery.<sup>7</sup> In an overall rating, 79 of 103 reported their quality of life had improved greatly, and an additional 15 reported slight improvement.

**ROM and hand function.** Active ROM of the thumb, particularly opposition, and dexterity usually improve after CMC arthroplasty. Increased radial and palmar abduction widen the web space, making it easier to open the hand to grasp large objects. However, the results of some studies of ligament reconstruction/tendon interposition arthroplasty indicate that preoperative and postoperative ROM is essentially unchanged. Although evidence is limited, surface replacement arthroplasty is thought to produce greater improvement in ROM compared with soft tissue procedures, especially in the short term.<sup>41,69,143,144</sup> However, results of a recent study of total surface replacement arthroplasty (two-component, metal-plastic design) demonstrated that although significant pain relief and improvement of bilateral hand function occurred in some tests, there was no significant improvement in range of opposition or grip and pinch strength at a mean follow-up of 3 years after surgery.<sup>69,142</sup>

In contrast, other studies that follow patients for several years after surgery indicate that measurements of pinch and grip strength as well as performance of functional tasks improve significantly.<sup>41</sup> The most successful long-term functional outcomes have been reported for patients who use the hand primarily for low-demand activities.<sup>12,14,69</sup>

**Complications.** Complications vary with the type of CMC arthroplasty. Overall, the rate of complications is low, with inadequate pain relief and recurrence of joint instability the most common complications that necessitate revision arthroplasty. In a retrospective study of 606 primary tendon interposition-ligament reconstruction arthroplasties performed over a 16-year period, only 3.8% were known to have required a revision procedure for mechanically based pain.<sup>42</sup> Neuropathic pain also can develop after CMC arthroplasty. The pain may be caused by damage to or impingement of the radial nerve (radial sensory neuritis), carpal tunnel syndrome, or complex regional pain syndrome.<sup>14</sup>

For arthroplasties that include implantation of prosthetic components, loosening and dislocation are the most common complications. Overall, implant loosening is more likely to occur with uncemented fixation but has been reported to occur in cemented procedures as well.<sup>69,142</sup>

## Tendon Rupture Associated With RA: Surgical and Postoperative Management

### Background and Indications for Surgery

Tendon ruptures in the hand are common in patients with chronic tenosynovitis associated with RA. The site of the rupture may be in the wrist or the hand. When a tendon ruptures, there is a sudden loss of active control of one or more of the digits. Rupture of a single or multiple tendons is usually painless and occurs during unremarkable use of the hand.<sup>16,59,61,124</sup> Such ruptures are evidence of severely diseased tendons.

The extensor tendons are affected far more frequently than the flexor tendons. In order of frequency, extensor tendons that most often rupture are the common extensor tendons to the small and ring fingers and the extensor pollicis longus (EPL). The most common flexor tendon to rupture is the flexor pollicis longus (FPL).<sup>2,59,61,81,124,125</sup>

The causes of rupture include infiltration of proliferative synovium in the tendon sheaths and into tendons, which subsequently weakens the affected tendon; abrasion and fraying of a tendon as it moves over a bony prominence roughened or eroded by synovitis; periodic use of local steroid injections over time; or ischemic necrosis caused by direct pressure from hypertrophic synovium, particularly at the dorsal retinaculum, that compromises blood supply to a tendon. Common sites of abrasion that affect the extensors are the distal ulna, Lister's (Radial) tubercle, and the volar aspect of the scaphoid where it contacts the flexor tendons.<sup>2,59,61,81,124,125</sup>

The indication for surgery is loss of function of the hand. Rupture of a single tendon, such as the extensor digiti minimi, may not impair a patient's function, whereas rupture of multiple

tendons simultaneously or over a period of time may cause significant limitations of function and disability.

## Procedures

The surgical procedures available for treatment of tendon ruptures in RA vary depending on which tendon(s) has ruptured, the number of ruptured tendons, the location of the rupture, the condition of the tendon at the site of rupture, and the quality of the remaining intact tendons of the hand. Options include:<sup>16,38,59,81,124</sup>

- **Tendon transfer.** A tendon is removed from its normal distal attachment and attached at another site. For example, the extensor indicis (EI) can be transferred if the EPL has ruptured. A flexor tendon can also be transferred to the dorsal surface of the hand to act as an extensor if multiple extensor tendons have ruptured.<sup>38,59,81,124,125</sup>
- **Tendon graft reconstruction.** A portion of another tendon that acts as a “bridge” is inserted between and sutured to the two ends of the ruptured tendon. The palmaris longus tendon is often selected as the donor tendon. A wrist extensor tendon may be selected if a wrist arthrodesis is performed at the time of the tendon reconstruction.<sup>38,59,81</sup>
- **Tendon anastomosis (side-to-side tenorrhaphy).** The ruptured tendon is sutured to an adjacent intact tendon. This is a common option at the wrist for the finger extensor tendons.<sup>81,124,125</sup>
- **Direct end-to-end repair.** The two ends of the ruptured tendon are re-opposed and sutured together. This option is used only occasionally because the ends of the ruptured tendons in patients with RA are usually frayed. Therefore, a considerable portion of the frayed tendon(s) must be resected, which shortens the tendon, making it difficult to suture end to end.<sup>59,124</sup>

Concomitant procedures in the rheumatoid hand include tenosynovectomy, removal of osteophytes from bony prominences, and ligament reconstruction or arthrodesis for instability. If late-stage MP joint disease also is present and passive extension of the MP joints is significantly limited, arthroplasty of the involved joints may be indicated as well, either simultaneously with the tendon procedure or during two separate operations as determined by the surgeon. Without adequate joint mobility, the transferred or reconstructed extensor tendons become adherent, resulting in a poor outcome.<sup>124,125</sup>

## Postoperative Management

The guidelines described in this section apply only to management of tendon transfer, reconstruction, or repair of extensor tendons in the rheumatoid hand. As mentioned previously, rupture of extensor tendons occurs far more frequently than flexor tendon rupture. As with postoperative management for other surgeries described in this chapter, pain and edema control and exercises for the uninvolved joints are always essential components of rehabilitation.

Tendon transfers and reconstruction are delicate procedures requiring ongoing communication between the therapist and surgeon and active involvement of the patient in the

postoperative program. The goal of any tendon transfer is to redistribute power in the hand in order to improve function. Communication with the patient and establishing realistic goals and expectations is important, as the tendon transfer does not return normal joint motion but rather improves current function. Therefore, patient education is woven into every phase of rehabilitation.<sup>81</sup>

## Immobilization

A bulky compression dressing is applied to the hand and wrist at the close of extensor tendon surgery to control edema. The surgical compression dressing is removed after several days, and the wrist and hand are then immobilized in a forearm-based volar resting orthosis, which holds the wrist in 30° to 40° extension and the MP joints in 10° to 20° of flexion with the IP joints free to minimize any possible tension on the transfer.<sup>81,125</sup>

For example, after side-to-side finger extensor transfer or extensor tendon reconstruction, the wrist and all fingers are immobilized in extension in the orthosis, but the thumb is free to move. After reconstruction of a ruptured EPL tendon or transfer of the EI tendon to restore thumb extension, the wrist is immobilized in extension, the thumb in palmar abduction, and the MP and IP joints in neutral to slight extension with the fingers free to move.<sup>81</sup>

Continuous immobilization of the wrist and digits is maintained for approximately 3 to 4 weeks to protect the healing tendons.<sup>59,81,124,125</sup> Use of a daytime orthosis is discontinued at about 12 weeks; however, use of a night orthosis typically continues for 6 months or longer.

## CLINICAL TIP

Use of dynamic orthosis and early mobilization (a few days after surgery) is not typically recommended for tendon reconstruction or transfers in the rheumatoid hand. Tissue healing is slower and the risk of re-rupture higher postoperatively for patients with long-standing, systemic disease (who likely have been treated periodically with corticosteroids) than in otherwise healthy patients who have sustained an acute laceration or rupture of a tendon in the hand.<sup>59,124,125</sup>

## Exercise Progression

During each phase of postoperative rehabilitation after extensor tendon transfer or reconstruction, exercises are progressed very slowly and very gradually. Precautions during exercise and functional use of the hand are summarized in Box 19.7.

### Exercise: Maximum Protection Phase

During the first 6 weeks after surgery, the priorities of rehabilitation are edema control and protection of the transferred or reconstructed tendon(s), followed by carefully controlled mobility of the operated areas to prevent adherence of healing tissues. It is usually permissible to remove the protective orthosis for exercise at around 3 to 4 weeks. If tendon quality is poor and the security of the sutured tissues is in question, exercise may be delayed until about 6 weeks postoperatively.<sup>81</sup>

### BOX 19.7 Precautions After Extensor Tendon Transfers or Reconstruction in the Rheumatoid Hand

- During the early phase of rehabilitation, do not initiate MP extension from full, available MP flexion to avoid excessive stretch on the operated tendon(s).
- Postpone stretching to increase MP flexion if there is a deficit in active extension.
- Avoid activities or hand postures that combine finger flexion or thumb radial abduction and radial adduction with wrist flexion, as this places extreme stress on the reconstructed or transferred extensor tendons. If a patient must use the hands for transfer activities, avoid weight bearing on the dorsum of the hand.
- Avoid vigorous gripping activities that could potentially overstretch or rupture the reconstructed or transferred extensor tendon(s).

**Goals and interventions.** The goals and intervention during the first phase of rehabilitation include the following:<sup>61,81</sup>

- **Maintain mobility of the elbow and forearm, uninvolved digits, and other uninvolved joints.**
  - While the operated hand is immobilized, perform active ROM of all necessary joints.
- **Re-establish mobility and control of the repaired or transferred extensor muscle-tendon units.**
  - When the orthosis may be removed for exercise, initiate active wrist motions with the fingers relaxed.
  - Begin assisted MP extension of each of the fingers or thumb with the wrist and IP joints of each digit stabilized in neutral.
  - Perform *place and hold* exercises by passively positioning the operated MP joint first in a neutral and later in a slightly extended position. Have the patient briefly hold the position. This emphasizes end-range extension to prevent an extensor lag.
  - Progress to active MP extension with the wrist in neutral, initially from slight MP flexion with the palm of the hand on a table and the fingers relaxed over the edge.

#### CLINICAL TIP

To help a patient learn the new action of a transferred tendon, initially have the patient focus on the original action (function) of the muscle-tendon unit. For example, if the EI was transferred to replace the action of the EPL of the thumb, have the patient think about extending the index finger when trying to actively extend the thumb. Use biofeedback or functional electrical stimulation (FES) to assist with the motor learning.<sup>81</sup>

- **Regain active flexion of the digits.**

- Initiate MP flexion of the fingers by having the patient relax the ED after active extension rather than actively flexing the fingers.
- Progress to active MP flexion within a protected range with the wrist and PIP joints stabilized in neutral. With the wrist and MP joints stabilized in extension, actively flex (hook fist/intrinsic minus position) and extend (straight hand position) the PIP joints. Performing PIP flexion while in wrist and MP extension prevents stiffness of the IP joints without placing a stretch on the repaired ED tendon(s). It is important to attain full fist closure with the wrist in extension in the first 4 weeks because an inability to achieve a full fist, particularly of the ring and small fingers, indicates a functional restriction as opposed to a slight extensor lag.<sup>124</sup>

#### Exercise: Moderate and Minimum Protection Phases

By 6 to 8 weeks postoperatively, the transferred or reconstructed tendon can withstand greater stresses. Use of the hand for light functional activities usually begins at this time. At about 8 weeks, use of a daytime orthosis is gradually decreased and typically discontinued by 12 weeks postoperatively; however, use of an orthosis at night may continue for up to 6 months depending on the function of the transfer.<sup>81</sup>

**Goals and interventions.** Consider the following goals and interventions to progress the rehabilitation program:

- **Continue to increase active mobility of the operated digits.**
  - Add gentle passive stretching to increase MP extension or flexion if one or both motions are restricted.
  - Continue active MP extension exercises to prevent an extensor lag. If MP extension to neutral is possible (no extensor lag), perform active MP extension with the palm of the hand on a flat surface, and extend each finger beyond neutral.
  - With the wrist in neutral or slight extension, gradually increase MP flexion by touching each fingertip to the palm of the hand (first straight and then full-fist positions) or the thumb to each fingertip and gradually to the base of the fifth finger.
- **Regain strength, control, and functional use of the hand.**
  - Incorporate active movements of the digits into manual dexterity and coordination activities that simulate functional activities. Remove the orthosis for functional activities that involve light grasp, such as picking up or holding light objects or folding clothing.
  - Around 8 to 12 weeks add isometric and dynamic, *sub-maximal* resistance exercises to improve functional strength and endurance of the hand.
  - Through ongoing patient education, reinforce principles of joint protection during functional use of the hand.

#### Outcomes

The results of surgical intervention and postoperative management of ruptured tendons in the hands of patients with RA is highly dependent on the extent of involvement in the

joints and soft tissues of the hand and wrist preoperatively. It is often difficult to differentiate postoperative functional improvement strictly as the result of a tendon transfer or reconstruction from procedures performed concurrently, such as joint arthroplasty or arthrodesis.

Barring complications, the most common of which is tendon re-rupture, a few generalizations can be made.<sup>59,61</sup> Patients with a recent rupture of a single tendon, who have full passive ROM of the affected joint, realize an optimal postoperative outcome: full functional grasp and no extensor lag in the involved digit. The greater the number of tendon ruptures or associated impairments, such as joint contractures, fixed deformities, or joint instabilities, the more complicated the surgical treatment and the poorer the results.<sup>59</sup>

## Repetitive Trauma Syndromes/Overuse Syndromes

Disorders from cumulative or repetitive trauma in the wrist and hand lead to significant loss of hand function and lost work time.<sup>58</sup> The causes are related to repeated movements over an extended period of time. The resulting inflammation can affect muscles, tendons, synovial sheaths, and nerves. Diagnoses include carpal tunnel syndrome, trigger finger, de Quervain's disease, and tendinopathy (tendonitis/tenosynovitis). Management of carpal tunnel syndrome and nerve compression in the tunnel of Guyon is described in Chapter 13.

## Tendinopathy

### Etiology of Symptoms

Pathological breakdown of the tendon structure results from continued or repetitive use of the involved muscle beyond its ability to adapt, the effects of RA, a stress overload to the contracting muscle (such as strongly gripping the steering wheel during a motor vehicle accident), or roughening of the surface of the tendon or its sheath.<sup>45,58,117,149</sup>

### Common Impairments of Structure and Function

- Pain whenever the related muscle contracts or whenever there is movement that causes gliding of the tendon through the sheath.
- Warmth and tenderness with palpation in the region of inflammation.
- In RA, synovial proliferation and swelling in affected tendon sheaths, such as over the dorsum of the wrist or in the flexor tendons in the carpal tunnel.
- Frequently, an imbalance in muscle length and strength or poor endurance in the stabilizing muscles. The fault may be more proximal in the elbow or shoulder girdle, causing excessive load and substitute motions at the distal end of the chain.

## Common Activity Limitations and Participation Restrictions

A common limitation of tendinopathy is the inability to perform repetitive or sustained work, recreational, or leisure gripping activities or hand motions that require contraction of the involved musculotendinous unit due to pain that worsens with the provoking activity.<sup>57</sup>

### Management: Protection Phase

Follow the guidelines for acute lesions described in Chapter 10, with special emphasis on education, relieving the stress in the involved musculotendinous unit, and maintaining a healthy environment for healing with nondestructive forces.

- **Patient education.** Inform the patient how the mechanism of injury and repetitive activity is provoking the symptoms. Explain the necessity to modify the activity to allow healing. Engage the patient in the rehabilitation program.
- **Rest the part.** Rest the involved joints and involved tendon with the use of an orthosis.<sup>78</sup>
- **Tendon mobility.** If the tendon is in a sheath, apply transverse friction massage while the tendon is in an elongated position, so mobility develops between the tendon and sheath.<sup>78</sup>
  - Teach the patient gentle stretching and tendon-gliding exercises to improve mobility and prevent adhesions. (These are described in the exercise section of this chapter.)
- **Muscle integrity.** Teach the patient how to perform multi-angle muscle setting isometrics in pain-free positions followed by pain-free ROM.

### Management: Controlled Motion and Return to Function Phases

- **Exercise progression.** Progress to dynamic exercises, adding resistance within the tolerance of the healing musculotendinous structure.
- **Biomechanical assessment.** Assess the biomechanics of the functional activity provoking the symptoms and design a program to regain a balance in the length, strength, and endurance of the muscles. Frequently, problems arise in the wrist and hand because of poor stabilization or endurance in the shoulder or elbow.
- **Prevention.** Continue to emphasize the importance of self-monitoring the symptoms, maintaining a safe exercise program, and unloading the wrist/hand when symptoms occur.<sup>45</sup>

### FOCUS ON EVIDENCE

Backstrom<sup>10</sup> reported a case study of a patient diagnosed with de Quervain's disease of 2 months' duration in which MWM was used in addition to physical agents, exercise, and transverse friction massage. Pain was markedly reduced from 6/10 to 3/10 (50%) by the third intervention, and by the completion of 12 sessions, it was 0 to 1/10. The author proposed that the subtle malalignment in the wrist joints associated

with the overuse syndrome perpetuated the symptoms and that the MWM helped restore normal arthrokinematics. The MWM techniques used included active movements of the thumb and wrist while a passive radial glide of the proximal row of carpals was applied (similar to Fig. 19.7). The principles of MWM are described in Chapter 5.

## Traumatic Lesions of the Wrist and Hand

### Simple Sprain: Nonoperative Management

After trauma from a blow or a fall, an excessive stretch force may strain the supporting ligamentous tissue. There may be a related fracture, subluxation, or dislocation.

#### Common Impairments of Structure

- Pain at the involved site whenever a stretch force is placed on the ligament
- Possible hypermobility or instability in the related joint if supporting ligaments are torn

#### Common Impairments of Function, Activity Limitations, and Participation Restrictions

- With a simple sprain, pain may interfere with functional use of the hand for a couple of weeks whenever the joint is stressed. Consider the use of an orthosis or tape to protect the ligament without a limitation of function provided the orthosis does not interfere with the task.
- With significant tears, there is instability, and the joint may sublux or dislocate with provoking activities, requiring surgical intervention.

### Management

Follow the guidelines in Chapter 10 for treating acute lesions with emphasis on maintaining mobility while minimizing stress to the healing tissue. If immobilization is necessary to protect the part, only the involved joint should be immobilized. Joints above and below should be free to move. This maintains mobility of the long tendons in their sheaths that cross the involved joint. Avoid positions of stress and activities that provoke the symptoms while healing.

### Lacerated Flexor Tendons of the Hand: Surgical and Postoperative Management

#### Background and Indications for Surgery

Lacerations of flexor tendons can occur in various areas (zones) along the volar surface of the fingers, palm, wrist, and distal forearm and cause an immediate loss of hand function, consistent with the tendons severed. The musculotendinous structures damaged depend on the location and depth of the

wound. Damage to one or more tendons may be accompanied by vascular, nerve, and skeletal injuries, which can cause additional loss of function and complicate management. An acute rupture of a flexor tendon may also occur as the result of a closed traumatic injury to the hand.<sup>3,12,101,129,137</sup>

The volar surfaces of the forearm, wrist, palm, and fingers are divided into five zones; the thumb is divided into three zones. These zones are illustrated in Figure 19.11. The anatomical landmarks for each of the zones are described in Box 19.8.<sup>65,82,90,127,129,134,137</sup> Use of this system of classifying lacerations improves consistency of communication and can provide a basis for predicting outcomes.<sup>137</sup>

**FIGURE 19.11** Flexor tendon zones; volar aspect of the hand and wrist.

Knowledge of the complex anatomy, kinesiology of the hand, and tendon healing properties is essential to understand the impairments and functional implications caused by damage to the flexor tendons in each of these zones. Box 19.9 identifies common impairments associated with damage in each of the zones.<sup>90,112</sup>

When severed or ruptured, flexor tendons readily retract, thus requiring surgical intervention in most instances to restore function to the hand and prevent deformity. Repair and rehabilitation of lacerations in zone II, traditionally referred to as “no-man’s land,” pose a particular challenge to hand surgeons and therapists.<sup>82,95,122,127,129,137,153</sup> Because of the confined space in which the extrinsic flexors of the fingers lie and the limited vascular supply to the tendons in zone II, healing tissues in this area are prone to excursion-restricting adhesions. Scar tissue formation during the healing process can interrupt tendon-gliding in the synovial sheath and subsequently restrict ROM of the involved fingers.<sup>122,137</sup>

### BOX 19.8 Flexor Tendon Zones: Anatomical Landmarks

#### Zones of the Fingers, Palm, Wrist, and Forearm

- I—from the insertion of the FDP on the distal phalanx to just distal of the FDS insertion on the middle phalanx
- II—from the distal insertion of the FDS tendon to the level of the distal palmar crease (just proximal to the neck of the metacarpals)
- III—from the neck of the metacarpals, proximally along the metacarpals to the distal border of the carpal tunnel
- IV—the carpal tunnel (area under the transverse carpal ligament)
- V—area just proximal to the wrist (proximal edge of the carpal ligament) to the musculotendinous junction of the extrinsic flexors in the distal forearm

#### Zones of the Thumb

- T-I—from the distal insertion of the FPL on the distal phalanx of the thumb to the neck of the proximal phalanx.
- T-II—from the proximal phalanx, across the MP joint to the neck of the first metacarpal.
- T-III—from the first metacarpal to the proximal margin of the carpal ligament.

In zone IV (the carpal tunnel), the extrinsic flexor tendons of the digits (FDS, FDP, and FPL) lie in close proximity to each other. An injury in this zone may lead to adherence of adjacent tendons to each other in the carpal tunnel and impairment of differential gliding between the tendons.<sup>68</sup>

## Procedures

### Types and Timing of Operative Procedures

Many factors influence the type of surgical repair selected to manage a flexor tendon injury.<sup>65,90,127,134</sup> Injury-related factors include the mechanism of injury; the type and location (zone)

of the laceration; the extent of associated skin, vascular, nerve, and skeletal damage; the degree of wound contamination; and the time elapsed since the injury. Surgery-related factors include timing of the repair, if there is a need to stage surgeries, and the hand surgeon's background and experience. Patient-related influences are the patient's age, health, and lifestyle (especially nutrition and smoking). These factors also have a significant impact on postoperative rehabilitation and outcomes of a tendon repair.<sup>82,95,137,153</sup>

**Types of repair or reconstruction.** Surgical options for repair of lacerations or a closed rupture of flexor tendons can be classified by the *type* of procedure.<sup>65,90,98,137</sup>

- **Direct repair.** An end-to-end repair in which the tendon ends are re-opposed and sutured together.
- **Tendon graft.** An autogenous donor tendon (autograft), such as the palmaris longus, is sutured in place to replace the damaged tendon. This is necessary when the ends of the severed tendon(s) cannot be brought together without undue tension. Tendon grafts are performed in one or more stages depending on the severity, type, and location of injury.

A straight laceration usually lends itself well to a direct (end-to-end) repair, whereas a jagged laceration that frays the tendon may require a tendon graft.<sup>150</sup>

**Timing of a repair.** Another method of classifying and describing tendon repairs is the *timing* of the repair, as related to the elapsed time since the injury. The timing of a repair after an acute tendon injury is critical because the severed ends of the tendon begin to soften and deteriorate quickly and the proximal portion of the tendon retracts. These factors make it difficult to reattach the tendon with a strong repair at its normal length. However, only a tendon laceration associated with major damage to the vascular system is considered an emergency situation.<sup>90,122,127</sup> Although better outcomes are thought to occur if the repair is done within the first few days,

### BOX 19.9 Consequences of Injury to the Volar Surface of the Hand, Wrist, and Forearm

- **Zone I.** Only one tendon, the FDP, can be severed as can the A-4 and A-5 retinacular pulleys, which are important for maintaining the mechanical advantage of the FDP for complete finger flexion (full fist).
- **Zone II.** FDS and FDP tendons, a double-layered synovial sheath and multiple annular pulleys (including A-1) of the flexor retinaculum (the fibrous sheath that approximates the tendons to the underlying bones and maintains them relatively close to the joints for full tendon excursion) can all be damaged. Inability to flex the PIP and DIP joints occurs if both tendons are severed. Potential damage to the vincula, the vascular structures that provide blood, and supplement nutrition derived from synovial diffusion can compromise tendon healing.
- **Zone III.** In addition to loss of the FDP and FDS, damage to lumbricals can disrupt MP flexion.
- **Zone IV.** Damage in this zone (in the carpal tunnel) can affect all three extrinsic flexors of the digits—FDP, FDS, and FPL—which disrupts finger and thumb flexion. Synovial sheath also sustains damage. Nerve injury frequently accompanies laceration in this zone.
- **Zone V.** Laceration in the forearm can cause major damage to flexor tendons of the digits and wrist, resulting in loss of wrist and digital flexion. The median and ulnar nerves and the radial and ulnar arteries also lie superficial in this zone.
- **Zones T-I and T-II.** Damage to the retinacular pulley system of the thumb, synovial sheath in addition to the FPL, and possibly the distal insertion of the FPB can occur; IP and MP flexion are disrupted.
- **Zone T-III.** Potential damage to the thenar muscles.

a delay of up to 10 days yields results equal to those of an immediate repair. Delays beyond 2 weeks are associated with poorer outcomes.<sup>127,137,150</sup> If a repair must be delayed for more than 3 to 4 weeks, a direct repair is no longer possible, which necessitates a tendon graft.<sup>127</sup>

Categories of surgeries based on elapsed time include:<sup>65,90,127,134</sup>

- **Immediate primary repair:** A repair done within the first 24 hours after injury.
- **Delayed primary repair:** A repair performed up to 10 days after injury.
- **Secondary repair:** A repair done 10 days to 3 weeks after injury.
- **Late reconstruction:** Surgery performed well beyond 3 to 4 weeks, sometimes months after the injury.
- **Staged reconstruction:** Multiple separate surgeries performed over a period of weeks or months.<sup>98,121,122</sup> A staged reconstruction enables a surgeon to prepare an extensively damaged or scarred tendon bed months prior to a tendon graft, so adhesions are less likely to develop.

A simple, clean, acute laceration of a tendon without associated injuries of the hand is most often managed with a *direct primary repair*, either immediate or delayed a few days.<sup>82,127,134</sup> However, if the wound is not clean, a *delayed primary repair* allows time for medical intervention to reduce the risk of infection. Lengthy delays that necessitate a *secondary repair* or *late reconstruction* are often associated with multiple injuries, such as extensive skin loss, fractures that cannot be stabilized immediately, or long-standing scarring and contractures. If there is damage to one or more of the tendon pulleys, these must be repaired before the lacerated tendon can be repaired effectively.<sup>121,122,127,137</sup>

Of the multiple-stage reconstructions for extensive and complex flexor tendon injuries of the hand, the *Hunter two-stage reconstruction passive or active implant* is most widely known. During the first stage of this procedure, the scarred and adherent portions of the damaged flexor tendon are resected. An implant (rod) made of silicone is then secured in place to act as a *tendon spacer* around which a new sheath develops over a period of 3 months. In addition, a damaged retinacular pulley system is reconstructed, and any contractures are released during the first surgery. During the second phase, the implant is removed, and a donor tendon (graft) is drawn through the new sheath and sutured in place.<sup>98,121,127,137,153</sup>

### Operative Overview

Some general aspects of the many variations of operative procedures for primary flexor tendon injuries are described in this section.<sup>65,90,98,122,127,134,137</sup> However, careful review of a patient's operative report and close communication with the hand surgeon are necessary sources of specific details of each patient's surgery.

**Surgical approach.** For example, for repair of lacerated finger tendons in zone II, a volar, zigzag approach, designed to avoid the lines of stress or a lateral incision, may be elected

by the surgeon although the zig-zag approach is more common. When surgically repairing a lacerated tendon, the incision is made between the annular pulleys to ensure optimal excursion. This approach preserves the function of these fibrous sheaths, which encircle the finger flexors and keep the tendons close to the joints, preventing bowstringing of the tendon.

**Suturing technique.** For a direct repair after the tendon ends are located, prepared, and re-opposed, there are a number of delicate suturing techniques that can be employed.<sup>65,82,90,127,129,134,137,150</sup> Core sutures and epitendinous sutures are used to hold the tendon ends together. A larger number of suture strands across the repair site (e.g., four or six strands instead of two) produces a proportionally stronger repair. Running, locked epitendinous sutures used in addition to core sutures appear to further increase the initial strength of the repair.<sup>65,127,129,149</sup>

### CLINICAL TIP

Suturing technique and the number of suture strands influence the initial strength of the repair and consequently the type and timing of motion allowable postoperatively.

Suturing technique must also address the vascular supply to the repaired tendon. Nonreactive sutures are placed in the nonvascular volar aspect of the tendon so as not to disturb the vincula, which lies in the dorsal aspect of the tendon and provides its blood supply.<sup>129,134,137</sup> When present, as in zones II and IV, the synovial sheath is also repaired to re-establish circulation of synovial fluid, an important source of nutrition to the healing tendons.<sup>65,129</sup>

**Closure.** After all repairs have been completed, the incision(s) is closed, and the hand and wrist are immobilized in a bulky compression dressing and elevated to control edema. The compression dressing remains in place for 1 to 3 days. When the bulky surgical dressing is removed, it is replaced with a light compressive dressing and an orthosis.

### Postoperative Management

**General considerations.** After surgical intervention for a flexor tendon injury, a strong, well-healed tendon that glides freely is the cornerstone for restoring functional mobility and strength in the hand.<sup>3,55,68,112</sup> Every effort is made to prevent excursion-restricting adhesions from forming while simultaneously protecting the repaired tendon as it heals. Box 19.10 summarizes the factors that contribute to adhesion formation after tendon repair.<sup>55,68,112,127</sup>

Many of the same patient and injury-related factors—already noted—that a surgeon weighs when determining the most appropriate approach to surgical management for a patient's hand injury also influence the complex components and progression of postoperative rehabilitation. In addition,

### BOX 19.10 Factors That Contribute to Adhesion Formation After Tendon Injury and Repair

- Location of the injury and repair: higher risk in flexor zone II and extensor zone III; tendons glide in a closely confined area
- Extent of trauma: higher risk with extensive trauma and damage to associated structures
- Reduced blood supply, subsequent ischemia, and reduced nutrition to healing tendons
- Excessive handling of damaged tissues during surgery
- Ineffective suturing technique
- Damage or resection of components of the tendon sheath
- Prolonged immobilization after injury or repair, which prevents tendon-gliding
- Gapping of the repaired tendon ends associated with excessive stress to the healing tendon

surgery-related factors, including the type and timing of the repair, suturing technique, strength of the tendon repair, and the need for concomitant operative procedures, affect rehabilitation and eventual outcomes. Furthermore, therapy-related factors—in particular the time at which therapy is initiated, the use of early or delayed mobilization procedures, the quality of the orthosis, the expertise of the therapist, and ultimately the quality and consistency of the patient's involvement in the rehabilitation process—influence outcomes.

Extensive research has been done on the process of tendon healing, the tensile strength of tendon repairs, adhesion formation, and tendon excursion and imposed stresses (loading) on a repaired tendon during digital motion. A number of sources provide an in-depth analysis and summary of basic and clinical studies, typically animal and cadaveric, but some are *in vivo* human studies, as they apply to rehabilitation.<sup>3,29,55,66,127,129,134</sup>

The purpose of this section is to examine and summarize current concepts and approaches to immobilization and exercise used in rehabilitation after flexor tendon injury and repair. Therapists treating patients after tendon repair must be familiar with the various postoperative protocols or guidelines used by referring hand surgeons and those described in the literature.

A therapist's knowledge of the underlying concepts in any protocol is essential for effective communication with the surgeon. A therapist's skill in applying and teaching exercise procedures is equally necessary for effective patient education and helping a patient achieve optimal functional outcomes. This knowledge enables a therapist to make sound clinical judgments to determine when the progression of activities in a protocol preferred by a referring surgeon is safe or when activities must be adjusted based on each patient's responses. Remember, a regimented protocol is only safe and effective when there are no postoperative variables, a situation that certainly does not occur in the clinical setting.<sup>39,112</sup>

**Approaches to postoperative management.** There are two basic approaches to management after flexor tendon repair

characterized by the timing and type of exercises in the program. They are categorized as *early controlled motion*, either passive or active, and *delayed motion*.

Numerous published protocols with considerable variability fall within these categories. Most current-day programs emphasize early controlled (protected) motion after surgery and include both passive and active exercises of the operated digit(s). Advances in surgical management (in particular, improved suturing techniques) that establish a relatively strong initial tendon repair allow the use of early motion.

### FOCUS ON EVIDENCE

Trumble and colleagues<sup>140</sup> studied 103 patients with zone II flexor tendon repair who were randomized to either early active motion with place and hold or a passive motion protocol. ROM was measured at 6, 12, 26, and 52 weeks following the repair. Outcome measures also included dexterity tests, the DASH outcome questionnaire, and a satisfaction score. Ninety-three patients completed the study. At all points in the study, patients treated with the active motion protocol had greater ROM. At 52 weeks, the total active motion (TAM) for the active place and hold group was a mean of 156° +/- 25°, compared with 128° +/- 22° ( $p < 0.05$ ) in the passive group. The authors also report that the active motion group had significantly smaller flexion contractures and greater satisfaction scores ( $p < 0.05$ ). There was no difference between groups in either the DASH score or dexterity tests. They concluded that active motion therapy provides greater active finger motion than passive motion therapy after zone II flexor tendon repair without risk of tendon rupture (3%). In addition, they reported that concomitant nerve injuries, multiple digit injuries, and a history of smoking negatively impact the final outcome of tendon repairs.

Box 19.11 summarizes the rationale for early protected motion as soon as a day or two after tendon repair based on four decades of evidence derived from scientific studies.<sup>29,55,65,66,68,82,112,127,131,132</sup> However, there are instances when a traditional, delayed motion approach must be used. Indications for prolonged (3 to 4 weeks) immobilization after tendon repair (and therefore delayed motion) are noted in Box 19.12.<sup>48,112,122,127</sup>

Key elements of early passive and active motion approaches and the delayed motion approach with regard to immobilization and selection and progression of exercises are presented in the following sections. More detailed descriptions of these approaches, as well as specific protocols advocated by various practitioners and researchers, are available in many sources.<sup>29,39,55,66,68,112,131,134,147,150</sup>

With all approaches, the postoperative goals and interventions for pain reduction, edema control, and maintenance of function in uninvolved regions (e.g., the elbow and shoulder) are consistent with management following other operative procedures previously discussed in this chapter. Patient

### BOX 19.11 Rationale for Early Controlled Motion After Tendon Repair

- Decreases postoperative edema.
- Maintains tendon-gliding and decreases the formation of adhesions that can limit tendon excursion and that consequently limit functional ROM. Gliding deteriorates by 10 days after repair when a tendon is immobilized.
- Increases synovial fluid diffusion for tissue nutrition, which increases the rate of tendon healing.
- Increases wound maturation and the tensile strength of the repaired tendon more rapidly than continuous immobilization by means of *appropriate-level* stresses achieved with early tendon motion. The repair site loses strength during the first 2 weeks after surgery.
- Decreases gap formation at the repair site, which in turn increases the tensile strength of the repair.

### BOX 19.12 Indications for Use of Prolonged Immobilization and Delayed Motion After Flexor Tendon Repair

- Patients who are unable to comprehend and actively participate in an early controlled motion exercise program. This includes:
  - Children less than 5 years of age
  - Patients with diminished cognitive capacity associated with head injury, developmental disability, or psychological impairment
- Patients who have the cognitive ability to understand and follow an early controlled motion program but who are unlikely to adhere to the program. This includes:
  - The unmotivated patient
  - The overzealous, impatient individual with a history of a previously failed repair
  - Patients in whom repair of other hand injuries or surgeries necessitates extended immobilization of the hand

education is of the utmost importance for effective outcomes after hand surgery.

**NOTE:** Unless otherwise noted, the guidelines described in this section for immobilization and exercise are for injury and primary repair or one-stage tendon grafts of the FDS and/or FDP muscle-tendon units in zones I, II, and III. The guidelines are similar but not addressed for zones T-I and T-II of the thumb. Postoperative guidelines for multistage or late reconstructions are progressed in a similar but more cautious manner. Refer to other resources for this information.<sup>48,55,66,68,112,131</sup>

#### Immobilization

The duration, type, and position of immobilization must be considered.

**Duration of immobilization.** With some exceptions previously noted (see Box 19.12), when prolonged immobilization (3 to 4 weeks) is necessary, the repaired tendon is continuously immobilized after surgery for up to 5 days while the bulky compression dressing is kept in place. This allows some time for postoperative edema to decrease.

**Type or method of immobilization.** This usually depends on the preference of the hand surgeon and therapist, the approach to postoperative exercise, and the stage of tissue healing. If motion of the operated digit is to be delayed for 3 to 4 weeks, a cast or static orthosis provides the immobilization. Early controlled motion approaches require the fabrication of different types of customized orthoses.

There are three general types of orthoses used after flexor tendon repair: a static dorsal blocking orthosis;<sup>50,55,68,112,127</sup> a dorsal blocking orthosis with dynamic traction, originally proposed by Kleinert<sup>75,79</sup> and subsequently modified and improved by clinicians and researchers;<sup>55,112,122</sup> and a dorsal tenodesis orthosis with a wrist hinge.<sup>29,112,127,134</sup> Descriptions of these static and dynamic orthosis techniques for immobilization and/or exercise are noted in Box 19.13. Figure 19.12 shows an example of a dorsal blocking orthosis with dynamic traction. The orthosis allows active extension of the involved finger, and the elastic band passively returns the finger to a flexed position. (See Fig. 19.13A for a depiction of a dorsal tenodesis orthosis.)

**Position of immobilization.** The typical position of immobilization for repairs of flexor tendons in zones I, II, and III is

A

B

**FIGURE 19.12** A dorsal-blocking orthosis with dynamic traction for early controlled motion after flexor tendon repair; (A) showing active extension and (B) passive flexion.

**BOX 19.13 Static and Dynamic Dorsal Blocking Orthoses: Position and Use****Static Dorsal Blocking Orthosis**

- Covers the dorsal surface of the entire hand and two-thirds of the forearm (the thumb is free).
- Positioned in wrist and MP flexion and IP extension to avoid excessive tension on the repaired flexor tendon. The degrees of flexion may vary with the philosophy of the surgeon or therapist and the approach (protocol) implemented.
- Fabricated with straps placed across the volar aspect of the hand and forearm to hold the wrist and fingers in the correct position.
- Restricts wrist and MP extension.
- Worn during early phases of rehabilitation. Distal straps of the orthosis are loosened or removed for early exercises.
- Also worn as a protective night orthosis.

**Dorsal Blocking Orthosis With Dynamic Traction**

- Allows early motion of the operated joint while the hand is in the orthosis.
- Fabricated with an elastic band (or nylon cord), which is attached to the nail of the operated finger (or all four fingers),

passes under a palmar bar that acts as a pulley, and then is attached proximally at the wrist.

- At rest, the elastic band provides dynamic traction that holds the operated finger in flexion.
- Allows *active extension* of the IP joints to the surface of the dorsal orthosis.
- When PIP and DIP extensors relax, tension from the elastic band pulls on the finger, causing *passive flexion*.

**Dorsal Tenodesis Orthosis With Wrist Hinge**

- Worn *exclusively* for exercise sessions.
- No dynamic traction with elastic bands.
- Allows full wrist flexion and limited (approximately 30°) wrist extension but maintains the MP joints in at least 60° of flexion and the IP joints in full extension when the straps are secured.
- Loosening of straps across the fingers allows active wrist extension during initial passive IP flexion and later when finger flexion is maintained for several seconds by a static contraction of the IP flexors.

wrist and MP flexion coupled with PIP and DIP extension. This position prevents full lengthening and undue stress on the repaired FDS and/or FDP tendons while minimizing the risk of IP flexion contractures. The recommended degrees of wrist and MP flexion differ somewhat from one source to another. Recommended positions range from 10° to 45° of wrist flexion and from 30° to 70° of MP flexion with the IP joints in full but comfortable extension depending on the zone.<sup>29,50,55,68,112,127,134</sup> The wrist typically is positioned in less flexion than the MP joints. The trend over the years has been to fabricate orthoses that allow less wrist and MP flexion than early protocols increasing patient comfort and reducing the risk of carpal tunnel syndrome.<sup>55,112</sup>

The wrist is typically positioned at neutral with 60° to 70° MP flexion following a zone IV repair.<sup>68</sup>

**Exercise: Early Controlled Motion Approaches**

There are two basic approaches to the application of early, controlled motion to maintain tendon-gliding and prevent tendon adhesions after flexor tendon repair: early passive motion and early active motion. The way in which passive or active motion of the repaired tendon is achieved, however, varies among protocols.

**Early controlled passive motion.** Historically, the use of early passive motion has been based on the work of Duran and Houser<sup>50</sup> and of Kleinert and associates.<sup>75,79</sup> Both groups proposed early passive flexion of the IP joints within a protected range postoperatively, but they used different approaches to the use of orthoses and exercise. Duran advocated use of a static dorsal blocking orthosis and early removal of the orthosis or loosening of the stabilization straps for passive ROM exercise of the IP joints of the operated finger(s). Kleinert and

colleagues advanced use of a dorsal blocking orthosis with dynamic traction for early exercise (see Fig. 19.12). Within the confines of the orthosis, the patient performs *active extension* of the operated finger with the elastic bands producing passive flexion allowing excursion of the repaired tendon without active tension in the finger flexors. A gentle manual push into full composite flexion using the uninvolved hand may be added to increase passive flexion.

**NOTE:** When a dynamic traction orthosis is used during the day, a static dorsal blocking orthosis is worn at night. The night orthosis holds the IP joints in extension, the wrist in 10° to 30° of flexion, and the MP joints in 50° to 70° flexion to prevent IP flexion contractures.

These original passive motion protocols have been modified over the past 3 decades. Today, some surgeons and therapists use selected elements (use of an orthosis and/or exercise) of these passive motion approaches.<sup>29,31,113,122,140</sup> However, use of early *active* motion that imposes controlled stresses on the repaired tendon is gradually replacing passive motion approaches.<sup>31,68,113,140</sup>

**Early controlled active motion.** The primary feature that distinguishes an early active motion from an early passive motion approach is the use of *minimum-tension, active contractions* of the repaired muscle-tendon units initiated during the acute stage of tissue healing, often by the first 24 to 72 hours but no later than 5 days postoperatively.<sup>29,55,68,112,127,134,140</sup> Some passive exercises are also incorporated into active regimens.

Based primarily on experimental studies using animal models, it is hypothesized that gentle stresses placed on a repaired tendon by means of a very low-intensity static or dynamic muscle contraction, which “pulls” the repaired tendon

through its sheath, is a more effective method of creating tendon excursion (gliding) than “pushing” the tendon with passive motion.<sup>3,39,55,57,66</sup> Early active motion has become more widely accepted because stronger suturing techniques produce a repair that can withstand early, controlled stresses.

**PRECAUTION:** Proponents of early, active tendon mobilization caution that this approach is recommended only for primary tendon repairs, using the stronger four- and six-strand core and epitendinous suture techniques (in contrast to two-strand suturing) in carefully selected patients who have access to rehabilitation with an experienced hand therapist and are most likely to adhere to the prescribed exercise and orthosis regimen.<sup>29,31,55,66,127,131,134,137</sup>

There are two ways in which early active motion can be implemented. Both methods are founded on an analysis and application of evidence in the scientific literature on tendon repair and healing, tendon excursion, and imposed loading on repaired tendons.<sup>31,39,55,134</sup>

- **Place-and-hold approach.** One approach uses “place-and-hold” exercises by means of *static* muscle contractions to generate active tension of the finger flexors and impose controlled stress on the repaired tendon. (Place-and-hold exercises are described in the phase-specific exercises that follow.) This approach to early active motion is used in the Indiana protocol.<sup>29,31,134,151</sup>
- **Dynamic approach.** The other approach to early active motion, developed by Evans,<sup>55,57</sup> uses *dynamic*, short-arc, minimum muscle tension exercises to impose initially low-intensity stresses on the healing tendon.
- **Combined approach.** Groth<sup>66</sup> proposed a conceptual model for the use of early active motion and application of progressive forces to the healing tendon after flexor tendon repair that combines elements of both the place-and-hold and dynamic approaches. In addition, in the rationale for this model, Groth discusses the effects of each level of exercise on internal tendon loads and tendon excursion supported by key evidence from the literature when available.
  - A unique feature of Groth’s model is that it is criterion based rather than time based. By providing criteria for progressing exercises based on optimal tendon loading, this program provides a mechanism for an individualized sequence of exercises adjusted for each patient rather than using predetermined timelines for progression.
  - The model contains eight progressive levels of active exercises, from the least to the greatest levels of loading on the tendon. The sequence is preceded by warm-up exercises (slow, repetitive passive finger motions in protected ranges). As with other early active motion approaches, exercises are begun during the first few days after surgery and are progressed until conclusion of postoperative rehabilitation. Box 19.14 describes the eight-level sequence of exercises in Groth’s conceptual model.<sup>66,112,137</sup>

### BOX 19.14 A Sequence of Exercises for Early Active Motion With Progressive Tendon Loading After Flexor Tendon Repair <sup>66</sup>

#### Warm-Up

Warm-up exercises (passive finger motions within protected ranges precede each exercise session).

#### Progressive Levels of Exercise\*

- Level 1—place-and-hold finger flexion
- Level 2—active composite finger flexion
- Level 3—hook and straight fist finger flexion
- Level 4—isolated finger joint motion
- Level 5—continuation of levels 1–4 of exercise and discontinuation of protective orthosis with introduction of gradually increasing use of the hand for functional activities
- Level 6—resisted composite finger flexion
- Level 7—resisted hook and straight fist exercises
- Level 8—resisted isolated joint motion.

\**Note:* Exercise sequence is from least to greatest tendon loading. Repetitions are highest at the lowest level of loading and least at the highest level of loading. Progression to the next level occurs when specific criteria are met.

A number of retrospective studies and prospective, non-randomized case series have been published describing the effectiveness of early active motion or early passive motion approaches to postoperative rehabilitation following flexor tendon repair.

### FOCUS ON EVIDENCE

Chesney and colleagues<sup>31</sup> performed a systematic review of flexor tendon rehabilitation protocols in zone II of the hand. The authors looked at all rehabilitation protocols published with the exception of immobilization. The protocols were broadly classified as either passive flexion and active extension protocols (Kleinert-type), controlled passive motion protocols (Duran-type), combined “controlled passive motion” protocols (combined Kleinert and Duran with elements from both), and early active motion protocols (protocols utilizing place and hold). The primary outcomes they considered were the rate of tendon rupture, the ROM of the injured digit, as well as quality of life and patient satisfaction. Results of their review demonstrated that both early active motion protocols and combined protocols result in low rates of tendon rupture and acceptable ROM; however, there isn’t a protocol that is superior to another. The takeaway is that the literature does not support any one protocol and that more research is needed including randomized controlled trials comparing the different protocols side by side to not only determine the most effective protocol, but also to determine which protocol is most cost effective.

### Exercise: Maximum Protection Phase

**NOTE:** The guidelines for exercises described in this section focus on the application of early active motion after *zone I, II, or III primary flexor tendon repairs* and are drawn from several resources.

The maximum protection phase of rehabilitation begins within the first few days after surgery and continues for 3 to 5 weeks. This is the period of time when the tendon repair is weakest. The goals of this phase of rehabilitation are pain and edema control and protection of the newly repaired tendon while imposing very low-level, controlled stresses on the tendon to maintain adequate tendon gliding and prevent adhesions that can restrict tendon excursion. Interventions in this phase include elevating the hand, orthosis use and care, wound management and skin care, and passive and active exercises.

During the first phase of rehabilitation, exercises are performed in a static dorsal blocking orthosis or in a wrist tenodesis orthosis (Fig. 19.13 A) specifically designed for exercise. With both methods, the stabilization straps are loosened to allow finger flexion. The following exercises are performed frequently (hourly) during the day and continue for about the first 4 weeks.

- **Passive ROM exercises.** On an hourly basis perform passive MP, PIP, and DIP flexion and extension of each individual joint to the extent the dorsal orthosis allows, followed by composite passive flexion in the confines of the orthosis. Composite flexion can include passive movements into full fist and straight fist positions.
- **Independent motions of the PIP and DIP joints for differential gliding of the FDP and FDS tendons.** For example, the DIP joint must be flexed and extended separately while each PIP joint is stabilized in flexion. In this way, as the DIP joint is passively extended, the FDP repair site glides distally, away from the FDS repair.<sup>68,112</sup>

**PRECAUTION:** It is essential to maintain the MP joints in flexion during passive ROM of the IP joints to avoid excessive stretch of the repair site, which could cause gapping of the opposed tendon ends during IP extension.

- **Place-and-hold exercises.** Many programs initiate place-and-hold exercises of the repaired digit with the patient wearing either a dorsal blocking orthosis<sup>55,151</sup> or a tenodesis orthosis.<sup>29,39,66,112</sup> With the MP joints in flexion, passively place the IP joints in a partially flexed position and have the patient hold the position independently for 5 seconds with a minimum static contraction of the finger flexors. If the patient is wearing a tenodesis orthosis, combine place-and-hold finger flexion with active wrist extension (Fig. 19.13 B and C). Have the patient relax and allow the wrist to passively flex and the digits to passively extend. Initially, have the patient practice this with the uninjured hand or use biofeedback to learn how to hold the position with a minimum of force production in the FDP and FDS.

**FIGURE 19.13** Orthosis and exercise for early active motion post-flexor tendon repair. **(A)** Following removal of the surgical compression dressing and fabrication of a static dorsal-blocking splint, a tenodesis splint with a wrist hinge is fabricated. **(B)** The tenodesis orthosis allows full wrist flexion but limits wrist extension to 30°. During early movement of the fingers, the MP joints are maintained in at least 60° of flexion, as the IP joints are passively moved and placed in composite flexion. **(C)** Then the patient actively extends the wrist while maintaining the flexed finger position with a static muscle contraction and the least amount of tension possible in the finger flexors. (From Strickland, JW: *Flexor tendon injuries*. In Strickland, JW, and Graham, TJ [eds]: *Master Techniques in Orthopedic Surgery—The Hand*, ed. 2. Philadelphia: Lippincott Williams & Wilkins, 2005, p 262, with permission.)

### FOCUS ON EVIDENCE

Research has shown that it is preferable to perform place-and-hold exercises with the wrist extended and the MP joints placed in flexion because wrist extension is the position in which the IP joints can be moved by contraction of the FDS and FDP with the *least* amount of contraction force and, therefore, a very low-level load on the repaired tendon.<sup>29,39</sup>

- **Minimum-tension, short-arc motion (SAM).** Some programs begin active, dynamic finger flexion during the first few days after surgery if the suturing technique and strength of the repair allow.<sup>39,55,112</sup> Active contractions that generate minimum tension—just enough tension to overcome the resistance of the extensors and cause flexor tendon excursion—are performed with the wrist in slight extension and the MP joints flexed.

#### Exercise: Moderate Protection Phase

The moderate protection phase begins at about 4 weeks and continues until 8 weeks postoperatively. The focus during this phase is on safely increasing stresses on the repaired tendon and achieving full active flexion and extension of the wrist and digits and differential gliding of the tendons. If a tenodesis orthosis was worn for early active exercises, it is discontinued at the beginning of this phase. However, use of the static dorsal blocking orthosis continues during the day except for exercise until at least 6 to 8 weeks. Use of a night orthosis continues for protection or to decrease or prevent a flexion contracture. Exercises include:

- **Place-and-hold exercises.** Continuation of place-and-hold exercises but with gradually increasing tension.
- **Active ROM.** Continuation or initiation of active composite flexion and extension of the IP joints with the MP joints flexed, MP flexion/extension with the IP joints relaxed and active wrist flexion and extension with the fingers relaxed.
- **Tendon-gliding and blocking exercises.** These exercises are initiated at about 5 to 6 weeks (see Figs. 19.16 and 19.17 and the descriptions in the final section of this chapter).

**PRECAUTION:** Avoid finger extension combined with wrist extension for about 6 to 8 weeks, as this position places extreme tension on the repaired flexor tendon.

#### Exercise: Minimum Protection/Return to Function Phase

The minimum protection/return to function phase begins at approximately 8 weeks postoperatively and is characterized by gradually progressed resistance exercises to improve strength and endurance, dexterity exercises, and use of the hand for light (1 to 2 lb) functional activities. (Refer to the final section of this chapter for suggested exercises and activities.)

Use of a protective orthosis is discontinued; however, intermittent use of an orthosis may be necessary if the patient has a persistent extensor lag or flexion contracture. After primary flexor tendon repairs, most patients return to full activity by 12 weeks after surgery.

#### Exercise: Delayed Motion Approach

In instances where continuous immobilization of a repaired flexor tendon extends for 3 to 4 weeks (see Box 19.12 for indications), some degree of tendon healing and adhesion formation already has occurred by the time exercises can be initiated.

**PRECAUTION:** Despite the extended period of immobilization, at 3 to 4 weeks, the tendon repair must still be protected in a dorsal blocking orthosis and exercises must be performed in protected positions and progressed gradually.

Exercises such as passive ROM, tendon-blocking and tendon-gliding, and active ROM can be initiated when the cast is removed. Exercises used in early motion approaches are appropriate. The reader is also referred to additional resources that provide detailed exercise programs when delayed mobilization is necessary.<sup>48,112</sup>

### Outcomes

**Functional outcomes.** There is a substantial body of evidence on flexor tendon repairs, some of which is based on longitudinal clinical outcome studies.<sup>137</sup> A literature review<sup>129</sup> indicated that with the advances made in flexor tendon surgery and rehabilitation techniques over the past few decades, recovery of good or excellent function can be expected in 80% or more of patients after flexor tendon injury and repair. Two factors that have contributed considerably to a high rate of favorable outcomes are the use of improved suturing techniques that produce a strong repair site and implementation of early motion in rehabilitation programs.

There are several quantitative assessment tools used in outcome studies of tendon repair.<sup>112</sup> It is helpful to become familiar with the more frequently used assessments in order to understand the findings of studies. With some of these tools, results are reported as excellent, good, fair, and poor. For the most part, these terms are not simply subjective descriptors but rather are associated with objective measurement tools. For example, in the Strickland system,<sup>31</sup> the terms refer to a percentage of “normal” TAM (total active flexion minus deficits in active extension) of the PIP and DIP joints achieved after zone I, II, or III repairs and rehabilitation.

Some generalizations can be made about outcomes after flexor tendon repair. Findings in the literature indicate that immediate primary and delayed primary repairs (up to 10 days after injury) yield equally positive outcomes.<sup>122</sup> However, late reconstructions and multistage reconstructions, not surprisingly, result in poorer outcomes (less active and passive ROM, greater functional limitations) than primary repairs.<sup>48,98,127</sup> This is consistent with the findings that the greater the severity and number of associated injuries, the less favorable the outcomes.<sup>112</sup>

Studies dating back to the 1980s have documented that the use of 4 weeks of uninterrupted immobilization leads to a slower return of tensile strength in the repaired tendon and greater adhesion formation than the use of early mobilization.<sup>112</sup> Although extended immobilization continues to be the treatment of choice for children less than 7 to 10 years of age,<sup>54</sup> there is emerging evidence demonstrating positive results using both early active and early passive motion protocols depending on the child’s developmental maturity and caregiver support.<sup>94,106,141</sup>

Studies of various approaches to early motion (passive or active) after flexor tendon repair demonstrate superior outcomes when compared with outcomes after extended immobilization. Although the use of early motion in rehabilitation after flexor tendon repair has been well documented in the literature and is now the “norm” for treatment, there continues

to be limited evidence to definitively indicate any one protocol as superior over the others.<sup>31</sup>

The prospective randomized study by Trumble and coinvestigators<sup>140</sup> highlighted previously in this section lends further support for the use of early active motion for the management of repaired flexor tendons; however, additional research including randomized controlled trials is still needed.<sup>31</sup>

**Complications.** The most frequent early complication after surgery is rupture of the repaired tendon, and the most frequent late complication is flexion contracture or a deficit in active extension of the repaired DIP and/or PIP joints, typically as the result of tendon adhesions.<sup>51,134</sup> Overall, the rate of postoperative complications is higher in zone II repairs than in other zones.<sup>95</sup> Most ruptures usually occur around 10 days postoperatively when the repaired tendon is in its most weakened state.<sup>95</sup> A rupture may occur during strong gripping activities or as the result of encountering an unexpected high load, but it also may occur while the patient is asleep if the hand is unprotected during the first few months after surgery.

Although there is general agreement that early motion after tendon repair reduces adhesion formation, there have been concerns that initiating early active contractions (static or dynamic) of the PIP or DIP flexors, which place active tension on the newly repaired tendon, may increase the risk of tendon rupture. Overall, however, rupture rates are low and appear to be relatively equal to those seen with early passive flexion/active extension programs.<sup>51</sup> In the systematic review by Chesney<sup>31</sup> and colleagues, rupture rate was lowest in the combined Kleinert and Duran protocols (2.3%) and highest in the Kleinert protocols (7.1%); however, no statistical difference was found. Equal rupture rates (4%) have occurred in zone II tendon repairs when early passive motion and early active motion (place-and-hold) approaches to therapy were implemented.<sup>140</sup>

## Lacerated Extensor Tendons of the Hand: Surgical and Postoperative Management

### Background and Indications for Surgery

Laceration and traumatic rupture of the extensor tendons of the fingers, thumb, or wrist are often considered as being less serious than flexor tendon injury. Treatment and rehabilitation are often believed to be less intricate, less time-consuming, and associated with a more favorable prognosis than flexor tendon injuries. Experience, however, demonstrates that extensor tendon injuries can be just as complex, time-consuming, frustrating, and disappointing.<sup>39,91,119</sup> Their superficial location makes the extensor tendons vulnerable to damage when trauma occurs to the dorsum of the hand. Furthermore, extensor tendons in the digits are substantially thinner than flexor tendons, making them more prone to traumatic rupture and difficult to repair.<sup>52,105,119,130</sup>

As with the flexor surface, the extensor surface of the hand, wrist, and forearm is divided into zones (Fig. 19.14). The

dorsal surface of the fingers and wrist are divided into seven zones, and the thumb into four zones. Each of these zones is identified by specific anatomical landmarks, as noted in Box 19.15.<sup>52,56,91,105,119</sup> The odd-number zones correspond to the location of the DIP, PIP, MP, and wrist joint regions, while the even-number zones correspond to the bones. Although not depicted in Figure 19.14, the dorsal surface of the distal and middle forearm is often identified as zones VIII and IX,

**FIGURE 19.14** Extensor tendon zones; dorsal aspect of the hand and wrist.

### BOX 19.15 Extensor Tendon Zones: Anatomic Landmarks

#### Zones of the Dorsal Surfaces of the Fingers, Hand, Wrist, and Forearm

- I—DIP joint region
- II—middle phalanx
- III—PIP joint region
- IV—proximal phalanx
- V—apex of the MP joint region
- VI—dorsum of the hand
- VII—wrist region/dorsal retinaculum
- VIII and IX—distal and middle forearm

#### Zones of the Thumb

- T-I—IP joint region
- T-II—proximal phalanx
- T-III—MP joint region
- T-IV—metacarpal
- T-V—carpometacarpal joint region

respectively. The area at the CMC joint of the thumb is often identified as zone T-V.<sup>52,56,105</sup>

The extensor mechanism of the hand and wrist is complex. The structural characteristics of these mechanisms vary in each zone. Damage in one zone produces compensatory imbalances in adjacent zones. Knowledge of the anatomy and kinesiology of the extensor mechanism is basic to an understanding of how a patient's physical impairments and functional limitations occur according to the structures damaged in each zone. Box 19.16 identifies key structures and characteristic impairments associated with tendon rupture or laceration by zone.<sup>52,91,119,126,130</sup> Of all the extensor zones, injuries in zones III and VII pose the greatest surgical and rehabilitative challenges due to the complexity of the underlying structures in that area and the potential for residual functional loss or deformity. However, injuries in zone V are by far the most common. Injuries to zone V frequently happen as a result of a punch to another's mouth, called a *fight bite*. With these cases, there is a high risk of infection and they usually become septic. This requires surgical debridement and intravenous antibiotics, in addition to the repair of the tendon.<sup>91,130</sup> Other injuries also occur in zone V, including blunt trauma, which can cause rupture to the sagittal bands. Acute injuries in zone V can be treated by an MP extension orthosis for 6 weeks or the sagittal band bridge orthosis (similar to the "relative extension" orthosis described by Howell and associates), which places the MP of the involved finger in relative hyperextension as compared to the adjacent fingers (25° to 35°) and is worn for 8 weeks. However, chronic injuries in zone V are treated with primary repair rather than sagittal band reconstruction.<sup>56,67,68,91,130</sup>

Depending on the type and location of injury to the extensor mechanism and the extent of associated skeletal, joint, vascular, or nerve damage, surgery may or may not be

indicated. The tendons of the extensor system distal to the dorsum of the hand have many soft tissue attachments along various structures, making extensor tendons far less likely to retract when lacerated or ruptured than flexor tendons.<sup>105</sup> Consequently, with a rupture (closed injury) or a simple laceration in zones I to III, the tendon is re-opposed and managed by uninterrupted immobilization in an orthosis for 6 to 8 weeks as it heals.<sup>39,52,119,126,130</sup> For example, this is a common course of treatment for a *mallet finger* (or thumb) deformity, which is a closed rupture of the terminal extensor tendon in zone I, usually from forceful hyperflexion.<sup>39,52,105,119,126,130</sup>

Nevertheless, surgical intervention, even for a simple distal tendon injury, may be necessary to restore active ROM, muscular balance, strength, and function to the hand and prevent contractures and deformity. Although the extensor muscles of the digits are substantially weaker than the flexors, an intact extensor mechanism is essential for functional grasp and release.<sup>119</sup>

## Procedures

### Types of Repairs and Reconstruction

Surgical options for extensor tendon repair include a direct (end-to-end) repair or a reconstruction. As with flexor tendon repair or reconstruction, surgeries are classified as primary (immediate repair or delayed up to 10 days), secondary repair, or reconstruction, which may involve a tendon lengthening, tendon grafts (for larger defects that cannot be addressed by tendon lengthening procedures), or tendon transfers.<sup>119,126,130</sup> These terms already have been defined in the previous section of this chapter on flexor tendon repair and rehabilitation. Operative procedures, such as tendon transfers, for ruptured, diseased extensor tendons associated with RA also were described earlier in the chapter.

### BOX 19.16 Consequences of Injury to the Dorsal Structures of the Hand and Wrist

- **Zones I and II.** Damage to the terminal extensor leads to inability to actively extend the DIP joint (extensor lag) and eventual DIP flexion contracture and deformity (mallet finger). A swan-neck deformity secondary to an unopposed central slip and migration of the extensor mechanisms proximally may also develop. Damage in those zones is usually the result of a closed rupture rather than a laceration.
- **Zones III and IV.** Damage to the central slip and possibly the lateral bands results in an inability to actively extend the PIP joint from a 90° flexed position. Flexion contracture of the PIP joint and eventually a boutonnière deformity develop as the lateral bands slip volarly and cause hyperextension of the DIP joint.
- **Zone V.** Damage to the common extensor tendons (ED), extensor indicis (EI), extensor digiti minimi (EDM), and sagittal bands that surround the MP joints causes inability to actively extend the MP joints, eventually resulting in MP flexion contractures.
- **Zones VI and VII.** The juncturae tendinum along the dorsum of the hand (VI) and the dorsal retinaculum (VII) under which multiple extensor tendons of the wrist and digits pass in close proximity can be damaged. A bowstring effect occurs in the extensor tendons if the retinaculum, which acts as a pulley, is lacerated. The synovial sheath through which the tendons glide in zone VII can also be damaged, subsequently compromising synovial diffusion and nutrition to the tendons. Injuries in zones VI and VII can result in loss of extension of the digits and wrist.
- **T-I and T-II.** Damage to the EPL and possibly the EPB (if laceration is in the proximal region of the proximal phalanx) leads to loss of hyperextension of the IP joint (mallet thumb deformity) and weakened MP extension.
- **T-III and T-IV.** Damage to EPB leads to weakened MP extension and transfers extension forces to IP joint, leading to a flexion deformity of the MP joint and a hyperextension deformity of the IP joint if the EPL is intact.

### Operative Overview

Although similar definitions exist for extensor and flexor tendon procedures, there are substantial differences in operative techniques used to repair extensor versus flexor tendons. These differences are based largely on the fact that extensor tendons are morphologically thinner and flatter than flexor tendons. This fact led to the belief that extensor tendon repairs are more prone to gapping, have less tensile strength, and are more likely to rupture than flexor tendons after repair. However, stronger suturing techniques, specifically designed for extensor tendon repair and reconstruction, are used more frequently today, allowing early postoperative mobilization of the repaired tendon while lessening concerns of gapping and rupture.<sup>52,91,119,126</sup>

**Zone III primary repair.** Operative procedures for repair of lacerated or ruptured extensor tendons vary significantly in the distal versus the proximal zones. In this overview, only repair of a zone III laceration is described, simply as an example. Detailed descriptions of operative techniques for primary repair and late reconstruction of extensor tendons in all zones of the hand, wrist, and forearm can be found in several sources.<sup>16,52,91,105,126,130</sup>

Closed or open injury to the extensor mechanism over the PIP joint in zone III may injure the central slip, the lateral bands, or both. This can result in a PIP joint extensor lag and DIP joint hyperextension, called a boutonniere deformity. The cause of a closed boutonniere deformity involves blunt trauma to the dorsum of the PIP joint and volar dislocation that results in an avulsion of the central slip, with or without a piece of bone. Treatment for acute central slip injuries in zone III, includes using an orthosis in full PIP extension for 6 weeks in order to allow the central slip to heal, during which time active DIP flexion exercises are done hourly in order to draw the lateral bands dorsally. After the initial 6 weeks, a night orthosis is used for an additional 4 to 6 weeks.<sup>52,133</sup> For open injuries to zone III, the central slip is repaired, and if the central slip is not robust enough for a direct repair, a suture anchor can be used to the middle phalanx to facilitate tendon-to-bone fixation.<sup>52,133</sup>

If damaged, the lateral bands are repaired. If a boutonniere deformity is evident or likely to develop, a K-wire may be inserted to immobilize the PIP joint in extension for about 3 weeks and then removed. After closure of the area, a bulky compression dressing immobilizes the repaired tissues and controls edema.<sup>52,57,133</sup>

### Postoperative Management

**General considerations.** The overall goal of postoperative rehabilitation after extensor tendon injury and repair is the same as after flexor tendon repair—that is, to restore mobility and strength to the hand and wrist for functional activities. Adhesion formation is a concern in the extensor tendons after repair, just as it is after repair of the flexor tendons. As noted previously, extensor tendons of the fingers are less likely to retract after laceration or rupture because of the extensor mechanism's multiple soft tissue linkages to surrounding structures.

However, these attachments make extensor tendons prone to adhesion formation and loss of excursion during the healing process.<sup>91,105,119</sup> As with management after flexor tendon repair, emphasis after extensor tendon repair is placed on preventing adhesions that restrict tendon gliding, limit joint ROM, and functional use of the hand. (Refer to Box 19.10 to review factors that contribute to adhesion formation.)

The components and progression of postoperative rehabilitation and eventual outcomes after extensor tendon repair are influenced by many of the same factors that influence rehabilitation and outcomes of flexor tendon repair, including the location (level) and severity of the injury; the specifics of the surgical procedure(s), particularly the type of suturing technique and strength of the repair; and the timing of and the patient's access and commitment to a supervised rehabilitation program with an experienced hand therapist.<sup>39,56,57,91,119</sup>

**Approaches to postoperative management.** Two general approaches to rehabilitation after surgical repair of extensor tendon injuries are described in the literature: prolonged, uninterrupted immobilization with motion of the injured region(s) delayed for 3 to 6 weeks or, in carefully selected patients, early controlled passive or active motion initiated during the first few postoperative days. The latter is based on the same rationale as for early mobilization of flexor tendon repairs (see Box 19.11).

There are situations when an extended immobilization/delayed motion approach is the only appropriate method of management (see Box 19.12). Some studies continue to show that in many instances this traditional approach yields acceptable results in certain cases.<sup>39,56</sup> However, some studies have shown that extensor tendon repairs, managed with prolonged immobilization, are more likely to develop adhesions, resulting in only marginal outcomes (increased incidence of extensor lag, joint contracture, and boutonniere deformity). In addition, these and other studies have demonstrated that early motion programs after *primary* repair of acute extensor tendon injuries in zones III and VII are effective and safe<sup>25,56,57,130</sup> and produce superior outcomes compared with prolonged immobilization/delayed motion programs.<sup>39,56</sup> Consequently, early motion approaches have become more widely used in recent years.

It should be noted, however, that prolonged immobilization continues to be the most frequently selected method of treating zone I and II extensor tendon injuries.<sup>39,56,57,119,126,130</sup> Late reconstruction, which is more complex and usually involves tendon grafts, also is managed in most cases with continuous, extended immobilization and delayed motion.<sup>126</sup>

### Immobilization

Immobilization typically is maintained with a volar (palmar) orthosis after the bulky surgical dressing is removed a few days postoperatively. The duration of immobilization, the type(s) of immobilization selected, the joints immobilized, and the position of immobilization are based on the location (zone) of the injury and repair and the structures involved.

**Duration of immobilization.** If a patient is a good candidate for an early motion program, the duration of uninterrupted immobilization often is just a few days. If delayed motion is a more appropriate course of action, uninterrupted immobilization ranges from 3 to 6 weeks. In early motion programs, some type of a protective orthosis is used during exercise for about 6 weeks after surgery.

**Types of immobilization.** Either static or dynamic orthoses or a combination of both is used. Depending on the joints immobilized, a forearm and wrist-based or a hand-based orthosis is indicated to block excessive flexion at the region of the repair and prevent stretching of the repaired tendon(s). A static orthosis is considered a low-profile orthosis, whereas a dynamic orthosis (see Fig. 19.10) with its outrigger secured to the dorsal surface of the orthosis for the elastic band and sling attachments is a high-profile orthosis. The slings and elastic band attachments hold the digits in extension at rest but allow active flexion.

For a delayed motion program, a static volar or a removable circumferential orthosis is fabricated and worn on a continuous basis (other than daily skin care). A dynamic orthosis, worn during the day for frequent exercise sessions, is an integral component of many early motion programs, but a static orthosis must be worn at night to protect the repair. Some early active motion programs use only static orthoses that allow active motion when the straps are loosened but otherwise prevent excessive motion of joints. Special static orthoses for the repaired digits are fabricated and used only during short-arc exercises to limit the range of allowable motion (see Fig. 19.15).<sup>56,83</sup>

The joints are immobilized in an extended position or a position that places only minimal tension on the tendon to protect the repair from excessive stretch and potential gapping. As examples, for a zone I or II repair, the DIP is placed in hyperextension, for a zone III/IV repair, the PIP and sometimes the DIP joints are placed in extension, but for a zone V/VI repair, the wrist is held in 30° of extension and the MP joints in 30° to 45° of flexion. Recommended positions of the joints proximal or distal to the injured zone vary considerably. Several resources provide detailed information on immobilization and use of orthoses after extensor tendon repairs.<sup>30,39,56,83</sup>

### Exercise: Early Controlled Active Motion Approach

As interest in the application of early active motion after tendon repair has grown, so have the number of studies describing details of exercise programs and outcomes. In addition to one example of an early active motion program for zone III/IV repairs presented in this section, guidelines for early mobilization of zones V, VI, and VII also have been proposed and detailed in the literature.<sup>27,30,56,57,67,83,93</sup>

### CLINICAL TIP

The distinguishing feature common to all early active motion programs following extensor tendon repair is that low-intensity and controlled active contractions of the repaired

muscle-tendon units are initiated during the first few postoperative days, albeit in the confines of some type of static volar orthosis.

As noted previously, extensor tendon repairs in zones III and IV are especially prone to adhesion formation because of multiple soft tissue attachments of the extensor mechanism to surrounding structures and the broad bone-tendon interface of the proximal phalanx along which the extensor mechanism must glide.<sup>56,57,105,119</sup> Evans<sup>56,57</sup> proposed an early motion program of using orthoses and exercise for repairs of the central slip that involves minimal active tension of the repaired extensors for controlled SAM of the PIP and DIP joints.

### FOCUS ON EVIDENCE

Evans<sup>56</sup> compared the results of a prolonged immobilization/delayed motion program and an early SAM program in 55 patients who had undergone primary repair of 64 fingers for injury of the central slip. Patients in one group (36 digits) were managed with 3 to 6 weeks (mean 32.9 days) of continuous immobilization, whereas patients in the early motion group (28 digits) began active motion in a protected range at 2 to 11 days (mean 4.59 days) after surgery. After 6 weeks of treatment, patients in the delayed motion group had significantly less PIP flexion (44°) than the early motion group (88°). At discharge, the delayed motion group continued to have significantly less PIP flexion (72° after 76 days) than the early motion group (88° at 51 days). In addition, at discharge, the delayed motion group had significantly less DIP flexion than the early motion group (37.6° and 45.0°, respectively). It also is interesting to note that at discharge, the delayed motion group compared to the early motion group had significantly greater PIP extensor lag (8.1° and 2.9°, respectively). However, at the initiation of treatment, the delayed motion group had a 13° PIP extensor lag, whereas the early motion group had only a 3° lag.

Key elements of the early, short-arc, active motion program for central slip repairs include the following orthosis and exercise procedures:<sup>30,56,57,83</sup>

**Use of customized static volar orthoses.** Several types of customized orthoses are used with this approach. A static, hand-based volar orthosis is fabricated and applied as soon as the surgical dressing is removed. It holds only the PIP and DIP joints in 0° extension; the wrist and MP joints are free. This orthosis is removed for exercise on an hourly basis during the day but replaced between exercise sessions.

- A forearm-based resting orthosis is worn at night for protection for at least 6 weeks postoperatively.
- Two static, volar, finger-based, template orthoses are fabricated and worn only during exercise to limit joint motion,

extensor tendon excursion, and the level of stress on the repaired central slip. One orthosis is molded to limit PIP flexion to 30° and DIP flexion to 20° or 25° during exercise. A second template orthosis is fabricated to hold the PIP joint in full extension during isolated DIP flexion limited to 30° to 35° (Fig. 19.15).

- The PIP exercise orthosis is revised during the second week of exercise to allow 40° of flexion if no extensor lag is present. The PIP flexion allowed by the orthosis is increased incrementally by 10° each week thereafter.

**Exercise progression.** The patient is taught the concept of minimum active tension (MAT) to protect healing tissues during tendon excursion. MAT is just enough tension generated during an active muscle contraction to overcome the elastic resistance of an antagonist.<sup>56</sup>

- Exercises are initiated within the first few postoperative days and performed hourly during the day. While actively holding the wrist in 30° of flexion and manually stabilizing the MP joint in neutral to slight flexion, the patient performs active PIP and DIP flexion within the limits allowed by the PIP exercise orthosis (Fig. 19.15 A), followed by full active extension held for several seconds (Fig. 19.15 B).
- The patient also performs active, isolated DIP flexion/extension in the second volar template orthosis that stabilizes the PIP joint in full extension.
- Exercises continue regularly during the day for several weeks using revised exercise orthoses. Ideally, by the end of 4 weeks, the patient achieves 70° to 80° of active flexion and full extension of the PIP joint.
- Composite MP, PIP, and DIP flexion (full fist) is postponed for at least 4 weeks or when the exercise orthoses have been discontinued.
- By 6 to 8 weeks, low-intensity resisted exercises are initiated along with gradual use of the hand for functional activities.

#### Exercise: Delayed Mobilization Approach

If a traditional approach to postoperative management of extensor tendon repairs is used, exercises are delayed for at least several weeks after surgery. Special considerations and

precautions for exercise using a delayed motion approach are summarized by zones in Box 19.17.<sup>30,56</sup>

Guidelines for resistance exercises to strengthen the hand and continuation or modification of an orthosis for protection are not addressed in this summary. In general, an orthosis is continued during the day if an extensor lag persists and at night for protection for about 12 weeks. If grasp is limited because of insufficient finger flexion, passive stretching is initiated, or a dynamic flexor orthosis may be incorporated into the program by alternating the flexion and extension orthoses.

Resistance to the repaired muscle-tendon unit is not initiated until 8 to 12 weeks postoperatively regardless of the site of the repair. First, emphasis is placed on gradually strengthening the extensors to prevent or minimize an extensor lag. After 10 to 12 weeks, *low-intensity* resisted grasp and pinch activities are initiated to gradually strengthen the flexors if no extensor lag is present.

#### Outcomes

Outcomes, including complications, after extensor tendon repair and postoperative rehabilitation are well documented in the literature. Early and late complications are similar to those occurring after flexor tendon repair, including rupture, adhesion formation, and limited motion. Outcomes typically measured and reported after extensor tendon repair are ROM of the wrist and/or digits and grip strength with only limited information reported on use of the hand for functional activities.

Digital motion often is expressed in terms of “pad-to-palm” distances or TAM (active flexion minus extensor lag). These figures are then compared to the contralateral hand or to the “normal” population and are typically expressed as excellent, good, fair, or poor. For example, if ROM is only 75% of that found in normal individuals or if there is < 15° of extensor lag in a digit and sufficient digital flexion to touch the pad of the distal phalanx to the mid-palm, the result is described as “good.” To understand the results of studies on tendon repair, it is necessary to have some understanding of the various assessment tools.

**FIGURE 19.15** One of two static volar template orthoses used during early short-arc exercises of the PIP and DIP joints after repair of the extensor mechanism in zones III/IV. During exercise, the patient actively holds the wrist in approximately 30° of flexion and manually holds the MP joint in neutral to slight flexion. **(A)** Using minimal active tension during combined active PIP and DIP flexion, the orthosis initially limits PIP and DIP flexion to 30° and 20° to 25°, respectively, to prevent excessive stretch of the repair site. **(B)** The patient actively and slowly extends the PIP and DIP joints to full extension and briefly holds the extended position.

### BOX 19.17 Special Considerations for Exercise After Extensor Tendon Repair and Extended Immobilization

#### Zones I and II

- Tendon injuries in these zones are typically managed nonoperatively.
- PIP and MP AROM while the DIP is continuously immobilized in extension for at least 4 weeks but more often 6 to 8 weeks.
- When orthosis can be removed for exercise, perform active DIP extension and very gentle active flexion with the MP and PIP joints stabilized in neutral. Briefly hold the extended position with each repetition.
- Emphasize active extension more than flexion to avoid an extensor lag.
- After initiating exercises, use an orthosis between exercise sessions an additional 2 weeks or longer if an extensor lag develops.

**PRECAUTION:** Increase active flexion of the DIP joint *very gradually*, initially limiting flexion to 20° to 25° during the first week of exercise. The strong FDP can easily place excessive stress on the terminal extensor tendon and cause gapping or rupture of the repair. Progress active flexion by about 10° per week. Do not attempt full DIP flexion for about 3 months.

#### Zones III and IV

- If the lateral bands were intact, begin DIP AROM 1 week postoperatively while the PIP joint is immobilized in extension in a volar orthosis or cylinder cast. Early DIP motion prevents adherence and loss of extensibility of the lateral bands and oblique retinacular ligaments and loss of mobility of the DIP joint.
- If the lateral bands were damaged and repaired, postpone DIP ROM until 4 to 6 weeks postoperatively.
- At a minimum of 3 to 4 weeks but more often at 6 weeks, the volar orthosis is removed for active ROM of the PIP joints with the MP joints stabilized. Emphasize active extension more than flexion.

**PRECAUTIONS:** Progress PIP flexion in *very gradual* increments; limit PIP flexion to 30° the first week of PIP ROM exercises. Increase an additional 10° per week if no extensor lag.

- If the wrist and MP joints have been immobilized postoperatively, include active ROM of the wrist with the MP and PIP joints stabilized and active MP ROM with the wrist and PIP joints stabilized in extension.

#### Zones V and VI

- When the volar orthosis can be removed for exercise (between 3 and 4 weeks or as late as 6 weeks postoperatively), begin active or assisted MP extension and passive flexion with the wrist and IP joints stabilized in neutral and the forearm *pronated*. Actively hold the extended position for a few seconds with each repetition. Let the extensors relax to flex the MP joints.
- Add carefully controlled active MP flexion within a protected range with the wrist stabilized in extension.
- Emphasize active MP extension more than flexion to prevent an extensor lag.

**PRECAUTION:** Initially limit active MP flexion to 30° in the index and middle fingers and 35° to 40° in the ring and small fingers.

- During active IP flexion and extension exercises, stabilize the MP joints in neutral and the wrist in slight extension. Encourage full-range DIP motion.
- Combine active MP extension with active PIP flexion (hook fist position) and PIP extension (straight hand position).
- Incrementally progress to full fist position over several weeks if no extensor lag develops.

#### Zone VII

- If the wrist extensors are intact and only extrinsic finger extensors have been repaired follow the guidelines for zone V/VI repairs.
- If the wrist extensors were repaired, begin active wrist extension from neutral to full extension in a gravity-eliminated position (forearm in mid-position) at 3 to 4 weeks.
- Incrementally increase wrist flexion beyond neutral between 5 and 8 weeks postoperatively.
- Perform radial and ulnar deviation with the wrist in neutral.

Some generalizations about outcomes can be drawn from the literature regarding the severity and location of the injury. As with flexor tendon injuries, the greater the extent of associated skeletal, joint, vascular, or nerve injuries, the poorer are the results of the repair with respect to extensor lag and digital flexion for grasp. For example, in a study of outcomes after extended immobilization following extensor tendon repair, 64% of patients with simple tendon injuries had good results, whereas only 47% of patients with associated skeletal or joint injuries had good results.<sup>105</sup> In the same study, investigators found that repairs of distal injuries (zones I to IV) had less

favorable results than repairs of more proximal injuries (zones V to VIII).

Outcomes of the various approaches to postoperative management of extensor tendon injuries are reported in the literature on an ongoing basis. With regard to the timing of the surgical intervention, for example, primary repairs of acute injuries (rupture or laceration), whether repaired immediately or delayed for up to 10 days, yield equally good results.<sup>119</sup> As noted throughout this section on extensor tendon injury and repair, numerous studies have been published describing outcomes of the various

approaches to postoperative management. Although some studies support the use and effectiveness of prolonged immobilization of extensor tendon repairs, there is growing use and ongoing modification and refinement of early controlled motion approaches to help patients achieve the best possible outcomes.

For example, a dynamic extension orthosis, a mainstay of early passive mobilization protocols for more than 20 years, now is being re-evaluated. Although some studies<sup>25,120</sup> have demonstrated that high-profile, dynamic orthoses continue to be used and are effective, other studies reflect a return to the use of low-profile, static orthoses if coupled with early active motion.<sup>56,93</sup>

In a prospective, randomized, controlled trial, Kitis<sup>74</sup> and associates compared static and dynamic orthosis management of extensor tendon repairs in zones V to VII. Between January 2009 and June 2011, they compared the results of patients randomized into a static group (n = 25) or a dynamic group (n = 27). All patients underwent extensor tendon repair within 24 hours using Kessler's method using a two-strand core suture of 4.0 nylon and a circumferential running suture of 6.0 nylon. Following surgery, the patients were seen in the clinic 3 to 5 days postoperatively. Twenty-five patients with 39 fingers were treated with controlled movement with a volar static orthosis (wrist in 30°-35° extension and MP joints in 45° of flexion with the orthosis extending distally to the middle of the proximal phalanx), and 27 patients with 44 fingers were treated with a dynamic orthosis. Those in the static group were allowed to actively flex and extend their IP joints within the limits of the orthosis. Active motion of the wrist was initiated after 3 weeks with gravity eliminated, followed by extension of the MPs, followed by full extension of the IPs. Exercises were performed 10 times each waking hour. At 4 weeks, the orthosis was removed and wrist AROM was initiated against gravity. At 6 weeks, the patients were allowed to use the involved hand for light ADLs, and at 8 weeks, gradual resistance was initiated. The dynamic group was placed in an extension orthosis positioned dorsally, which allowed full IP motion and 30° of active MP flexion with passive rubber band extension. The patients were instructed to actively flex the MP joints to 30° as permitted by the orthosis 10 times every waking hour. At 4 weeks, the dynamic group was allowed active MP and IP extension, and the dynamic orthosis was discontinued except at night. At 5 weeks, active wrist flexion and extension was allowed, as well as a full active fist. Between 8 to 12 weeks, the dynamic group progressed to resistive exercises and was allowed to perform normal hand activities. Outcome measures included the measurement of TAM, grip strength, and the DASH questionnaire, which were measured in both groups at 4 weeks, 12 weeks, and 6 months postoperatively. The authors reported no ruptures in either group and concluded that the use of dynamic orthoses for extensor tendon lacerations in zones V to VII provides improved functional outcomes when compared with the use of static orthoses.

## Exercise Interventions for the Wrist and Hand

### Techniques for Musculotendinous Mobility

Active muscle contraction and specific motions of the digits and wrist are used to maintain or develop mobility between the multijoint musculotendinous units and other connective tissue structures in the wrist and hand. Because adhesions between the various structures can become restrictive or incapacitating, *tendon-gliding exercises* and *tendon-blocking exercises* are used whenever possible to develop or maintain mobility. This is particularly important when there has been immobilization after trauma, surgery, or fracture and scar tissue adhesions have developed. If restrictions occur as a result of scar tissue adherence between tendons or between tendons and surrounding tissues, mobilization techniques described in this section may be necessary. General stretching techniques also may be necessary; they are described in the next section. The tendon-gliding and tendon-blocking exercises described here may also be used to develop neuromuscular control and coordinated movement.

### Tendon-Gliding and Tendon-Blocking Exercises

#### Place-and-Hold Exercises

Place-and-hold exercises are a form of gentle muscle setting (static/isometric) exercises that are used during the early postoperative period following tendon repair before active ROM is initiated but when a minimal level of stress on the repaired tendon and passive joint movement are beneficial for maintaining joint mobility and tendon excursion.

- Following flexor tendon repair, the patient usually wears a dorsal blocking orthosis<sup>39,55,56,57</sup> or a tenodesis orthosis.<sup>29,112,134</sup> With the MP joints in flexion, passively place the IP joints in a partially flexed position and have the patient hold the position independently for 5 seconds with a minimum static contraction of the finger flexors.
- If the patient is wearing a tenodesis orthosis, combine place-and-hold finger flexion with active wrist extension (see Fig. 19.13 B and C). Have the patient relax and allow the wrist to passively flex and the digits to passively extend.
- Following extensor tendon repair, when the volar blocking orthosis may be removed for exercise, passively position the joint in the zone of the repair first in a neutral and later in a slightly extended position utilizing the sagittal band bridge or relative extension orthoses. Have the patient hold the position for 5 to 10 seconds. This emphasizes end-range extension to prevent an extensor lag.

- Have the patient practice the exercise with the uninjured hand or use biofeedback to learn how to hold the position with a minimum of force production.

### Flexor Tendon-Gliding Exercises

Flexor tendon-gliding exercises are designed to maintain or develop free gliding between the FDP and FDS tendons and between the tendons and bones in the wrist, hand, and fingers.<sup>112</sup> There are five positions in which the fingers move during tendon-gliding exercises: straight hand (all the joints are extended); hook fist (MP joints are extended, IP joints are flexed); full fist (all the joints are flexed); table-top position, also known as the intrinsic plus hand (MP joints are flexed, IP joints are extended); and straight fist (MP and PIP joints are flexed, DIP joints are extended) (Fig. 19.16). The following progression is suggested:

- Initiate the exercises with the wrist in neutral position.
- Once full range of the finger motions is achieved, progress to doing the gliding exercises with the wrist in flexion and in extension to establish combined finger and wrist mobility.
- Full excursion and tendon-gliding of all the extrinsic muscles are accomplished by starting with the wrist and fingers in full extension, then moving to full wrist and finger flexion, and then reversing the motion.

**FIGURE 19.16** The five finger positions used for flexor tendon-gliding exercises: (A) straight hand, (B) hook fist, (C) full fist, (D) table top (intrinsic plus), and (E) straight fist.

**Hook-fist position.** Have the patient move from the straight hand to the hook-fist position by flexing the DIP and PIP joints while maintaining MP extension (Fig. 19.16 A and B). Maximum gliding occurs between the profundus and superficialis tendons and between the profundus tendon and the bone. (There is also gliding of the extensor digitorum tendons; this motion is used with the extensor gliding exercises.)

**Full fist.** Have the patient move to the full fist position by flexing all the MP and IP joints simultaneously (Fig. 19.16 C). Maximum gliding of the profundus tendon with respect to the sheath and bone as well as over the superficialis tendon occurs.

**Straight fist.** Have the patient move from the table-top position (Fig. 19.16 D) to the straight fist position by flexing the PIP joints while maintaining the DIP joints in extension (Fig. 19.16 E). Maximum gliding of the superficialis tendon occurs with respect to the flexor sheath and bone.

**Thumb flexion.** Have the patient flex the MP and IP joints of the thumb full range. This promotes maximum gliding of the flexor pollicis longus.

### Flexor Tendon-Blocking Exercises

Blocking exercises for the flexor tendons (Fig. 19.17) not only develop gliding of the tendons with respect to the sheaths and related bones; they also require neuromuscular control of individual joint motions. Therefore, they use the mobility gained by the flexor tendon-gliding exercises and are a progression of the flexor tendon-gliding exercises. Progress to manual resistance as the tissues heal and can tolerate resistance.

**FIGURE 19.17** Flexor tendon blocking exercises: (A) isolated MP flexion of one digit, (B) isolated PIP flexion (flexor digitorum superficialis) of one digit, and (C) isolated DIP flexion (flexor digitorum profundus) of one digit.

**PRECAUTION:** These exercises should not be used in the early stages of flexor tendon healing after repair because of the stress placed on the tendons.

**Patient position and stabilization:** Sitting with the forearm supinated and the back of the hand resting on a table. The opposite hand provides stabilization and “blocking” against unwanted movement. Each finger performs the exercise separately.

**Isolated MP flexion (lumbricals and palmar interossei).** With the patient's hand stabilized, have the patient flex only the MP joint of one digit (Fig. 19.17 A). If necessary, stabilize the rest of the fingers in extension against the table with the other hand. With improved control, the hand does not have to be stabilized against the table.

**PIP flexion (flexor digitorum superficialis).** Have the patient stabilize the proximal phalanx of one digit with the opposite hand and, if possible, flex just the PIP joint of the one digit while keeping the DIP joint extended and the rest of fingers on the table (Fig. 19.17 B).

If the patient has difficulty doing this, stabilize the other digits in extension with the opposite hand.

**DIP flexion (flexor digitorum profundus).** Have the patient attempt to flex just the distal phalanx (Fig. 19.17 C). Stabilize the middle phalanx of one digit with the other hand. Vary this exercise by increasing the range of MP and PIP flexion to the point at which the patient just begins to lose DIP motion; stabilize in this position and have the patient attempt DIP flexion.

**Full fist.** When full independent tendon-gliding is available, the patient should be able to make a full fist. Progress the exercises described by adding resistance.

### Exercises to Reduce an Extensor Lag

The extrinsic finger extensors (extensor digitorum, extensor indicis, and extensor digiti minimi) are more superficial than the flexor tendons and therefore more easily damaged. Their prime function is to extend the MP joints. Extension of the IP joints requires active interaction with the intrinsic muscles of the hand via the extensor mechanism. Adhesions within their sheaths at the wrist or between tendon and bone restrict tendon-gliding both proximally (restricting active finger extension) and distally (restricting active and passive finger flexion).

When full passive range of extension is available but the person cannot actively move the joint through the full range of extension, it is called an *extensor lag*. An extensor lag can occur as the result of weakness but is frequently caused by adhesions that prevent gliding of the tendons when the muscles contract.

One purpose of the following exercises is to maintain mobility and thus prevent adhesions. The exercises also are used to regain control of finger extension. Mobilization of adhesions is described immediately following the differential gliding of extensor tendon exercises. Stretching techniques are described in the next section.

**Isolated MP extension.** Have the patient move from the full fist position (see Fig. 19.16C) to the hook-fist position (see Fig. 19.16 B).

- If the patient has difficulty maintaining the IP joints in flexion, have him or her hook the fingers around a pencil while extending the MP joints.
- Begin with the wrist in neutral and progress to positioning the wrist in flexion and extension while performing MP extension.

**Isolated PIP and DIP extension.** Extension of the IP joints requires intrinsic and extrinsic muscle (extensor digitorum) control.

- For strongest participation of the lumbricals, stabilize the MP joint in flexion while the patient attempts IP extension, moving from the full fist position (see Fig. 19.16 C) to the table-top position (see Fig. 19.16 D).
- Progress to stabilizing the palm of the hand on the edge of a table (or block) with the PIP or DIP joint partially flexed over the edge.
- Have the patient extend the involved phalanx through the ROM.

**Terminal-range extension of IP joints.** Progress to the terminal range by stabilizing the entire hand, palm side down on a flat surface, and have the patient extend the involved phalanx into hyperextension. If there is not enough range available, place a pencil or block under the proximal phalanx or middle phalanx so the PIP or DIP joint can go through a greater range (Fig. 19.18).

**FIGURE 19.18** Terminal extension of the PIP joint. The MP joint is stabilized in extension, and the patient lifts the middle and distal phalanges off the table.

### Extensor Tendon-Gliding Exercises

Differential gliding of the extensor digitorum tendons to each of the fingers can be achieved by the following progression.

- Teach the patient to passively flex the MP and IP joints of one finger with the opposite hand while actively maintaining the other fingers in extension.
- If the patient has difficulty doing this, begin with the involved hand resting on a table with the palm up. Stabilize three of the four fingers against the table while passively flexing one of the digits (Fig. 19.19). Then instruct the patient to attempt to actively keep the fingers against the table while one of the digits is passively flexed.
- Progress by having the patient actively maintain the fingers in extension with the fingers spread out and then actively flex each finger in turn while the other fingers remain extended.
- Have the patient flex the middle and ring fingers while maintaining extension of the index and little fingers (long horn sign). This promotes isolated control of the extensor indicis and extensor digiti minimi tendons and promotes their gliding on the extensor digitorum tendons.

**FIGURE 19.19** Differential gliding of the extensor digitorum tendons. Move each digit into flexion while stabilizing the other digits in extension.

## Scar Tissue Mobilization for Tendon Adhesions

Ideally, the tendon-gliding exercises described previously in this section maintain or develop mobility between the long tendons and surrounding connective tissues or within their sheaths. However, when there has been inflammation and immobilization during the healing process following trauma or surgery, scar tissue adhesions may form and prevent gliding of the tendons. Contraction of the muscle does not result in movement of the joint or joints distal to the site of the immobile scar.

Techniques to mobilize the adhesive scar tissue include the application of friction massage directly to the adhesion. This is superimposed on active and passive stretching techniques (described in the next section) and the tendon-gliding techniques already described. To apply friction massage, hold the tendon in its lengthened position; apply pressure with your thumb, index, or middle finger and massage perpendicular to the tendon and longitudinally in proximal and distal directions. A sustained force against the adhesion allows for creep and eventual movement of the scar. Techniques to mobilize the flexor and extensor tendons follow.

### To Mobilize the Long Finger Flexor Tendons

Adhesions between the flexor tendons and their sheaths or between tendons and underlying bones restrict tendon-gliding in both a proximal and distal direction so the joints distal to the scar do not flex when the muscle contracts. Passive movement into flexion of the joints distal to the adherent scar is possible if there are no capsular restrictions. Full range of extension of the joints distal to the scar is not possible actively or passively owing to the inability of the tendon to glide distally.

The following is a suggested progression in intensity of scar tissue mobilization:

- Begin the stretching routine by passively moving the tendon in a distal direction by extending the finger joints as far as possible and applying a sustained hold to allow for creep. Follow this with active contraction of the flexor muscle to create a stretch force against the adhesion in a proximal direction using the patterns of movement described for tendon-gliding exercises (see Fig. 19.16).

- If active and passive stretching, described in the above technique, does not release the adhesion, extend the MP and IP joints as far as allowed, stabilize them, and apply friction massage with your thumb or finger at the site of the adhesion while the tendon is held in its stretched position. Apply the massaging stretch force across the tendon and in a longitudinal direction, both proximally and distally. When applying friction massage in a proximal direction, ask the patient to simultaneously contract the flexor muscle in order to superimpose an active stretch force.
- After friction massage, have the patient repeat the flexor tendon-gliding exercises to utilize any gained mobility.

### To Mobilize the Extensor Tendons and the Extensor Mechanism

If the extensor tendons or extensor mechanism has restricted mobility because of adhesions, muscle action is not transmitted through the mechanism to extend the joint or joints distal to the restriction. Without free gliding, an extensor lag may result. As defined earlier, an extensor lag is the loss of active extension when there is full passive extension. The following is a progression in intensity of scar tissue mobilization:

- Stretch the adhesion in a distal direction by passively flexing the joint distal to the site. Follow this by having the patient attempt to actively extend the joint and put tension on the scar in a proximal direction.

**PRECAUTION:** If the extensor lag increases (i.e., flexion increases, but there is no active extension through the increased range), the tendon distal to the adhesion, rather than the adhesion, may be stretching. Do not continue with passive stretching into flexion, but rather emphasize friction massage applied to the scar tissue.

- Apply friction massage at the site of the adhesion with the tendon kept taut by holding the joint at the end of its range of flexion. Apply friction massage across the fibers and in a distal and proximal direction. When applying friction massage in a proximal direction, have the patient actively contract the extensors to assist with the mobilization effort.
- Follow these mobilization techniques with extensor tendon-gliding exercises, as described in the previous section.

## Exercise Techniques to Increase Flexibility and Range of Motion

Stretching the muscles and connective tissue structures of the wrist and hand requires knowledge of the unique anatomical relationships of the multijoint musculotendinous units and the extensor mechanism of the digits. These are described in the first section of this chapter. The principles

and techniques of stretching are presented in Chapter 4, and special note is made of the importance of stabilization when stretching the multijoint muscles of the hand and fingers. This is re-emphasized here. In addition, because scarring and adhesions can restrict tendon-gliding and therefore motion of the digits, it is important to recognize these restrictions and utilize specific techniques that address the adhesions as presented in the previous section. Before stretching muscle or connective tissue, there should be normal gliding of the joint surfaces to avoid joint damage. Use joint mobilization techniques to stretch the joint capsule and restore gliding (see Chapter 5).

**NOTE:** The patient position for most wrist and hand exercises is sitting with the forearm supported on a treatment table unless otherwise noted.

## General Stretching Techniques

When stretching to increase wrist flexion or extension, it is important that the fingers are free to move so the extrinsic finger flexor and extensor musculotendinous units do not restrict motion at the wrist. Similarly, when stretching ligaments and other periarticular connective tissues across individual finger joints, it is important that there is no tension on the multijoint tendons. The following techniques are initially applied by the therapist and then are taught to the patient as self-stretching techniques for a home exercise program when he or she understands how to safely apply the stretch force and stabilization.

### To Increase Wrist Extension

- Have the patient place the palm of the hand on a table with the fingers flexed over the edge. Use the other hand to stabilize the dorsal surface of the hand to maintain the palm against the table. Then have the patient move the forearm up over the stabilized hand (similar to Fig. 19.21 except the fingers are over the edge of the table so they are free to flex and the stretch occurs only at the wrist).
- Have the patient place the palms of the hands together at right angles to each other and allow the fingers to intertwine and flex. Instruct the patient to press the restricted hand in a dorsal direction with the palm of the other hand and sustain the stretch.

### To Increase Wrist Flexion

- Have the patient place the dorsal surface of the hand on a table. Use the other hand to provide stabilization against the palm of the hand. Have the patient move the forearm up over the stabilized hand.
- Have the patient sit with the forearm pronated and resting on a table and the wrist at the edge of the table. Press against the dorsal surface of the hand with the opposite hand to flex the wrist.
- Have the patient place the dorsum of both hands together. Then, with the fingers relaxed, move the forearms so the wrists flex toward 90°.

## To Increase Flexion or Extension of Individual Joints of the Fingers or Thumb

To increase extension at any one joint, begin by positioning the patient's forearm on a table in supination; to increase flexion, position the forearm in pronation. Place the phalanx to be stretched at the edge of the table. Show the patient how to apply the stretch force against the distal bone while stabilizing the proximal bone against the table.

## Stretching Techniques for the Intrinsic and Multijoint Muscles

### Self-Stretching the Lumbricals and Interossei Muscles

Have the patient actively extend the MP joints, flex the IP joints, and apply a passive stretch force at the end of the range with the opposite hand (Fig. 19.20A).

**FIGURE 19.20** Self-stretching (A) the lumbricals with MP extension and IP flexion and (B) the adductor pollicis with CMC abduction of the thumb. To increase thumb abduction, it is critical that the stretch force is applied against the metacarpal head, not the proximal or distal phalanges.

### Self-Stretching the Interossei Muscles

Have the patient place the hand flat on a table with the palm down and the MP joints extended. Instruct the patient to abduct or adduct the appropriate digit and apply the stretch force to the distal end of the proximal phalanx. Holding the adjacent digit provides stabilization.

### Self-Stretching the Adductor Pollicis

Have the patient rest the ulnar border of the hand on the table and palmarly abduct the thumb. Instruct the patient to apply the stretch force with the crossed thumb and index or long finger of the other hand against the metacarpal head of the thumb and index finger and attempt to increase the web space (Fig. 19.20 B).

**PRECAUTION:** It is critical that the patient does not apply the stretch force against the proximal or distal phalanx. This places stress on the ulnar collateral ligament of the MP joint of the thumb and can lead to instability at that joint and poor functional use of the thumb. Palmar and radial abduction occur at the CMC joint at the articulation between the metacarpal and the trapezium.

### Manual Stretching of the Extrinsic Muscles

Because they are multijoint muscles, the final step in a stretching progression is to elongate each tendon of the extrinsic muscles over all the joints simultaneously. However, do not initiate stretching procedures in this manner because joint compression and damage can occur to the smaller or less stable joints. Begin by allowing the wrist and more proximal finger joints to relax; stretch the tendon unit over the most distal joint first. Stabilize the distal joint at the end of the range, and then stretch the tendon unit over the next joint. Next, stabilize the two joints and stretch the tendon over the next joint. Progress in this manner until the desired length is reached.

**PRECAUTION:** Do not let the PIP and MP joints hyperextend as the tendons are stretched over the wrist.

### Self-Stretching the Flexor Digitorum Profundus and Superficialis

Have the patient begin by resting the palm of the involved hand on a table; then extend the DIP joint, using the other hand to straighten the joint. While keeping it extended, have the patient straighten the PIP and MP joints in succession. If the patient can actively extend the finger joints to this point, the motion should be performed unassisted. With the hand stabilized on the table, have the patient then begin to extend the wrist by bringing the arm up over the hand. The patient moves just to the point of feeling discomfort, holds the position, and then progresses as the length increases (Fig. 19.21).

**FIGURE 19.21** Self-stretching of the extrinsic finger flexor muscles, showing stabilization of the small distal joints. To isolate stretch to the wrist flexors, allow the fingers to flex over the edge of the table.

### Self-Stretching the Extensor Digitorum

The fingers are flexed to the maximum range, beginning with the most distal joint first and progressing until the wrist is

simultaneously flexed. The opposite hand applies the stretch force.

## Exercises to Develop and Improve Muscle Performance, Neuromuscular Control, and Coordinated Movement

Exercises described in this section are for use during the controlled motion and return to function phases of rehabilitation when the tissues are in the subacute and chronic stages of healing and require only moderate or minimum protection. In addition to the conditions already described in this chapter, imbalances in the length and strength of the wrist and hand muscles may be caused by nerve injury, trauma, disuse, or immobilization.

Appropriate exercises to develop fine finger dexterity or strength and muscular endurance for strong or repetitive gripping can be selected from the following exercises or their adaptations. The flexor tendon-blocking exercises and extensor tendon-gliding exercises described previously in this section may be used to strengthen the musculature by adding resistance manually or mechanically. Exercises for shoulder, elbow, and forearm strength and muscular endurance also should be included to restore proper function in the upper extremity.

### Techniques to Strengthen Muscles of the Wrist and Hand

If the musculature is weak, use progressive strengthening exercises, beginning at the level of the patient's ability. Use active-assistive, active, or manual resistance exercises as described in Chapters 3 and 6 of this text. Use mechanical resistance to progress strengthening exercises.

#### To Strengthen Wrist Musculature

Allow the fingers to relax. Exercise the wrist muscles in groups if their strength is similar. If one muscle is weaker, the wrist should be guided through the range desired to minimize the action of the stronger muscles. For example, with wrist flexion, if the flexor carpi radialis is stronger than the flexor carpi ulnaris, have the patient attempt to flex the wrist toward the ulnar side as you guide the wrist into flexion and ulnar deviation. If the muscle is strong enough to tolerate resistance, apply manual resistance over the fourth and fifth metacarpals.

**Wrist flexion (flexor carpi ulnaris and radialis) and extension (extensor carpi radialis longus and brevis and extensor carpi ulnaris).** Have the patient sit with the forearm supported on a table, grasping a weight or elastic resistance that is secured on the floor. The forearm is supinated to resist flexion or pronated to resist extension (Fig. 19.22).

**FIGURE 19.22** Mechanical resistance to strengthen wrist extension. Note that the forearm is pronated. To resist wrist flexion, the forearm is supinated.

**Wrist radial deviation (flexor and extensor carpi radialis muscles and abductor pollicis longus) and ulnar deviation (flexor and extensor carpi ulnaris muscles).** While standing, have the patient hold a bar with a weight on one end. To resist radial deviation, the weight is on the radial side of the wrist (Fig. 19.23A); to resist ulnar deviation, the weight is on the ulnar side of the wrist (Fig. 19.23 B).

**FIGURE 19.23** Mechanical resistance to strengthen (A) radial deviation and (B) ulnar deviation of the wrist using a weighted bar.

**Functional progression for the wrist.** Progress to controlled patterns of motion requiring stabilization of the wrist for functional hand activities such as repetitive gripping, picking up and releasing objects of various sizes and weights, and opening and closing the screw lid on a jar. Develop muscular endurance and progress to the desired functional pattern by

loading the upper extremity to the tolerance of the wrist stabilizers. When the stabilizers begin to fatigue, stop the activity.

### CLINICAL TIP

Functional progression of exercises for the wrist and hand should incorporate the entire upper extremity. When performing shoulder, elbow, or forearm exercises, emphasize safe wrist patterns of motion or wrist stabilization (i.e., do not let the wrist collapse into end-range flexion or extension).

### To Strengthen Weak Intrinsic Musculature

**NOTE:** Imbalance from weak intrinsic muscles leads to a claw hand.

#### MP joint flexion with IP joint extension (lumbricals).

Begin with the MP joints stabilized in flexion. Have the patient actively extend the PIP joint against resistance along the middle phalanx (the final position is table top). Increase the resistance by resisting the distal phalanx. Resistance may be applied manually or with rubber bands.

- Have the patient start with the MP joints extended and the PIP joints flexed; then actively push the fingertips outward, performing the desired combined motion (Fig. 19.24A and B). For resistance, have the patient push the fingers into the palm of the other hand (Fig. 19.24C), or push the fingers into exercise putty with the desired motion.

**FIGURE 19.24** To strengthen intrinsic muscle function for combined MP flexion and IP extension, the patient begins with (A) MP extension and IP flexion and (B) pushes his fingertips outward. The same motion is resisted by (C) pushing the fingertips against the palm of the other hand.

- Begin with all the finger joints extended. Have the patient maintain the IP joints in extension and flex the MP joints to the table-top position. Apply resistance against the proximal phalanx.

#### Isolated or combined abduction/adduction of each finger (dorsal and volar interossei).

Have the patient rest the palm of the hand on a table. Apply resistance at the distal end of the proximal phalanx, one finger at a time, for either abduction or adduction.

- For self-resisted adduction, have the patient interlace the fingers of both hands (or intertwine with your fingers)

and squeeze the fingers together or squeeze exercise putty between two adjacent fingers.

- For self-resisted abduction, place a rubber band around two digits and have the patient spread them apart.

**Palmar abduction of the thumb (*abductor pollicis brevis and longus*).** Have the patient rest the dorsum of the hand on a table. Apply resistance at the base of the first phalanx of the thumb as the patient lifts the thumb away from the palm of the hand.

- Place a rubber band or band of exercise putty around the thumb and base of the index finger and have the patient abduct the thumb against the resistance.

**Opposition of the thumb (*opponens pollicis*).** Have the patient use various prehension patterns such as tip-to-tip and tip-to-pad, with the thumb opposing each digit in succession, and pad-to-side, with the thumb approximating the lateral side of the index finger.

- Have the patient pinch exercise putty, a pliable ball, or a spring-loaded clothespin.

### To Strengthen Weak Extrinsic Muscles of the Fingers

**NOTE:** The wrist must be stabilized for the action of the extrinsic hand musculature to be effective. If wrist strength is inadequate for stabilization, manually stabilize it during exercises and use an orthosis for functional activities.

**Metacarpophalangeal extension (*extensor digitorum, indicis, and digiti minimi*).** Place the hand on a table with the palm down and digits over the edge. Place a small strap over the distal end of the proximal phalanx with a small weight hanging from it or secure an elastic band or tubing around the proximal phalanx and have the patient extend the MP joint.

**IP flexion (*flexor digitorum profundus and superficialis*).** Have the patient apply self-resistance by starting with the hands pointing in opposite directions and placing the pads of each finger of one hand against the pads of each finger of the other hand (or against your hand) and then curl the fingers against the resistance provided by the other hand (Fig. 19.25).

**FIGURE 19.25** Self-resistance to strengthen extrinsic finger flexor muscles.

### Mechanical Resistance Techniques for Combined Intrinsic and Extrinsic Muscle Function

**NOTE:** Proper stabilization is important; either the patient's stabilizing muscles must be strong enough or the weakened areas must be supported manually. If a weight causes stress because the patient cannot control it, the exercise is detrimental rather than beneficial.

**Towel or newspaper crumple.** Spread a towel out on a table. Have the patient place the palm of the hand down at one end of the towel and crumple the towel into the hand while maintaining contact with the heel of the hand. The same exercise can be carried out by placing a stack of newspapers under the hand. The patient crumples the top sheet into a ball, tosses it into a basket for coordination and skill practice, and repeats the exercise with each sheet in succession.

**Disk weight resistance.** Have the patient grasp a disk weight in the manner described in each of the following exercises:

- With the forearm pronated (palm down), pick up the disk with the tips of all five digits spread around the outer edge. Have the patient hold the position for isometric resistance. To increase the effect of the resistance to the flexors, have the patient extend one digit at a time.
- Pick up the side of the disk with either tip-to-tip or pad-to-pad prehension of thumb and fingers.
- With the hand palm down on a table, place the disk on the dorsum of the fingers; then lift the disk by hyperextending the fingers.

**Other resistance aids.** Resistive devices, such as putty, spring-loaded hand exercisers, and various grades and sizes of soft balls, can be used for specific muscles or general strengthening. Observe the pattern used by the patient and be sure he or she does not substitute or develop damaging forces.

## Dexterity and Functional Activities

### Fine-Finger Dexterity

Functional use of the hand for manipulating small objects or skillfully controlling delicate devices requires use of the thumb in opposition to the index and middle fingers. Have the patient perform activities such as picking up small objects of various sizes, twisting nuts on and off bolts, drawing, writing, tying a string or ribbon, opening and closing small bottles or boxes, and typing on a keyboard.

### Functional Activities

Progress to specific activities needed for ADLs, work, hobbies, or recreational function. For the patient to return to independent function using the hand, he or she must not only have neuromuscular control and strength, but must also have muscular endurance, coordination, and fine finger dexterity for the desired activity. This requires careful questioning and analysis of the patient's desired outcomes. Consider each of the power grips and prehension patterns and adapt the exercises to meet the goals.

## Independent Learning Activities

### Critical Thinking and Discussion

1. Review all of the power grips and prehension patterns and identify the primary muscles that function when performing each action.
2. Summarize the sensory and motor impairments, deformities, and associated activity limitations and/or participation restrictions that may occur in the wrist and hand as the result of a lesion of (1) the median nerve, (2) the radial nerve, and (3) the ulnar nerve.
3. Differentiate between a boutonnière deformity and a swan-neck deformity of the fingers. What are the underlying factors that contribute to these deformities? After surgical repair of each of these deformities, how should an exercise program be designed to increase hand function but prevent recurrence of these deformities?
4. Identify key structures by the zone in the hand and wrist that could be damaged as the result of a laceration at each zone of the dorsal and volar aspects of the hand and wrist. What functional impairments occur as the result of damage in each zone?
5. Make a case for the use of early controlled motion after surgical repair of a flexor or extensor tendon injury. Explain the key features of different approaches to the use of early motion in an exercise program. Also identify circumstances in which the use of early controlled motion would be inadvisable or not possible.
6. Analyze and summarize the similarities and differences in the components and progression of exercise programs after flexor or extensor tendon repairs using early controlled mobilization versus delayed mobilization approaches.

### Laboratory Practice

1. Mobilize each forearm, wrist, and finger joint with joint mobilization and passive stretching techniques (refer to Chapters 4 and 5).
2. Practice each tendon-gliding exercise and identify the purpose for each one.
3. Teach your partner strengthening exercises for each muscle or muscle group in the hand using resistance putty.
4. Identify three alternative resistance devices that can be used to strengthen each muscle and pattern of motion in the hand.
5. Observe someone tying laces on a shoe, identify the muscles functioning, and design an exercise program that could be used to develop neuromuscular control or strengthen each of the muscles.

### Case Studies

1. A patient is referred to you early in the development of symptoms that stem from RA. He currently is in remission

after his first serious flare of the disease and desires a home exercise program to safely improve the use of his hands. He is a sales associate who travels frequently. He keeps his records on a computer. His grip strength is reduced 50%; he has 25% loss of joint ROM and decreased joint play in the wrist, MP, and IP joints. Detectable synovial hypertrophy is minimal, and there are no joint subluxations. Consider what precautions should be followed with this disease to prevent the deforming forces of improperly applied exercises and daily forces. Establish a program of intervention for this patient.

2. A patient is referred to you 2 months after a distal radius fracture. Her hand is swollen and sensitive to touch, and she currently is developing contractures and weakness in the hand related to complex regional pain syndrome (CRPS) (see Chapter 13). Joint contractures exist in the forearm, wrist, and hand. You determine that the patient is in the second stage of the disease. Establish a plan for intervention.
3. A patient with RA who has just undergone MP implant arthroplasties of the ring and small fingers has been referred to you for an exercise program. For the past 4 weeks, the patient has been wearing a dynamic extension orthosis that allows active MP flexion and assists MP extension. The patient is now allowed to remove the orthosis for active ROM of the wrist and hand. Your examination reveals that the patient has an extensor lag and also has restricted flexion of the fingers. Design and progress an exercise program for this patient. What precautions should be incorporated into each phase of the program?
4. A patient who underwent a ligament reconstruction tendon interposition arthroplasty for posttraumatic arthritis of the CMC joint of the thumb 4 weeks ago has been referred to you. The thumb spica cast was removed at 3½ weeks postoperatively, and the patient is now wearing a thumb spica orthosis that may be removed for exercise. Develop and progress an exercise program for the patient. The patient has already returned to his or her position in an office. The patient would like to be able to resume golf on a recreational basis.
5. An 8-year-old child who sustained a zone III laceration of the volar aspect of the index and middle fingers of the nondominant hand while carving a pumpkin has been referred to you after surgical repair of the FDP and FDS tendons. The child's hand has been immobilized in a cast for 3 weeks after the repair in a position of wrist and finger flexion. The child is now wearing a dorsal blocking orthosis that may be removed for exercise. The child's active and passive extension is significantly limited. Design and progress an exercise program for this child. Identify activities that the child must do under direct supervision and those that he or she may do independently.

- Functional Progression for the Hip 762

### Independent Learning Activities 764

The hip is similar to the glenohumeral joint in that it is a tri-axial joint, functions in all three planes, and is the proximal link to its extremity. In contrast to the highly mobile shoulder, however, the hip is a stable joint that is adapted for upright standing and weight bearing activities. At the same time, at least 120° of hip flexion and 20° each of abduction and external rotation are necessary to carry out activities of daily living (ADLs) in what is considered a “normal” manner.<sup>120</sup> Because forces from the lower extremities are transmitted upward through the hips to the pelvis and trunk during gait and other lower extremity activities, and because the hips support the

weight of the head, trunk, and upper extremities, the health of the hip joint is vital for most functional activities.

This chapter is divided into three major sections. The first section briefly reviews the anatomy and function of the hip and its relation to the pelvis, lumbar spine, and knee. The second section describes common disorders of the hip and provides guidelines for conservative and postoperative management, expanding on the information and principles of management presented in Chapters 10 through 13. The reader should be familiar with that material as well as the components of a comprehensive examination of the hip and pelvis before

determining a diagnosis and establishing a therapeutic exercise program. The third section describes exercise interventions commonly used to meet the treatment goals for the hip region.

## Structure and Function of the Hip

The pelvic girdle links the lower extremity to the trunk and plays a significant role in the function of the hip as well as the spinal joints. The proximal femur and the pelvis comprise the hip joint (Fig. 20.1). The unique characteristics of the pelvis and femur that affect hip function are reviewed in this section. The function of the pelvis with respect to spinal mechanics is described in greater detail in Chapter 14.

**FIGURE 20.1** Bones and joints of the pelvis and hip.

## Anatomical Characteristics of the Hip Region

### Bony Structures

The structure of the pelvis and femur are designed for weight bearing and transmitting proximally and distally generated forces through the hip joint.

### The Pelvis

Each innominate bone of the pelvis is formed by the union of the ilium, ischium, and pubic bones and therefore is a structural unit. The right and left innominate bones articulate anteriorly with each other at the pubic symphysis and posteriorly with the sacrum at the two sacroiliac joints.<sup>93</sup> Slight motion occurs at these three joints to help attenuate forces transmitted through the pelvic region, but the pelvis basically functions as a unit in a closed chain.

### The Femur

The shape of the femur is designed to manage the effect of gravity on the head, arms, and trunk and to transmit ground

reaction forces to the acetabulum of the pelvis. In the frontal plane, the angle of inclination (normally 125°) between the axis of the femoral neck and the shaft of the femur allows a bending moment to attenuate these forces, and there is a slight anterior bowing of the shaft in the sagittal plane that also helps absorb and transmit force.<sup>93</sup> Similar to the humerus, there is an angle of torsion of the femur formed by the transverse axis of the femoral condyles and the axis of the neck of the femur. This angle ranges from 8° to 25°, with an average angle of 12°.

## Hip Joint Characteristics and Arthrokinematics

### Characteristics

The hip is a ball-and-socket (spheroidal) triaxial joint made up of the head of the femur and acetabulum of the pelvis. It is supported by a strong articular capsule that is reinforced by the iliofemoral, pubofemoral, and ischiofemoral ligaments. The two hip joints are linked to each other through the bony pelvis, which is integrated with the vertebral column through the sacroiliac and lumbosacral joints.<sup>93</sup>

### Articular Surfaces

The concave bony surface of the hip joint, the acetabulum, is located in the lateral aspect of the pelvis and is oriented laterally, anteriorly, and inferiorly (see Fig. 20.1). The concavity is deepened by a ring of fibrocartilage, the acetabular labrum. The articular cartilage of the acetabulum is horseshoe shaped and thicker in the lateral region, where the major weight-bearing forces are transmitted. The central portion of the acetabular surface is nonarticular.

The convex bony surface is the spherical head of the femur, which is attached to the femoral neck. The neck and head of the femur project anteriorly, medially, and superiorly.

### Ligaments

Three ligaments reinforce the joint capsule: the iliofemoral and pubofemoral ligaments are located anteriorly (Fig. 20.2 A), and the ischiofemoral ligament is located posteriorly (Fig. 20.2 B).<sup>93,117,121</sup>

**FIGURE 20.2** Ligaments supporting the hip joint. (A) Anterior view. (B) Posterior view.

There is general agreement in the literature that all three capsular ligaments limit excessive extension of the hip, and the iliofemoral ligament, also known as the Y ligament of Bigelow, is the strongest of the three.<sup>64,93,117,121</sup> In addition to their ability to limit extension, additional motions are limited by each individual ligament. The iliofemoral ligament, which reinforces the anterior portion of the capsule, is also thought to limit external rotation of the hip.<sup>117,121</sup> The pubofemoral ligament, which supports the inferior as well as anterior portion of the capsule, is believed to limit abduction.<sup>117,121</sup> Lastly, the ischiofemoral ligament, reinforcing the posterior aspect of the capsule, may also limit internal rotation and may limit adduction when the hip is flexed.<sup>64,117,121</sup>

### Arthrokinematics of the Hip Joint

During many activities, such as squatting, walking, or doing leg-press exercises, both the pelvis and femurs are moving. Therefore, joint mechanics can be described by the movement of the femur in the acetabulum or by the pelvis on the femur.

**Motions of the femur.** The convex femoral head slides in the direction opposite the physiological motion of the femur. Thus, with hip flexion and internal rotation, the articulating surface slides posteriorly; with extension and external rotation, it slides anteriorly; with abduction, it slides inferiorly; and with adduction, it slides superiorly. The arthrokinematics are summarized in ONLINE Box 20.1 available on the FA Davis website.

**Motions of the pelvis.** When the lower extremity is stabilized distally, as when standing or during the stance phase of gait, the concave acetabulum moves on the convex femoral head in the same direction as the pelvic motion. The pelvis is a link in a closed chain; therefore, when the pelvis moves, there is motion at both hip joints as well as at the lumbar spine.

## Influence of the Hip Joint on Balance and Posture Control

The joint capsule is richly supplied with mechanoreceptors that respond to variations in position, stress, and movement to control posture, balance, and movement. Reflex muscle contractions of the entire kinematic chain, known as balance strategies, occur in a predictable sequence when standing balance is disturbed and regained. Joint pathologies, restricted motion, or muscle weakness can impair balance and postural control. Refer to Chapter 8 for an in-depth discussion of these concepts.

## Functional Relationships in the Hip Region

The hip functions in both nonweight-bearing and weight-bearing activities, requiring the muscles to move the femur or control the femur and pelvis as outside forces are imposed on the region.

### Motions of the Femur and Muscle Function

Femur motions and muscle actions are typically described as occurring in the three primary planes: flexion/extension in the sagittal plane, abduction/adduction in the frontal plane, and internal/external rotation in the transverse plane. Most of the muscles at the hip can produce motion in several planes. The primary and secondary actions of the hip muscles are summarized in Table 20.1.<sup>63,93,118</sup>

**TABLE 20.1** Muscles of the Hip: Open-Chain (Nonweight-Bearing) Function

Action	Prime Movers	Secondary Movers (action depends on hip joint position)
<b>Flexion</b>	<ul style="list-style-type: none"> <li>■ Iliopsoas</li> <li>■ Rectus femoris (also extends knee)</li> <li>■ Tensor fasciae latae (also abducts and internally rotates hip and maintains tension in iliotibial band)</li> <li>■ Sartorius (also abducts and externally rotates hip and flexes and internally rotates knee)</li> </ul>	Pectineus Adductor longus Adductor magnus Gracilis
<b>Extension</b>	<ul style="list-style-type: none"> <li>■ Gluteus maximus (also externally rotates hip; superior fibers insert into iliotibial band)</li> <li>■ Hamstrings: long head of biceps femoris, semitendinosus, semimembranosus (also flex knee)</li> </ul>	Gluteus medius (posterior fibers) Adductor magnus Piriformis

**TABLE 20.1** Muscles of the Hip: Open-Chain (Nonweight-Bearing) Function—cont'd

Action	Prime Movers	Secondary Movers (action depends on hip joint position)
<b>Abduction</b>	<ul style="list-style-type: none"> <li>■ Gluteus medius</li> <li>■ Gluteus minimus</li> <li>■ Tensor fasciae latae (also flexes hip)</li> </ul>	Piriformis Sartorius Rectus femoris
<b>Adduction</b>	<ul style="list-style-type: none"> <li>■ Adductor magnus</li> <li>■ Adductor longus</li> <li>■ Adductor brevis</li> <li>■ Gracilis</li> <li>■ Pectineus</li> </ul>	Biceps femoris (long head) Gluteus maximus (posterior fibers) Quadratus femoris Obturator externus
<b>External (Lateral) Rotation</b>	<ul style="list-style-type: none"> <li>■ Obturator internus and externus</li> <li>■ Gemellus superior and inferior</li> <li>■ Quadratus femoris</li> <li>■ Piriformis</li> <li>■ Gluteus maximus</li> </ul>	Gluteus medius (posterior fibers) Gluteus minimus (posterior fibers) Sartorius Biceps femoris (long head)
<b>Internal (Medial) Rotation</b>	No prime movers	Gluteus medius (anterior fibers) Gluteus minimus (anterior fibers) Tensor fasciae latae Adductor longus and brevis Adductor magnus (posterior fibers) Pectineus

Note: Prime motions are described from the anatomic position; actions of some muscles change as the hip position changes.

## Motions of the Pelvis and Muscle Function

The pelvis is the connecting link between the spine and lower extremities (Fig. 20.3A). A consequence of pelvic movement, therefore, is motion at the hip joints and lumbar spine articulations. Another consequence of this linked system is that contraction of the hip musculature will cause pelvic motion through reverse action. In this case, if pelvic movement is not desired during femur motion at the hip joint, the pelvis must be stabilized using the trunk musculature.

### Anterior Pelvic Tilt

The anterior superior iliac spines of the pelvis move anteriorly and inferiorly and thus closer to the anterior aspect of the femur as the pelvis rotates forward around the transverse axis of the hip joints (Fig. 20.3 B). This pelvic motion results in hip flexion and increased lumbar spine extension.<sup>93</sup>

- Muscles causing this motion are the hip flexors and back extensors.
- If hip flexion through femur movement is the desired motion, the pelvis must be stabilized by the abdominals to prevent anterior pelvic tilting.

**FIGURE 20.3** (A) Neutral position of the pelvis. (B) Anterior pelvic tilt. (C) Posterior pelvic tilt. With anterior pelvic tilt, the decreased angle between the pelvis and femur results in hip flexion, and with posterior pelvic tilt, the increased angle results in hip extension.

- During standing, if the line of gravity of the trunk shifts anterior to the axis of the hip joints, the effect is an anterior pelvic tilt moment. Stability is provided by the abdominal muscles and hip extensor muscles.

### Posterior Pelvic Tilt

The posterior superior iliac spines of the pelvis move posteriorly and inferiorly, thus closer to the posterior aspect of the femur as the pelvis rotates backward around the axis of the hip joints (Fig. 20.3 C). This results in hip extension and lumbar spine flexion.<sup>93</sup>

- Muscles causing this motion are the hip extensors and trunk flexors (abdominals).
- If hip extension through femur movement is the desired motion, the lumbar extensors contract to stabilize the pelvis.
- During standing the line of gravity of the trunk normally falls posterior to the axis of the hip joints, creating a posterior pelvic tilt moment. Dynamic stability is provided by the hip flexors and back extensors and passive stability by the iliofemoral ligament.

### Pelvic Shifting

During standing, a forward translatory shift of the pelvis results in extension of the hip and extension of the lower lumbar spinal segments. There is a compensatory posterior shifting of the thorax on the upper lumbar spine with increased flexion of these spinal segments. This is often seen with slouched or relaxed postures (see Fig. 14.18 B in Chapter 14). Little muscle action is required; the posture is maintained by the iliofemoral ligament at the hip, anterior longitudinal ligament of the lower lumbar spine, and posterior ligaments of the upper lumbar and thoracic spine.

### Lateral Pelvic Tilt

Frontal plane pelvic motion results in opposite motions at each hip joint. Pelvic motion is defined by what is occurring to the iliac crest that is opposite the weight-bearing extremity (that is, the side of the pelvis that is moving). When one crest elevates, it is called hip hiking; when it lowers, it is called hip or pelvic drop. On the side that is elevated, there is hip joint adduction; on the side that is lowered, there is hip joint abduction (Fig. 20.4 A). These pelvic motions also result in

lumbar spine motion, with lateral flexion occurring toward the elevated crest (convexity of the lateral curve is toward the lowered side).<sup>93</sup>

- Muscles causing lateral pelvic tilting include the quadratus lumborum on the side of the elevated crest and reverse muscle pull of the gluteus medius on the stance side hip.
- When hip abduction through femur movement is the desired motion, the pelvis must be stabilized by the lateral abdominals (internal and external obliques) on the side of the moving femur. When standing, the stance side gluteus medius prevents the pelvis from tilting downward.
- With an asymmetrical slouched posture, the person shifts the trunk weight onto one lower extremity and allows the pelvis to drop on the other side. Passive support comes from the iliofemoral ligament and iliotibial band on the stance leg side.
- When standing on one leg, gravity creates an adduction moment at the hip, tending to cause the pelvis to drop on the unsupported side (hip or pelvic drop). This is prevented by the gluteus medius stabilizing the pelvis on the stance side.

### Pelvic Rotation

Pelvic rotation occurs around one lower extremity that is fixed on the ground. The unsupported lower extremity swings forward or backward along with the pelvis. When the unsupported side of the pelvis moves forward, it is called forward rotation of the pelvis.<sup>93</sup> The trunk concurrently rotates in the opposite direction, and the hip joint on the stabilized side rotates internally. When the unsupported side of the pelvis moves backward, it is called posterior rotation; the hip joint on the stabilized side concurrently rotates externally, and the trunk rotates opposite (Fig. 20.4 B).

- Muscles causing pelvic rotation are the hip rotators working in synergy with the oblique abdominal muscles, the transversus abdominis, and the multifidus.
- When hip rotation through femur movement is the desired motion, the pelvis must be stabilized by the trunk musculature.

**FIGURE 20.4 (A)** Lateral pelvic tilt. Elevation of the iliac crest (hip hiking) causes relative adduction of the hip on the elevated side, and lowering of the iliac crest (hip drop) causes relative abduction of the hip on the lower side. **(B)** Pelvic rotation. Forward motion (forward rotation) of the pelvis causes relative external rotation of the hip; and backward motion (posterior rotation) of the pelvis causes relative internal rotation of the hip.

## Pelvifemoral Motion

A combined movement occurs between the lumbar spine and pelvis during maximum forward bending of the trunk as when reaching toward the floor or the toes.<sup>93</sup> This motion is also known as lumbopelvic rhythm.<sup>26</sup> Although there is considerable variability in the participation of each of the joints, the motion typically is described as beginning with forward bending of the head.

- As the head and upper trunk initiate flexion, the pelvis shifts posteriorly to maintain the center of gravity over the base of support.
- The trunk continues to forward-bend, controlled by the extensor muscles of the spine, until approximately 45°. At this point for an individual with relatively normal flexibility, the posterior ligaments become taut, and the superior facets of the zygapophyseal joints slide upward, resulting in passive tension in the facet capsules.
- Once all of the vertebral segments are at the end of the range and stabilized by the posterior ligaments and facets, the pelvis begins to rotate forward (anterior pelvic tilt), controlled by the gluteus maximus and hamstring muscles.
- The pelvis continues to rotate forward until full muscle length is reached. Final range of motion (ROM) in forward bending is dictated by the flexibility of the various back extensor muscles and fascia as well as hip extensor muscles (including the hamstrings).

The return to the upright position begins with the hip extensor muscles rotating the pelvis posteriorly through reverse muscle action (posterior pelvic tilt), then with the back extensor muscles extending the spine from the lumbar region upward. Variations in the normal synchronization of this activity occur because of training (as with dancers and gymnasts), faulty habits, restricted muscle or fascia length, or injury and faulty proprioception.

## Hip, Knee, and Ankle Functional Relationships in Weight Bearing

During weight bearing, control of hip positions and motions affects the alignment and function of the entire lower extremity.

**Hip flexion/extension.** Hip flexion in weight bearing is typically accompanied by knee flexion and ankle dorsiflexion. These actions are controlled by the hip extensor (gluteus maximus and hamstrings), knee extensor (quadriceps femoris), and ankle plantarflexor (gastrocnemius and soleus) muscles. Hip extension in weight bearing causes knee extension by pulling the femur posteriorly and contributes to the locking mechanism at the knee.

**Hip abduction/adduction.** With unilateral weight bearing, gravity creates an adductor moment at the hip that is stabilized by the gluteus medius (preventing pelvic drop). Typically, this results in a varus moment at the knee, approximating the medial knee compartment. However, if the gluteus medius is

weak, there is increased adduction of the femur and increased valgus moment at the knee, imposing greater stress on the medial collateral ligament, medial patellofemoral ligament, and anterior cruciate ligament.<sup>133</sup>

**Hip rotation.** Internal rotation of the hip results in the femur rotating medially on a fixed tibia at the knee. The force through the tibia causes eversion of the calcaneus and pronation of the foot when weight bearing. The reverse occurs with hip external rotation. This total chain response occurs repeatedly during the loading and terminal stance phases of gait as the ground reaction forces are absorbed and the body is moved forward. A total chain response also occurs during loading of the extremities when descending stairs or landing a jump.

## Pathomechanics in the Hip Region

Abnormal structure or impaired function of the hip—such as a leg-length discrepancy, decreased flexibility, or muscle timing and strength imbalances—can contribute to stress through the spine or other joints of the lower extremities.

### Decreased Flexibility

Decreased flexibility of the structures around the hip joint may have the effect of weight-bearing forces and movement being transmitted to the spine rather than being absorbed by the pelvis. For example, tight hip flexors will cause increased lumbar extension (lordosis) as the thigh extends. Hip flexion contractures with incomplete hip extension during weight bearing also place added stresses on the knee because the knee cannot lock while the hip is in flexion unless the trunk is bent forward. During weight bearing, tight adductors cause pelvic drop opposite to the side of tightness and compensatory side-bending of the trunk toward the side of tightness. The opposite occurs with tight abductors.

### Muscle Weakness

Decreased hip abductor, extensor, and external rotator muscle strength is associated with valgus collapse at the knee (increased valgus and internal rotation of the femur) during weight-acceptance activities and may contribute to impairments throughout the lower extremity as described in the following examples.<sup>133</sup>

**Patellofemoral impairment.** Higher valgus moments at the knee as a result of weak hip abductors have been associated with patellofemoral impairments, which occur more often in women than in men (see Chapter 21).<sup>133,134</sup>

**Anterior cruciate ligament strain.** Valgus collapse and decreased hip extensor activation are more common in women than in men who have sustained an anterior cruciate ligament injury. It is suggested that this pattern increases anterior shear of the tibia and strain of the anterior cruciate ligament during loading (hip-knee flexion when landing following a jump).<sup>133</sup>

**Piriformis syndrome.** Hip extensor and abductor weakness resulting in hip adduction and internal rotation (valgus collapse) during functional activities has been identified as the possible cause of sciatic nerve compression secondary to piriformis muscle overuse. Strengthening and functional retraining of the gluteus maximus and gluteus medius along with correction of the faulty movement patterns were reported to alleviate the symptoms and functional improvement.<sup>159</sup>

### Hip Muscle Imbalances and Their Effects

It is important to recognize that imbalances in muscle function (dominance of one muscle over another when performing an activity) that cause faulty movement patterns may be due to muscle strength and length deficits as well as altered proprioception and neuromuscular control.<sup>63</sup> Faulty mechanics from any of these factors may cause hip, knee, or back impairments and pain.<sup>142</sup> Overuse syndromes, soft tissue pain, and joint pain may all develop in response to continued abnormal stresses. The following are common hip muscle imbalances that may result in lower extremity impairments.

**Shortened tensor fasciae latae (TFL) and/or gluteus maximus.** The TFL and approximately one-third of the gluteus maximus insert into the iliotibial (IT) band. Decreased flexibility in either of these muscles has an effect on the tension transmitted through the IT band. Postural impairments often associated with a shortened TFL or gluteus maximus include an anterior pelvic tilt posture, slouched posture, or flat back posture (see Fig. 14.18 and related discussion in Chapter 14).<sup>142</sup> Overuse syndromes associated with greater tension of the IT band include trochanteric bursitis in the hip region and IT band friction syndrome in the knee (see description of this in the patellofemoral impairment section in Chapter 21).

**Dominance of the TFL over the gluteus medius.** The imbalance resulting from an apparent weakness of the gluteus medius with compensatory dominance of the TFL functioning as a hip abductor results in increased tension on the IT band,<sup>142</sup> valgus collapse of the knee during weight bearing with hip/knee flexion (see Fig. 21.9), and increased dynamic Q-angle.<sup>63</sup> This may lead to lateral knee pain (IT band syndrome) or patellofemoral pain syndrome from increased bowstring effect on the extensor mechanism (see the description of the bowstring effect and Fig. 21.3 in Chapter 21).

**Dominance of the two-joint hip flexor muscles over the iliopsoas.** Dominance of the TFL, rectus femoris, and/or sartorius muscles may contribute to faulty hip mechanics or knee pain from overuse of these muscles as they cross the knee.

**Dominance of hamstring muscles over the gluteus maximus.** Faulty posture and decreased functional activation of the gluteus maximus may decrease the flexibility of this muscle and limit the range of hip flexion.<sup>142</sup> Excessive lumbar spine flexion may result whenever full range of hip flexion is attempted. Limited mobility of the gluteus maximus also causes increased tension on the IT band, an alteration associated with trochanteric or lateral knee pain.

With decreased activation of the gluteus maximus, the hamstrings dominate as hip extensors.<sup>142</sup> Overuse of the hamstring muscles may result in cramping of the muscle with high-intensity exercise<sup>165</sup> or may result in decreased hamstring flexibility and muscle imbalances with the quadriceps femoris muscles at the knee.<sup>142</sup> In this muscle imbalance, the hamstrings dominate the knee stabilizing function by increased posterior pulling on the tibia to extend the knee in closed-chain activities. This alters the mechanics at the knee and may lead to overuse syndromes in the hamstring tendons or in anterior knee pain from modified quadriceps forces.<sup>142</sup>

**Use of lateral trunk muscles for hip abductors.** Relying on the lateral trunk muscles to perform the task of controlling the pelvis normally accomplished by the hip abductors results in excessive trunk motion and increased stress on the lumbar spine.

### Asymmetrical Leg Length

Functional and structural asymmetries of the lower extremities affect the orientation and position of the pelvis.

**Unilateral short leg.** A unilateral short leg causes lateral pelvic tilting (drop on the short side) and side-bending of the trunk away from the short side (convexity of the lateral lumbar curve toward the side of short leg). This may lead to a functional—or eventually a structural—scoliosis. Causes of a short leg could be unilateral lower extremity faults, such as flat foot, genu valgum, coxa vara, tight hip muscles, anteriorly rotated innominate bone, poor standing posture, or asymmetrical bone growth.

**Coxa valga and coxa vara.** A pathologically large angle of inclination between the femoral neck and shaft of the femur is called *coxa valga*, and a pathologically smaller angle is called *coxa vara*. Unilateral coxa valga results in a relatively longer leg on that side and associated genu varum. Unilateral coxa vara leads to a relatively shorter leg with associated genu valgum.

**Anteversion and retroversion.** An increase in the torsion of the femoral neck is called *anteversion* and causes the shaft of the femur to be rotated medially. A decrease in the torsion is called *retroversion* and causes the shaft of the femur to be rotated laterally. Anteversion often results in genu valgum and pes planus. Unilateral anteversion results in a relatively shorter leg on that side; retroversion causes the opposite effect.

## The Hip and Gait

During the normal gait cycle, the hip goes through 40° of flexion and extension ROM (10° extension at terminal stance to 30° flexion at midswing and initial contact). There is also lateral pelvic tilt and hip abduction/adduction of 15° (10° adduction at initial contact, 5° abduction at initial swing) and hip internal/external rotation along with pelvic rotation totaling 15° transverse plane motion (peak internal rotation at the end of loading, peak external rotation at the end of

preswing). Loss of any of these motions affects the smoothness of the gait pattern.<sup>130</sup>

## Hip Muscle Function and Gait

### Hip Flexors

The hip flexors control hip extension at the end of stance and then contract concentrically to initiate swing.<sup>130</sup> With loss of flexor function, a posterior lurch of the trunk to initiate swing may be seen. Contractures of the hip flexors prevent complete extension during the second half of stance, thus shortening the stride. To compensate for a flexor contracture, a person increases the lumbar lordosis or walks with the trunk bent forward.

### Hip Extensors

The hip extensors control the flexor moment during the loading response, and the gluteus maximus initiates hip extension.<sup>124,130</sup> With loss of extensor function, a posterior lurch of the trunk occurs at foot contact to shift the center of gravity of the trunk posterior to the hip. With contractures of the gluteus maximus, some decreased range occurs in the terminal swing as the femur comes forward, or the person may compensate by rotating the pelvis increasingly forward. The lower extremity may rotate outward because of the external rotation component of the muscle, or the gluteus maximus may place greater tension on the iliotibial band through its attachment, leading to irritation along the lateral aspect of the knee with repetitive activity.

### Hip Abductors

The hip abductors control the lateral pelvic tilt during swinging of the opposite leg.<sup>124,130</sup> With loss of gluteus medius function, the trunk shifts laterally over the weak hip during stance when the opposite leg swings. This lateral shift also occurs with a painful hip to minimize the torque produced by gravity on the head, arms, and trunk and to subsequently decrease the abductor muscle force required. The tensor fasciae latae also functions as an abductor and can affect gait if it becomes tight.

## Effect of Musculoskeletal Impairments on Gait

Bone and joint deformities change alignment of the lower extremity and therefore the mechanics of gait. Painful conditions cause antalgic gait patterns, which are characterized by decreased stance time on the painful side to avoid the stress of weight bearing.

## Referred Pain and Nerve Injury

The hip is innervated primarily from the L3 spinal level; hip joint irritation is usually felt along the L3 dermatome reference from the groin, down the front of the thigh to the knee.<sup>38,90</sup>

For a detailed description of referred pain patterns and peripheral nerve injuries in the hip and buttock region, see Chapter 13.

## Major Nerves Subject to Injury or Entrapment

**Sciatic nerve.** Entrapment may occur when the sciatic nerve passes deep to the piriformis muscle (occasionally it passes over or through the piriformis).

**Obturator nerve.** Isolated injury is rare, although prolonged fetal head pressure during labor or damage from forceps delivery may occur.

**Femoral nerve.** Injury may result from fractures of the upper femur or pelvis, reduction of congenital dislocation of the hip, or pressure during a forceps labor and delivery.

## Common Sources of Referred Pain in the Hip Region

If painful symptoms are referred to the hip region from other sources, primary treatment must be directed to the source of the irritation. Common sources of referred pain in the hip region include:

- Nerve roots or tissues derived from spinal segments L1, L2, L3, S1, and S2.
- Lumbar intervertebral and sacroiliac joints.

## Management of Hip Disorders and Surgeries

To make sound clinical decisions when treating patients with hip disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and to identify each patient's presenting structural and functional impairments, activity limitations, and participation restrictions. In this section, common pathologies and surgeries of the hip region are described. Conservative and postoperative management of these conditions is also discussed in this section.

## Joint Hypomobility: Nonoperative Management

### Related Pathologies and Etiology of Symptoms

Osteoarthritis (OA), rheumatoid arthritis (RA), aseptic necrosis, slipped epiphyses, dislocations, and congenital deformities can lead to degenerative changes in the hip joint (see Fig. 11.2).

## Osteoarthritis (Degenerative Joint Disease)

OA is the most common arthritic disease of the hip joint. Etiological factors include the aging process, joint trauma, repetitive abnormal stresses, obesity, hip developmental disorders, or disease.<sup>32</sup> The degenerative changes include articular cartilage breakdown and loss, capsular fibrosis, and osteophyte formation at the joint margins.<sup>47</sup> These effects usually occur in regions undergoing the greatest loading forces, such as the superior weight-bearing surface of the acetabulum (see Fig. 11.6).

## Postimmobilization Hypomobility

Restricted capsular and surrounding periarticular tissue mobility may occur any time the joint is immobilized after a fracture or surgery.

## Common Impairments of Structure and Function

- Pain experienced in the groin and referred along the anterior thigh and knee in the L3 dermatome.
- Stiffness after rest.
- Limited motion with a firm capsular end-feel.<sup>153</sup> Initially, limitation is only in internal rotation; in advanced stages, the hip is fixed in adduction, has no internal rotation or extension past neutral, and is limited to 90° flexion.<sup>38</sup>
- Asymmetry in lower extremity weight bearing and an antalgic gait usually with a compensated gluteus medius (abductor) limp and slower speed (related to shorter step length and stance duration).<sup>36</sup>
- Limited hip extension leading to increased extension forces on the lumbar spine and possible back pain.
- Limited hip extension preventing full knee extension when standing or during gait, leading to altered knee stresses.
- Impaired balance and postural control.

A clinical prediction rule (CPR) recently developed by Sutlive and associates<sup>153</sup> (summarized in Box 20.1) identifies

### BOX 20.1 Clinical Prediction Rule for the Diagnosis of Osteoarthritis of the Hip<sup>153</sup>

#### Variables\*

- Squatting aggravates symptoms per self-report.
- Active hip flexion causes lateral hip pain.\*\*
- The scour test with adduction causes lateral hip or groin pain.
- Active hip extension causes pain.
- Passive internal rotation is less than or equal to 25°.\*\*

\*Results of the study indicated that if three of the five variables were present, the likelihood of having hip OA increased from a 29% to 68% probability; if four of the five variables were identified, the likelihood increased to 91%.

\*\*Interrater reliability for identifying the end feels of flexion and internal rotation was 0.85 and 0.88, respectively.

five examination variables that can be used for the diagnosis of hip OA. The diagnostic variables are based on a preliminary study of 72 subjects over the age of 40 with unilateral buttock, groin, or anterior thigh pain. Patients with radiographic changes had an increased likelihood of having clinically relevant symptoms. Neither a validation study nor an impact analysis of this CPR have been reported.

Other functional impairments, such as decreased muscle strength and limited functional abilities, have been identified in individuals with hip OA.

## FOCUS ON EVIDENCE

A cross-sectional study compared 26 patients with hip OA who were not surgical candidates with a matched control group without OA for function and disability. Significant differences between the groups included mild to moderate pain level, decreased knee extension strength, and decreased hip ROM in the hip OA group. Functionally, those with OA walked a shorter distance in 6 minutes, but there were no significant differences in strength of the hip flexors/extensors, knee flexors, or ankle dorsiflexors/plantarflexors.<sup>141</sup>

## Common Activity Limitations and Participation Restrictions

Hip joint impairments interfere with many weight-bearing activities and ADLs.<sup>31,141</sup>

**Early stages.** There is progressive pain with continued weight bearing and walking or at the end of the day after repetitive lower extremity activities. The pain may interfere with work or routine household activities that involve prolonged weight bearing.

**Progressive degeneration.** The individual experiences increased difficulty rising from a chair, walking long distances or on uneven surfaces, climbing stairs, squatting, and other weight-bearing activities and begins to have limitations in routine ADLs, such as bathing, toileting, and dressing (putting on pants, hose, socks).

## CLINICAL TIP

To measure the extent of impairments (e.g., pain, ROM, strength) and activity and participation restrictions (walking distance or speed, ability to climb/descend stairs, ADLs, and quality of life) use tools such as the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC), the Arthritis Impact Measurement Scale (AIMS), Lower Extremity Functional Scale (LEFS), the Hip disability and Osteoarthritis Outcome Score (HOOS), the Harris Hip Score, and others as identified in the *Clinical Practice Guidelines*.<sup>32,45</sup>

## Management: Protection Phase

Chapter 11 describes the general principles and plan of care in the treatment of OA and RA, and Chapter 10 describes general management of joints during acute, subacute, and chronic stages of tissue injury and repair. In conjunction with medical management of inflammation and pain, correcting faulty mechanics is an integral part of decreasing hip pain. Faulty hip mechanics may be caused by conditions such as obesity, leg-length differences, muscle length and strength imbalances, sacroiliac dysfunction,<sup>31,32</sup> poor posture, or injury to other joints linked to hip motion.<sup>25</sup> The following goals and interventions are emphasized when the symptoms are acute and during the protection phase of nonoperative management.

### Provide Patient Education

- Explain how the stresses of weight bearing and other activities impact symptoms and joint health and describe how interventions may minimize symptoms.
- Teach safe ambulatory patterns and a home exercise program that emphasizes nonimpact activities and frequent ROM.

### Decrease Pain at Rest

- Apply grade I or II oscillation techniques with the joint in the resting position.
- Have the patient rock in a rocking chair to provide gentle oscillations to the lower extremity joints and possibly a stimulus to the joint mechanoreceptors.

### Decrease Pain During Weight-Bearing Activities

- Provide assistive devices for ambulation to help reduce stress on the hip joint. If the pain is unilateral, teach the patient to walk with a single cane or crutch on the side opposite the painful joint.
- If leg-length asymmetry is causing hip joint stress, gradually elevate the short leg with lifts in the shoe.
- Modify chairs to provide an elevated and firm surface and adapt commodes with an elevated seat to make sitting down and standing up easier.

### Decrease Effects of Stiffness and Maintain Available Motion

- Teach the patient the importance of moving the hips through their ROM frequently throughout the day. When the acute symptoms are medically controlled, have the patient perform active or assisted ROM as they are able.
- If a pool is available, have the patient perform ROM in the buoyant environment.
- Initiate nonimpact activities such as swimming, gentle water aerobics, or stationary cycling.

## Management: Controlled Motion and Return to Function Phases

As symptoms subside, the emphasis of management includes the following goals and interventions.

### Progressively Increase Joint Accessory Motion and Soft Tissue Mobility

**Joint mobilization techniques.**<sup>32</sup> Progress joint mobilization to stretch grades (grade III sustained or grade III and IV oscillation) using glide directions that stretch restricting capsular tissue at the end of the available ROM (see Figs. 5.45 through 5.47 in Chapter 5). Vigorous stretching should not be undertaken until the chronic stage.

**Stretching techniques.** Stretch any range-limiting tissues. Suggested manual stretching techniques are described in Chapter 4, and self-stretching techniques are described in the exercise section later in this chapter.

### Improve Joint Tracking and Pain-Free Motion

Mobilization with movement (MWM) techniques<sup>110</sup> may be applied through the use of a mobilization belt to produce a pain-free inferolateral glide and then superimposing motion to the end of the available range. As with all MWM techniques, no pain should be experienced during application of the technique. Principles of MWM are described in Chapter 5; specific MWM techniques for the hip are described here.

#### Increase Internal Rotation

**Patient position:** Supine with the involved hip flexed and a mobilization belt secured around the proximal anterior-medial thigh and your pelvis.

**Procedure:** Stabilize the patient's pelvis with the palm of the hand closest to the patient's head. Use the mobilization belt to produce a pain-free inferolateral glide while the caudal hand grips around the flexed thigh and shin to create pain-free, end-range internal rotation (Fig. 20.5 A).

#### Increase Flexion

**Patient position:** Supine with the involved hip flexed and a mobilization belt secured around the proximal anterior-medial thigh and the pelvis.

**Procedure:** Stabilize the patient's pelvis with the palm of the hand closest to the patient's head. Use the mobilization belt to produce a pain-free inferolateral glide while the caudal hand grips around the flexed thigh and shin to create pain-free, end-range flexion (Fig. 20.5 B).

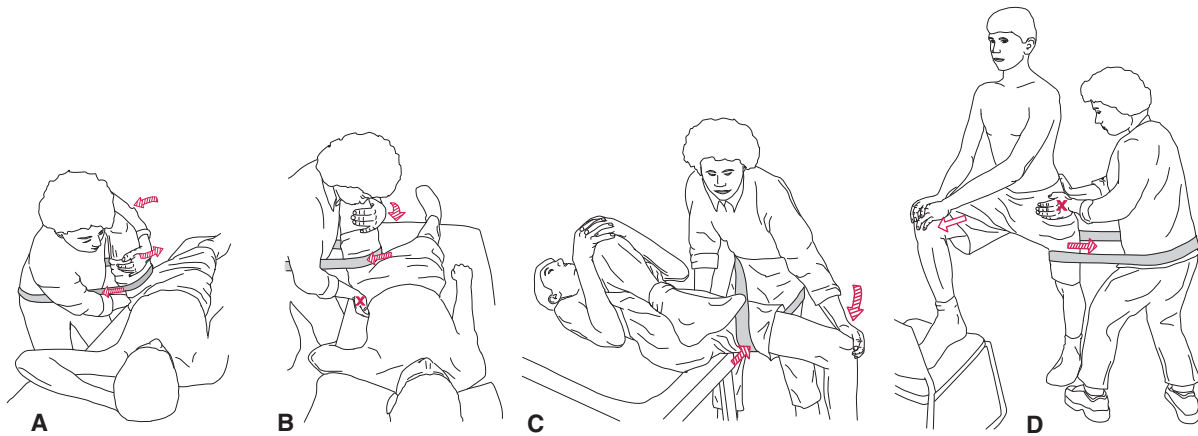

#### Increase Extension

**Patient position:** Supine with the pelvis near the end of the treatment table in the Thomas test position (opposite thigh held against the chest) and a mobilization belt secured around the proximal medial thigh and your pelvis.

**Procedure:** Stabilize the patient's pelvis with the palm of the hand closest to the patient's head. Use the mobilization belt to produce a pain-free, inferolateral glide, while the caudal hand presses against the extended thigh to create pain-free, end-range extension (Fig. 20.5 C).

#### Increase Extension During Weight Bearing

**Patient position:** Standing with the unaffected foot up on a stool and a mobilization belt secured around the proximal medial thigh and your pelvis.

**FIGURE 20.5** Mobilization with movement using an inferolateral glide increasing (A) pain-free internal rotation, (B) pain-free flexion, (C) pain-free extension, and (D) a lateral glide increasing extension during weight bearing.

**Procedure:** Stabilize the pelvis with both hands and apply a pain-free, lateral glide with the mobilization belt, while the patient lunges forward to produce painless extension of the affected hip (Fig. 20.5 D).

### Improve Muscle Performance in Supporting Muscles, Balance, and Aerobic Capacity

- Initiate exercises that develop strength and control of the hip musculature, especially the gluteus maximus, gluteus medius, and rotators, and that improve stability and balance when performing weight-bearing activities. Begin with sub-maximal isometric resistance; progress to dynamic resistance as the patient tolerates movement. If any exercises exacerbate the joint symptoms, reduce the intensity. Also reassess the patient's functional activities and adapt them to reduce the stress.
- Progress to functional exercises as tolerated using closed-chain and weight-bearing activities. The patient may require assistive devices while weight bearing. Use a pool or tank to reduce the effects of gravity to allow partial weight-bearing exercises without stress.
- Develop postural awareness and balance.
- Progress the low-impact aerobic exercise program (swimming, cycling, or walking within tolerance).

### Provide Patient Education

Help the patient establish a balance between activity and rest and teach them the importance of minimizing stressful, deforming forces by maintaining muscle strength and flexibility in the hip region.

### FOCUS ON EVIDENCE

Two systematic reviews of studies examining the effects of exercise in the management of hip and knee OA describe support for aerobic exercise and strengthening exercises to reduce pain and disability.<sup>138,139</sup> The consensus of the studies

is that there are few contraindications and that exercise is relatively safe in patients with OA.<sup>138</sup> However, exercise should be individualized and patient centered, with consideration for age, comorbidity, and general mobility.

An outcome review<sup>39</sup> summarized that moderate- or high-intensity exercises in patients with RA have minimal effect on the disease activity, but there is insufficient radiological evidence on the effect in large joints. Long-term moderate- or high-intensity exercises that are individualized to protect radiologically damaged joints improve aerobic capacity, muscle strength, functional ability, and psychological well-being in patients with RA.

A committee appointed by the Osteoarthritis Research International performed an extensive systematic review and developed a consensus recommendation for the management of hip and knee OA.<sup>172</sup> Suggested interventions included referral to a physical therapist for evaluation and instruction in exercises to “reduce pain and improve functional capacity” as well as use of assistive devices when appropriate. The report also supported the importance of regular aerobic exercise, muscle strengthening, and ROM.

**Clinical Practice Guidelines (CPGs) for Hip OA** developed by the Orthopaedic Section of the American Physical Therapy Association<sup>32</sup> recommend patient education; functional, gait, and balance training; manual therapy; and flexibility, strengthening, and endurance exercises.

## Joint Surgery and Postoperative Management

A number of surgical options are available to manage early- and late-stage hip joint injury or disease and fractures that compromise the vascular supply to the head of the femur. As a result of advances in arthroscopy of the hip, small- to medium-size, full-thickness lesions of the articular cartilage

of the acetabulum and head of the femur as well as other joint pathologies, such as acetabular labral tears, femoroacetabular impingement (FAI), and capsular laxity, are now managed arthroscopically.<sup>44,45, 175,177</sup> *Microfracture*, a type of *chondroplasty*, is a procedure designed to repair small lesions of the articular cartilage.<sup>44</sup> Other arthroscopic procedures for the hip include *debridement* for removal of a loose body within the joint, *labral resection* or *repair* for acetabular-labral fraying or a tear, *osteoplasty* and *rim trimming* for FAI, and *capsulorrhaphy* or capsular *plication* for capsular laxity.<sup>44</sup> In-depth information on FAI can be found in a later section on Painful Hip Syndromes in this chapter and in other resources.<sup>45, 175,176,177</sup>

Surgical procedures to manage late-stage deterioration of the hip joint include *osteotomy* (an extra-articular procedure) and arthroplasty, specifically *hip resurfacing arthroplasty* (*surface replacement*),<sup>55,69</sup> *hemiarthroplasty*,<sup>99</sup> and *total hip arthroplasty* (THA).<sup>37,76,94</sup> *Arthrodesis* and *resection arthroplasty* of the hip are considered salvage procedures after failure of arthroplasty and when revision arthroplasty is contraindicated or not feasible.<sup>94</sup>

The goals of joint surgery and postoperative management are to provide the patient with (1) a pain-free hip, (2) a stable joint for lower extremity weight bearing and functional ambulation, and (3) adequate ROM and strength of the lower extremity for functional activities.

For an effective, safe postoperative rehabilitation program, it is important for the therapist to have a basic understanding of the more common surgical procedures for hip joint disease and deformity, plus a thorough knowledge of appropriate therapeutic exercise interventions and their progression. An overview of two of the more common procedures—THA and hemiarthroplasty—and guidelines for postoperative management are described in the following sections.

## Arthroscopic Procedures for the Hip

### Indications for Surgery

The following are common indications for arthroscopic interventions from injuries and disorders affecting the hip joint:<sup>44,45,175,176,177</sup>

- Anterior hip/groin pain as the result of focal lesions of the articular cartilage acetabulum or femoral head and often found in conjunction with FAI and/or an acetabular labral tear or fraying that is not relieved by a course of conservative (nonoperative) treatment
- Intra-articular loose bodies leading to clicking, catching, or locking of the hip joint
- Laxity of the hip capsule typically leading to anterior instability of the hip
- Intra-articular examination of the hip

### Procedures

A surgeon's selection of one or more arthroscopic procedures for the hip to relieve or reduce a patient's structural or functional impairments is based on a number of criteria including

the type, size, and location of the defect or lesion and patient-related factors, such as age, desired activity level, and an ability to participate in a postoperative rehabilitation.<sup>44,45,175,176</sup>

**Chondroplasty/microfracture.** One of several arthroscopic procedures can be performed for repair of small to medium articular cartilage lesions. Microfracture involves creating small fractures of subchondral bone in the area of the chondral lesion to stimulate growth of fibrocartilage to replace the damaged hyaline cartilage.<sup>44</sup>

**Resection or repair of a labral tear of the acetabulum.** Arthroscopic resection and removal (debridement) of the unstable portion of a torn or frayed labrum, while preserving as much stable tissue as possible, is performed to reduce hip pain or the catching sensation a patient may have been experiencing over a period of time. Repair of a labral tear typically is selected for management of an acute tear, usually caused by trauma and to preserve the congruity of the hip joint.

**Osteoplasty and rim trimming.** These bony procedures are designed to reduce the structural abnormalities of the femoral head, acetabulum, or both and subsequent abutment of bony structures, which often lead to FAI and the development of labral fraying or tears and articular cartilage lesions.<sup>44,176</sup>

**Capsular modification:** plication or thermal-assisted capsulorrhaphy. These procedures are designed to surgically decrease or shrink the size of the joint capsule to reduce capsular laxity, joint instability, and the risk of labral tears and articular cartilage injury.<sup>44</sup>

### Postoperative Management

Rehabilitation following any of the arthroscopic procedures for the hip is criterion based and time based, is geared to the type and number of procedures carried out, and is individualized to each patient.

Interventions in the postoperative program include patient education emphasizing avoidance of symptom-provoking positions of the lower extremities; weight bearing with some degree of protection; and therapeutic exercises to improve ROM and flexibility, strength and endurance, and neuromuscular control and balance. Postoperative rehabilitation guidelines for the arthroscopic hip procedures described in this section are based on several resources in the literature and summarized in Table 20.2.<sup>44,45,175,176,177</sup>

**Additional postoperative interventions.** There are a number of interventions common to the arthroscopic surgical procedures for the hip addressed in Table 20.2. They include the use of a modified Bledsoe orthosis for 10 to 14 postoperative days to limit hip motion. Another range-limiting device is an antirotation bolster to limit external rotation for 10 to 14 days following labral resection or repair, microfracture, and osteoplasty and for up to 4 weeks after capsular plication or thermal-assisted capsulorrhaphy. However, active internal rotation from neutral while lying supine is initiated during the early postoperative days to reduce the risk of capsular adhesions. Sometimes a CPM unit for hip flexion and extension within a limited range

**TABLE 20.2** Guidelines for Postoperative Management Following Arthroscopic Procedures for the Hip

Type of Arthroscopic Procedure	Weight-Bearing Restrictions*	Exercise Guidelines and Progression*
<b>Microfracture/Chondroplasty</b>	<ul style="list-style-type: none"> <li>Restrict weight bearing to protect early fibrocartilage formation and for pain control</li> <li>Minimal (touch-down) weight bearing for 4–6 weeks<sup>44</sup> or up to 8 weeks<sup>176</sup> postop, progressing to weight bearing as tolerated</li> <li>Use of ambulation aids for joint protection</li> </ul>	<ul style="list-style-type: none"> <li>Hip ROM               <ul style="list-style-type: none"> <li>Active-assistive ROM on first postop day within protected ranges</li> <li>Full ROM permitted after 2 weeks</li> </ul> </li> <li>Strengthening and balance exercises               <ul style="list-style-type: none"> <li>Active ROM at 2 weeks; avoid supine SLRs for 3–4 weeks to minimize compressive forces on the hip</li> <li>Low-load PRE at 4–6 weeks</li> <li>Resistance and balance exercises in weight bearing after 6 weeks</li> </ul> </li> </ul>
<b>Resection or Repair of an Acetabular Labral Tear</b>	<ul style="list-style-type: none"> <li><i>After resection and debridement:</i> partial weight bearing for up to 2 weeks postop</li> <li><i>After repair:</i> partial weight-bearing for up to 4 weeks postop</li> <li>Gradual progression of weight bearing based on joint irritability and pain</li> <li>Use of ambulation aids for joint protection</li> </ul>	<ul style="list-style-type: none"> <li>Hip ROM               <ul style="list-style-type: none"> <li>Active-assistive ROM on first postop day, gradually progressing to active ROM</li> <li>Stationary cycling with seat raised (to limit hip flexion) within first postop week</li> <li>Limit hip flexion to 80°–90°</li> <li>Full ROM (abduction and external rotation) permitted by 2 weeks postop</li> </ul> </li> <li>Strengthening and balance exercises               <ul style="list-style-type: none"> <li>Active ROM by 2 weeks, progressing with low-load resistance</li> <li>Progressive weight bearing and balance exercises incorporating weight-bearing restrictions</li> </ul> </li> </ul>
<b>Osteoplasty and Rim Trimming</b>	<ul style="list-style-type: none"> <li>Minimal (touch-down) weight bearing for 4–6 weeks to allow bony healing, gradually progressing to weight bearing as tolerated</li> <li>Use of ambulation aids for joint protection</li> </ul>	<ul style="list-style-type: none"> <li>Hip ROM               <ul style="list-style-type: none"> <li>Active-assistive ROM within protected ranges on postop day 1</li> <li>Full ROM permitted by 2 weeks</li> </ul> </li> <li>Strengthening and balance exercises               <ul style="list-style-type: none"> <li>Active ROM permitted after 2 weeks; progress by adding light resistance.</li> <li>Avoid supine SLRs for 3–4 weeks postop to minimize compressive forces on the hip.</li> <li>When weight bearing is permitted as tolerated, begin weight-bearing exercises and balance progression.</li> </ul> </li> </ul>
<b>Capsular Modification: Plication or Thermal-Assisted Capsulorrhaphy</b>	<ul style="list-style-type: none"> <li>Partial weight bearing for 10–14 days;<sup>44</sup> up to 4 weeks<sup>176</sup></li> <li>Use of ambulation aids for protection of joint capsule</li> </ul>	<ul style="list-style-type: none"> <li>Hip ROM               <ul style="list-style-type: none"> <li>Active-assistive ROM on first postop day, gradually progressing to active ROM. After anterior capsular modification, limit external rotation beyond 10° for 3–4 weeks,<sup>44,176</sup></li> <li>Stationary cycling within first postop week</li> <li>Full ROM permitted after 4 weeks postop</li> </ul> </li> <li>Strengthening and balance exercises               <ul style="list-style-type: none"> <li>Resistance exercises in weight-bearing and balance exercises when full weight bearing allowed</li> </ul> </li> </ul> <p>SLRs = straight-leg raises</p>

\*NOTE: Weight-bearing and ROM restrictions vary based on the underlying diagnoses that necessitated the arthroscopic procedure(s)

is used postoperatively. Ankle pumping exercises to reduce the risk of a deep vein thrombosis (DVT) and setting exercises (quadriceps and gluteal muscles) are routinely begun on postoperative day 1 and 2, respectively. Typically, if full, passive hip ROM is not achieved by 4 to 6 weeks after surgery, stretching exercises are initiated to increase hip muscle flexibility. Stabilization exercises, targeting lumbopelvic musculature, also are an integral component of the rehabilitation program.

Standing and ambulation with crutches or a walker while partial-weight bearing on the operated side can begin on the day of or after surgery. Before full-weight bearing is permitted, aquatic activities and ambulation can also begin after the incision is well healed. Resumption of functional activities occurs gradually, but typically sooner after labral resection, labral repair, or capsular modification than after microfracture, osteoplasty, or rim trimming.

**Sport-specific rehabilitation.** As postoperative rehabilitation for management of arthroscopic procedures for the hip has evolved during the past decade, guidelines for sport-specific training for the intermediate and advanced phases of recovery are being developed in clinical settings and published in the literature.<sup>175,176</sup>

## Total Hip Arthroplasty

One of the most widely performed surgical interventions for advanced arthritis of the hip joint is THA (Fig. 20.6). OA is the underlying pathology that accounts for most primary total hip procedures.<sup>37</sup>

## Indications for Surgery

The following are common indications for THA, sometimes referred to as total hip replacement:<sup>37,46,50,101</sup>

- Severe hip pain with motion and weight bearing with significant motion limitation as the result of joint deterioration and loss of articular cartilage associated with OA, RA or traumatic arthritis, ankylosing spondylitis, or osteonecrosis (avascular necrosis)
- Nonunion fracture, instability or deformity of the hip
- Bone tumors
- Failure of conservative management or of previous joint reconstruction procedures (osteotomy, resurfacing arthroplasty, femoral stem hemiarthroplasty, and primary THA)

Because the projected life span of primary THA procedures is about 20 years, they were historically used for patients older than 60 to 65 years of age or for the very inactive younger patient with multijoint involvement, such as RA.<sup>37,50</sup> However, with advances in component design, materials, and fixation, plus improvements in surgical techniques, THA is now an option for some younger (< 60 years of age), moderately active individuals.<sup>8,51</sup> These individuals are counseled by the surgeon to anticipate the need for revision arthroplasty later in life.

There are a number of instances in which THA is contraindicated. Absolute and relative contraindications are noted in Box 20.2.<sup>8,14,37</sup>

## Preoperative Management

Preoperative contact with a patient prior to elective surgery typically occurs on an outpatient basis individually or in

**FIGURE 20.6** Total hip arthroplasty. **(A)** The preoperative film of a severely degenerative hip joint demonstrates the classic signs of degenerative joint disease. Arrow A shows a narrowed joint space with superior migration of the femoral head; B shows osteophyte formation at the joint margins of both the acetabulum and femoral head; C shows sclerosis of subchondral bone on both sides of the joint surface; and D shows acetabular protrusion (a bony outpouching of the acetabular cup in response to the progressive superior and medial migration of the femoral head). **(B)** Postoperative film shows a total hip arthroplasty. Both the acetabular and femoral portions of the joint have been resected and replaced with prosthetic components. (From McKinnis, LN: Fundamentals of Musculoskeletal Imaging, ed. 4. Philadelphia: F.A. Davis, 2014, p 354, with permission.)

### BOX 20.2 Contraindications to Total Hip Arthroplasty

#### Absolute

- Active joint infection
- Systemic infection or sepsis
- Chronic osteomyelitis
- Significant loss of bone after resection of a malignant tumor or inadequate bone stock that prevents sufficient implant fixation
- Neuropathic hip joint
- Severe paralysis of the muscles surrounding the joint

#### Relative

- Localized infection, such as bladder or skin
- Insufficient function of the gluteus medius muscle
- Progressive neurological disorder
- Highly compromised/insufficient femoral or acetabular bone stock associated with progressive bone disease
- Patients requiring extensive dental work—dental surgery should be completed before arthroplasty
- Young patients who must or are most likely to participate in high-demand (high-load, high-impact) activities

a group several days before surgery. Patient information sessions often are coordinated and conducted by a team of professionals from multiple disciplines who are likely to be involved with a patient's postoperative care. These sessions typically include a combination of patient education, assessment and documentation of the patient's preoperative status, and instruction regarding a pre-surgical exercise program.<sup>13,94,112,126</sup> Box 20.3 summarizes possible components of preoperative management.<sup>13,66,94,112,126</sup>

### FOCUS ON EVIDENCE

Wang and colleagues<sup>166</sup> conducted a randomized, controlled investigation to determine if a customized exercise program initiated before scheduled THA had an effect on the ambulatory abilities of patients after surgery. Gait function was evaluated with the 25-Meter Walk Test and the 6-Minute Walk Test. Participants in the exercise group ( $n = 15$ ) took part in two facility-based and two home-based exercise sessions of stationary bicycling and resistance training each week for 8 weeks prior to surgery. Individualized exercise programs resumed at 3 weeks postoperatively and continued through 12 weeks. Control group subjects ( $n = 13$ ) received only advice routinely provided by a hospital physical therapist. At 3 weeks postoperatively, the exercise group demonstrated significantly greater gait velocity and stride length, and at 12 weeks, they demonstrated significantly greater 6-minute walking distance than the control group. The investigators concluded that a customized strength and endurance training program prior to and after THA improved the rate of recovery of ambulatory function.

### BOX 20.3 Components of Therapy-Related Preoperative Management: Preparation for Total Hip Arthroplasty

- Examination and evaluation of pain, ROM, muscle strength, balance, ambulatory status, leg lengths, gait characteristics, use of assistive devices, general level of function, and perceived level of disability. Consider gathering preoperative information using a valid outcome measure, such as the Harris Hip Score, Hip Outcome Score, or Lower Extremity Functional Scale.
- Information for patients and their families about joint disease and the operative procedure in nonmedical terms.
- Postoperative precautions and their rationale including positioning and weight bearing.
- Functional training for early postoperative days including bed mobility, transfers, and gait training with assistive devices.
- Early postoperative exercises.
- Criteria for discharge from the hospital.

## Procedures

### Background

**Prosthetic designs and materials.** THA has been performed successfully since the early 1960s.<sup>37,50</sup> Sir John Charnley,<sup>29</sup> a surgeon from England, is credited with the initial research and clinical application of total hip replacement, which has evolved into contemporary hip arthroplasty. A variety of implant designs, materials, and surgical approaches have been developed and modified over the years.<sup>37,50,69</sup> Today, total hip implant systems are typically composed of an inert metal (cobalt-chrome and titanium) modular femoral component and a high-density polyethylene acetabular component. Occasionally, metal-on-metal<sup>69,149</sup> and ceramic surfaces are used in the design.<sup>37,69</sup>

**Cemented versus cementless fixation.** The revolutionary aspect of the early THA procedures was the use of acrylic cement (methyl methacrylate) for prosthetic fixation. Cement fixation allowed very early postoperative weight bearing, which shortened the period of rehabilitation, whereas prior to the use of cement fixation patients were subjected to months of restricted weight bearing and limited mobility.<sup>37</sup> Although cement fixation has its drawbacks, it continues to be used regularly today, particularly in THA for elderly and physically inactive younger patients.<sup>15,69,125,135</sup>

A significant postoperative complication associated with cement fixation is aseptic (mechanical) loosening of the prosthetic components at the bone-cement interface. This loosening subsequently leads to a gradual recurrence of hip pain and the need for surgical revision.<sup>15,37,135</sup> Patients who most often develop implant loosening are the younger, physically active patients. In contrast, loosening has not been shown to

be a particularly prevalent problem in elderly patients or in young patients with multijoint involvement and limited physical activity.<sup>50,135</sup>

The problem of mechanical loosening gave rise to the development and use of cementless (biological) fixation.<sup>37,50</sup> Cementless fixation is achieved by using implants that allow osseous ingrowth into a porous beaded or textured surface or by a precise press-fit technique.<sup>17,85,160</sup> Smooth (nonporous) femoral components also are being used with cementless arthroplasty. Some components are manufactured with a coating of a bioactive compound called hydroxyapatite, designed to promote initial osseous ingrowth.<sup>28</sup> Ingrowth of bony tissue occurs over a 3- to 6-month period with continued bone remodeling beyond that time period. Initial long-term studies of cementless fixation have demonstrated better fixation durability of the acetabular component than of the femoral stem component.<sup>69</sup>

Improvements in both cemented and cementless fixation continue, as does debate over the indications, benefits, and disadvantages of both forms of fixation. Cementless fixation is more often the choice for the patient under 60 years of age who is physically active and has good bone quality.<sup>17,85,160</sup> Its use continues to grow as the average age of the patient undergoing THA decreases and improvements in femoral stem fixation evolve.<sup>69</sup> However, cement fixation continues to be used routinely for elderly patients and those with osteoporosis and poor bone stock.<sup>15,125,135</sup> In some cases a combination of fixation procedures, known as a hybrid procedure, involving a cementless acetabular component and a cemented femoral stem component is used.<sup>113</sup>

### Operative Overview

The operative approaches used to gain access to the involved joint and to implant the prosthetic components during THA can be divided into two broad categories: *traditional (conventional or standard)* and *minimally invasive* approaches. Original hip arthroplasty procedures used long surgical incisions (15 to 25 cm) to expose the joint. Although long-term outcomes have been successful, *traditional* surgical approaches impose substantial trauma to soft tissues that may increase the postoperative recovery period.

A recent advance in primary hip arthroplasty—the use of minimally invasive approaches through “mini-incisions”—allows adequate exposure of the joint for insertion of the prosthetic components while decreasing soft tissue trauma. Brief overviews of the various types of *traditional* and minimally invasive surgical approaches follow, focusing on which muscles are incised or left intact during the procedure.<sup>3,42,59,69,71,88</sup> The integrity of the muscles and other soft tissues surrounding the prosthetic hip influences its postoperative stability and the extent of restrictions placed on the patient, most notably during the early phase of postoperative recovery.

**Traditional surgical approaches.** There are several approaches that may be used during traditional THA procedures: posterior (or posterolateral), lateral, anterolateral,

anterior, and transtrochanteric. Each has its advantages and disadvantages.<sup>3,42,59</sup> In addition to the following information, ONLINE Table 20.1 (available on the FA Davis website) summarizes the key features of each approach and their potential impact on function.

- **Posterior or posterolateral approaches.** These are the most frequently used approaches for primary THA. To access the joint through a posterior approach, the gluteus maximus is split in line with the muscle fibers. With a posterolateral approach, the interval between the gluteus maximus and medius is split. The piriformis and short external rotator tendons are transected near their insertion. The capsule is incised, and the gluteus maximus tendon may be released from its insertion on the femur in preparation for posterior dislocation of the hip and insertion of the components. Although an intact gluteus medius may result in earlier recovery of a normal gait pattern after surgery, the primary disadvantage of this approach is that it is associated with the highest incidence of postoperative joint instability and resulting subluxation or dislocation of the hip.<sup>71,81,106,107</sup> To reduce the risk of postoperative dislocation, repair of the posterior capsule and muscles is advocated to improve the soft tissue constraint to the posterior aspect of the joint.<sup>30</sup>
- **Direct lateral approach.** This approach requires longitudinal division of the tensor fasciae latae (TFL), release of up to one-half of the proximal insertion of the gluteus medius, and longitudinal splitting of the vastus lateralis.<sup>3,59</sup> The gluteus minimus also is partially detached from the trochanter. A lateral approach may also involve a trochanteric osteotomy. Disruption of the abductor mechanism is associated with postoperative weakness of this muscle group, leading to gait abnormalities such as a positive Trendelenburg sign.
- **Anterolateral approach.** With this approach, an incision is centered over the greater trochanter, lateral to the TFL. The IT band is split, and the anterior one-third of the gluteus medius and minimus are detached from their insertion on the greater trochanter to be reattached at closure.<sup>71,88,96</sup> In some instances, the anterior one-third of the vastus lateralis is detached as well.<sup>96</sup> Unlike the posterior/posterolateral approach, the external rotators usually remain intact in the anterolateral approach. A capsulotomy is performed and the hip dislocated anteriorly for adequate exposure of the joint. Although this approach allows for precise implant positioning, leg length correction, and excellent postoperative stability, it is associated with delayed recovery of the abductor muscles. Consequently, postoperative gait asymmetries persist for a longer period of time than with an anterior approach.<sup>88</sup> Compared with the posterior approach, the incidence of postoperative dislocation is lower in the anterolateral approach.<sup>37,59</sup> Therefore, it is also indicated for patients with muscle imbalances associated with stroke or cerebral palsy whose standing posture is characterized by hip flexion and internal rotation joint positions that place them at high risk of dislocation with a posterior approach.<sup>3,59</sup>

- **Anterior approach.** An incision is made lateral and distal to the anterior superior iliac spine, slightly anterior to the greater trochanter, and medial to the TFL. Although no muscles are detached with this approach, the rectus femoris and sartorius are retracted medially for exposure of the joint. The capsule is incised, and the hip is dislocated anteriorly in preparation for insertion of the components.<sup>88</sup> A key advantage of the direct anterior approach is that weight bearing as tolerated is permitted immediately after surgery. However, this approach is used infrequently for primary THA because visualization of the surgical field is more challenging.
- **Transtrochanteric approach.** This approach was first used with very early primary THA<sup>29</sup> but is now used primarily in complex revision arthroplasty. The transtrochanteric approach involves an osteotomy of the greater trochanter at the insertion of the gluteus medius and minimus and affords excellent exposure for insertion of the prosthetic components.<sup>71</sup> Following component placement, the trochanter is reattached and wired in place to stabilize the osteotomy site. The trochanter is often reattached in a position to improve the mechanical efficiency of the gluteus medius muscle.<sup>3,59</sup> An extended period of nonweight bearing and adherence to abduction precautions are required until bony healing has occurred. Complications associated with trochanteric osteotomy include nonunion and greater than usual soft tissue irritation and pain from a considerable amount of internal fixation.

**Minimally invasive approaches.** As with traditional THA, minimally invasive THA is an open procedure. With minimally invasive procedures, however, the joint is approached through one or two small incisions, usually less than or equal to 10 cm in length.<sup>14</sup> The characteristics of minimally invasive approaches for THA are summarized in Box 20.4.

The rationale for choosing minimally invasive THA over traditional THA is that the smaller incisions and muscle-sparing techniques reduce soft tissue trauma during surgery, potentially improving and accelerating a patient's postoperative recovery.<sup>9,14</sup>

Benefits cited by advocates of minimally invasive THA are:<sup>3,9,13,14,71,140</sup>

- Decreased blood loss.
- Reduced postoperative pain.
- Shorter length of hospital stay and lower cost of hospitalization.
- More rapid recovery of functional mobility.
- Better cosmetic appearance of the surgical scar.

Proponents of minimally invasive THA note that the procedures are more technically challenging, specifically with regard to insertion and alignment of the prosthetic components.<sup>4,10,170</sup> Depending on the surgeon's experience with the new approach and selection of patients, there is speculation that rates of postoperative complications will be higher.<sup>4,10</sup> In general, the results of studies have supported the in-hospital benefits of minimally invasive THA, such as less blood loss, less postoperative

#### BOX 20.4 Features of Minimally Invasive Total Hip Arthroplasty

- Length of incision: < 10 cm, depending on the location of the approach and the size of the patient<sup>14,71</sup>
- Most, if not all, muscles and tendons left intact
- Single-incision or two-incision surgical approach
  - *Single incision:* posterior,<sup>52</sup> anterior,<sup>95,96,131</sup> or occasionally lateral.<sup>10,68</sup>
  - *Two-incision:* two 4- to 5-cm incisions, one anterior for insertion of acetabular component and one posterior for placement of femoral component.<sup>5,13,140,154</sup>
- Incision location and muscles disturbed
  - *Posterior approach:* an incision extending mostly distal to the greater trochanter between the gluteus medius and piriformis muscles; short external rotators may or may not be incised (later repaired); abductor mechanism consistently is left intact.<sup>52,170</sup>
  - *Anterior approach:* an incision beginning just lateral and distal of the anterior superior iliac spine extending in a distal and slightly posterior direction along the belly of the tensor fasciae latae (TFL); sartorius and rectus femoris retracted medially and the TFL laterally; leaves all muscles intact; no postoperative precautions.<sup>13,95,96,131</sup>
  - *Lateral approach:* least commonly used; splits the middle-third of the gluteus medius; anterolateral incision into the capsule leaves the posterior capsule intact, eliminating the need to observe postoperative precautions for prevention of posterior dislocation.<sup>10,68</sup>

pain, and shorter hospital stay, when compared with traditional THA.<sup>122,137,170</sup> However, the claim of rapid recovery of functional mobility, typically measured by gait analysis following minimally invasive versus traditional THA, has yet to be determined.<sup>42,96,131,137</sup>

Numerous studies have compared MI and traditional procedures for in-hospital and postsurgical outcomes for THA. The most recent systematic reviews and meta-analyses of these studies report some small but minor benefit to using minimally invasive surgery.<sup>18,151,171</sup> When a posterior approach is used in patients with degenerative hip disease, MI results in statistically significant improvement in operating time, length of hospital stay, blood loss, and the Harris Hip Score for function.<sup>18</sup> The authors of this analysis note that the higher Harris Hip Scores for patients who have had the MI procedure do not reach the threshold for a clinically important difference. When analyzing studies using all surgical approaches for a variety of diagnoses, MI results in reduced length of hospital stay and reduced blood loss, but no other surgical, functional, or radiological benefits.<sup>171</sup> Details of studies that have compared these procedures are summarized in the outcomes section on THA.

**Implantation of components and closure.** After dislocation of the joint, an osteotomy is performed at the femoral neck, and the head is removed. Another option used by some

surgeons for minimally invasive procedures is to cut the femoral neck *in situ* without dislocating the hip.<sup>13,95,154</sup> The acetabulum is reamed and remodeled, and a high-density polyethylene cup is inserted into the prepared surface.<sup>125</sup> The intramedullary canal of the femoral shaft may be broadened if necessary, and the stemmed, metal prosthesis is inserted into the shaft of the femur.<sup>15,135</sup> With both components in place, the alignment is checked radiographically and stability and ROM are assessed.

After the prosthetic hip is reduced, the capsule typically is repaired. The remaining layers of soft tissues that were incised or detached are securely repaired and appropriately balanced for length and mobility prior to closure.

### CLINICAL TIP

Although published resources contain a wealth of information about implant design, methods of fixation, and soft tissues incised or detached in the various conventional and minimally invasive surgical approaches for THA, the best resource a therapist can use to understand the unique features of a patient's surgery and then plan an individualized postoperative rehabilitation program is the operative report found in the patient's medical record.

### Complications

The incidence of intraoperative and early and late postoperative complications after primary, traditional THA is relatively low. However, some surgeons are concerned that minimally invasive procedures will result in a higher incidence of complications due to decreased visual exposure of the hip joint during surgery and the more technically demanding nature of the approaches.<sup>4,10</sup> To date, this concern has not been consistently supported by evidence-based studies.<sup>69,71</sup> Although only a small percentage of complications require revision arthroplasty, any complication can hamper rehabilitation and diminish functional mobility.

**Intraoperative complications.** Intraoperative complications associated with THA include malpositioning of the prosthetic components, femoral fracture, insufficient equalization of leg lengths, and nerve injury.

**Early postoperative complications.** In addition to the medical complications, such as infection, DVT, or pneumonia that can occur after any surgery, postoperative complications that may occur during the early period of recovery (before 6 weeks or up to 2 to 3 months) include infection or delayed wound healing, dislocation of the prosthetic joint, disruption of a bone graft site before sufficient bone healing has occurred, and a persistent functional leg-length discrepancy.<sup>106</sup>

**Late complications.** Late complications include mechanical loosening of either implant at the bone-cement or bone-implant interface; polyethylene wear; atraumatic or traumatic periprosthetic fracture; and, in rare instances, heterotopic

ossification.<sup>71</sup> Of these late complications, mechanical loosening of the components is by far the most common and typically requires revision arthroplasty.

**Dislocation: a closer look.** Dislocation of the operated hip is a complication that occurs most frequently during the first 2 to 3 months postoperatively when soft tissues around the hip joint are healing. The frequency of early dislocation after primary THA is reported to be less than 1% to slightly more than 10%, with a mean of just less than 2%.<sup>100</sup> During the first postoperative year, revision arthroplasty rates (5.1%) are higher than rates for primary THA (1.7%).<sup>73</sup> Most dislocations are nontraumatic, occur in a posterior direction,<sup>81,107</sup> and are usually associated with a posterior surgical approach.<sup>3,59</sup> Although less common, dislocation can also occur after anterior, anterolateral, and direct lateral approaches.<sup>81,107,129</sup> Patient-related and surgery/prosthesis-related risk factors that may contribute to dislocation are noted in Table 20.3.<sup>73,100</sup> Precautions to reduce the risk of dislocation after THA are addressed in the following section on postoperative management (see Box 20.6). Although a first-time dislocation usually can be managed with closed reduction and conservative treatment, recurrent dislocation after THA typically requires additional surgery.

**Leg length inequality: a closer look.** Leg length inequality is one of the more common complaints during the early

**TABLE 20.3** Risk Factors Contributing to Joint Dislocation After Total Hip Arthroplasty

Patient-Related Factors	Surgery/Prosthesis-Related Factors
<ul style="list-style-type: none"> <li>■ Age &gt; 80 to 85 years<sup>100,107</sup></li> <li>■ THA for femoral neck fracture</li> </ul>	<ul style="list-style-type: none"> <li>■ Surgical approach: higher risk with posterior than anterior, anterolateral, or lateral approaches</li> </ul>
<ul style="list-style-type: none"> <li>■ Medical diagnosis: higher risk in patients with inflammatory arthritis (mostly RA) than patients with OA<sup>73,174</sup></li> </ul>	<ul style="list-style-type: none"> <li>■ Design of femoral component: higher risk with smaller-sized femoral head<sup>73</sup></li> <li>■ Malpositioning of the acetabular component</li> </ul>
<ul style="list-style-type: none"> <li>■ Poor quality soft tissue from chronic inflammatory disease</li> <li>■ History of prior hip surgery</li> <li>■ Preoperative and postoperative muscle weakness (particularly the abductor mechanism)<sup>69</sup> and contractures</li> <li>■ Cognitive dysfunction, dementia</li> </ul>	<ul style="list-style-type: none"> <li>■ Inadequate soft tissue balancing during surgery or poor quality soft tissue repair</li> <li>■ Experience of the surgeon</li> </ul>

recovery period after THA and is associated with pain and a sense of instability and exertion while walking.<sup>33,128</sup> Quite often a functional leg length discrepancy and pelvic obliquity that is evident during standing and walking is the result of muscle spasm, muscle weakness (particularly the gluteus medius), and residual contracture of hip muscles. This type of leg length discrepancy usually resolves with conservative management during the first postoperative year.<sup>33</sup> However, a true leg length discrepancy may be the result of over-lengthening the limb during surgery, malpositioning of the prosthetic implants (usually the acetabular component), or recurrent postoperative dislocation. If significant, it may necessitate further surgery or revision arthroplasty.<sup>128</sup> Leg length differences of greater than 20 mm are associated with significant gait abnormalities and protracted low back pain.<sup>173</sup>

## Postoperative Management

### Early Mobilization

After THA, there is no need for immobilization of the operated hip. To the contrary, postoperative rehabilitation emphasizes early movement and patients are encouraged to regularly move the hip through allowed ROM. An exception to this postoperative strategy may be required when the patient is lying supine in bed, depending on the surgical approach used and the stability of the prosthetic hip. In such cases, the operated limb is positioned in slight abduction and neutral rotation using an abduction pillow or wedge.<sup>94</sup>

### Weight-Bearing Considerations

After cemented THA, patients are usually permitted to bear as much weight as tolerated almost immediately after surgery.<sup>15,125,135</sup> In contrast, with cementless or hybrid THA, weight bearing on the operated limb is often restricted for the first few weeks or more. A number of factors affect the extent and duration of postoperative weight-bearing restrictions. Box 20.5 summarizes these factors.

Although it has been customary to limit weight bearing after cementless and hybrid THA,<sup>17,160</sup> this practice deserves a closer look. The rationale for restricted weight bearing is based on the assumption that early, excessive loading of the operated limb could cause micromovement at the bone-implant interface, thereby jeopardizing the initial stability of the implant(s), interfering with osseous ingrowth, and contributing to eventual loosening of the prosthetic implants. There is little evidence, however, to support these concerns.<sup>65</sup>

Moreover, there are potential benefits to safe levels of early weight bearing after THA, specifically the reduction of bone demineralization from decreased weight bearing and earlier recovery of functional mobility.<sup>20,22</sup> Gradually progressed weight bearing also promotes activation of the weakened hip abductor muscles for stabilization of the pelvis and a more symmetrical gait pattern.<sup>65</sup>

To further strengthen the case for early weight bearing as tolerated, it has been established that many patients have

## BOX 20.5 Early Postoperative Weight-Bearing Restrictions After Total Hip Arthroplasty

### Method of Fixation

- *Cemented.* Immediate postoperative weight bearing as tolerated.<sup>15,94,125</sup>
- *Cementless and hybrid.* Recommendations vary from partial weight bearing (toe-touch or touch-down) for at least 6 weeks<sup>17,76,81,97</sup> to weight bearing as tolerated (no restrictions) immediately after surgery.<sup>13,20,22</sup>

### Surgical Approach

- *Traditional versus minimally invasive.* Weight bearing usually more restricted after standard (traditional) approach because of more extensive surgical disturbance and repair than minimally invasive approach.<sup>14</sup> Weight bearing as tolerated may be permissible immediately after minimally invasive procedure.<sup>13</sup>
- *Trochanteric osteotomy.* Although used infrequently, restricted weight bearing at least 6 to 8 weeks or possibly 12 to 16 weeks for bone healing.

### Other Factors

- *Use of bone grafts.* Nonweight bearing or restricted weight bearing during bone healing.
- *Poor quality of patient's bone.* Extended restrictions so as not to jeopardize the stability of the prosthetic implants.

difficulty learning and integrating prescribed weight-bearing limitations into daily functional activities and consequently place greater loads than recommended on the operated extremity, particularly once postoperative pain has subsided.<sup>162</sup> For example, a recent analysis of walking on level surfaces and stairs showed that THA patients had foot loads of between 41% and 88% of their peak presurgical loading, even after being trained with a scale to use only 10% loading.<sup>143</sup> It is also known that some resisted movements of the lower extremity performed in the supine position impose loads on the hip considerably greater than body weight.<sup>120</sup>

In light of these considerations, the need for weight-bearing restrictions after cementless THA is being re-examined.

## FOCUS ON EVIDENCE

Several randomized, controlled investigations have demonstrated that immediate weight bearing as tolerated after cementless or hybrid hip arthroplasty does not result in higher rates of adverse effects.<sup>20,22,74</sup> Bottner et al<sup>22</sup> compared patients who were allowed immediate weight bearing with no restrictions to a group restricted to toe-touch weight bearing with the use of two crutches for 6 weeks. Boden et al<sup>20</sup> evaluated an immediate weight-bearing group that initially used one crutch to a group using two crutches and limited to 10% body weight for 3 months. Kishida et al<sup>74</sup> compared a group

that was allowed full weight bearing on the second day after surgery to a group limited to touchdown weight bearing for 3 weeks, partial weight bearing for the next 6 weeks, and full weight bearing at 6 weeks. None of the studies found significant between group differences in adverse effects, including implant fixation integrity, for up to 5 years after surgery. The authors suggest that early weight bearing as tolerated after cementless or hybrid primary THA can be safe in younger patients (< 60 to 65 years of age) with excellent bone quality. It is important to note that patients in these studies were relatively young compared with most patients undergoing hip arthroplasty.

A systematic review of the literature comparing unrestricted to restricted weight bearing notes moderate to strong evidence in support of immediate weight bearing to tolerance for a young, healthy population following cementless primary THA.<sup>65</sup> However, in the clinical setting, the responsibility of determining the need for protected weight bearing during the early phase of postoperative rehabilitation after THA remains with the surgeon.

### Exercise Progression and Functional Training

Therapeutic exercise has been part of postoperative rehabilitation for patients after THA for many years. Despite this, the optimal exercises and their doses are not fully established, perhaps because surgical procedures and approaches continue to evolve and interventions are still adapting to these changes. A consensus survey on physical therapy-related intervention for early inpatient total hip rehabilitation was a step forward in the development of consistent guidelines for postoperative THA management,<sup>43</sup> although many of the exercises and functional activities identified in this document have not been evaluated for effectiveness or efficacy.<sup>104</sup> The goals, guidelines, and precautions for exercise and functional activities after primary THA discussed in this section represent not only those interventions identified in the aforementioned consensus survey, but also exercises and activities selected from current literature.<sup>24,40,62,94,112,123,166</sup>

### FOCUS ON EVIDENCE

Several single-subject studies have measured *in vivo* hip forces acting and acetabular contact pressures during exercise and gait.<sup>53,79,80,152</sup> Although these studies analyzed only two patients after insertion of a femoral endoprosthesis, not a total joint replacement, the results raise questions about assumptions made by clinicians regarding the selection and progression of exercises and functional activities during THA rehabilitation. The results suggest that some active or resistive exercises—such as maximal effort gluteal setting, unassisted heel slides, and manually resisted isometric abduction—may generate acetabular contact pressures that are greater than weight-bearing contact pressures.<sup>53,152</sup>

### Accelerated Rehabilitation

One change in postoperative management is the trend toward accelerated rehabilitation, particularly for patients under 60 to 65 years of age who have undergone minimally invasive THA and wish to resume an active lifestyle as quickly as possible following surgery.<sup>13,41</sup> Although “accelerated rehabilitation” following minimally invasive THA has not been clearly defined, two characteristics stand out—a rapid progression to full weight bearing during ambulation and discontinuing crutch and cane use as soon as possible.

There is concern, however, that progressing ambulation at this rate in the presence of postoperative strength and balance deficits could result in persistent gait asymmetries, increase the risk of injury, or jeopardize short- and long-term outcomes.<sup>42</sup> In addition, during functional activities that require endurance, persistent muscular weakness and fatigue may increase the stresses placed on the prosthetic hip, thereby contributing to biomechanical loosening of the components over time.<sup>147</sup>

Therefore, before discontinuing use of an ambulation aid, it is important to regain sufficient strength of the hip abductors and extensors to maintain stability and symmetry during ambulation. With this in mind, it is clear that an individualized program of strengthening exercises must be an integral component of accelerated rehabilitation.<sup>65</sup>

### Exercise: Maximum Protection Phase After Traditional THA

Common impairments exhibited by patients during the acute and subacute stages of soft tissue healing and the initial phase of rehabilitation after THA are pain secondary to the surgical procedure, decreased ROM, muscle guarding and weakness, impaired postural stability and balance, and decreased functional mobility (transfers and ambulation activities). Depending on the type of component fixation used and the surgeon’s preference, weight-bearing restrictions may also interfere with some functional activities.

The emphasis of this phase of rehabilitation after a conventional surgical approach is on patient education to reduce the risk of early postoperative complications, in particular dislocation of the operated hip. (Risk factors for dislocation after THA are noted in Table 20.3.) Precautions during functional activities are determined by the surgical approach used and input from the surgeon about the intraoperative stability of the hip replacement (Box 20.6).<sup>81,94,106,107,129</sup>

Selected exercises and functional training begin as soon as the patient is medically stable, typically the day of surgery when possible. The frequency of treatment by a therapist is often twice a day until the patient is discharged from the hospital.<sup>43,123</sup> The average length of hospitalization after a THA is age dependent, with younger patients averaging 3 days and older patients 4 days.<sup>169</sup>

**Goals and interventions.** The following goals and interventions apply to the initial postoperative days while the patient is hospitalized and continue through the first few weeks after

**BOX 20.6 Early Postoperative Motion Precautions After Total Hip Arthroplasty\*****Posterior/Posterolateral Approaches****ROM**

- Avoid hip flexion > 90° and adduction and internal rotation beyond neutral.

**ADL**

- Transfer to the sound side from bed to chair or chair to bed.
- Do not cross the legs.
- Keep the knees slightly lower than the hips when sitting.
- Avoid sitting in low, soft chairs.
- If the bed at home is low, raise it on blocks.
- Use a raised toilet seat.
- Avoid bending the trunk over the legs when rising from or sitting down in a chair or dressing or undressing.
- When bathing, take showers, or use a shower chair in the bathtub.
- When ascending stairs, lead with the sound leg; when descending, lead with the operated leg.
- Pivot on the sound lower extremity.
- Avoid standing activities that involve rotating the body toward the operated extremity.
- Sleep in supine position with an abduction pillow; avoid sleeping or resting in a side-lying position.

**Anterior/ anterolateral and Direct Lateral Approaches****ROM**

- Avoid hip flexion > 90°. \*\*
- Avoid hip extension, adduction, and external rotation past neutral.
- Avoid the combined motion of hip flexion, abduction, and external rotation.

- If the gluteus medius was incised and repaired or a trochanteric osteotomy was done, do not perform active, antigravity hip abduction for at least 6 to 8 weeks or until approved by the surgeon.

**ADL**

- Do not cross the legs.
- During early ambulation, step to, rather than past, the operated hip to avoid hyperextension.
- Avoid activities that involve standing on the operated extremity and rotating away from the involved side.

**Transgluteal Approach (Trochanteric Osteotomy)\*\*\*****ROM**

- Avoid hip adduction past neutral
- No active, antigravity hip abduction for at least 6 to 8 weeks or until approved by the surgeon
- No exercises that involve weight bearing on the operated leg

**ADL**

- Sleep in supine position with abduction pillow
- Do not cross legs
- Maintain weight-bearing restrictions during all ADLs

\*Precautions apply to traditional total hip arthroplasty and may or may not be necessary after minimally invasive procedures, depending on the surgeon's guidelines.

\*\*Although a posterior surgical approach is associated with the highest risk of dislocation, all patients routinely are asked to limit hip flexion to < 90° and rotation to < 45° for about 6 weeks regardless of the surgical approach used.<sup>129</sup>

\*\*\*Follow weight-bearing restrictions for 6 to 8 weeks or up to 12 weeks for bone healing to occur.

surgery when the patient is at home or in a subacute health-care or skilled nursing facility.

- **Prevent vascular and pulmonary complications.**
  - Ankle pumping exercise to prevent venous stasis, thrombus formation, and the potential for pulmonary embolism.
  - Deep breathing exercise and bronchial hygiene until the patient is regularly mobile to prevent postoperative atelectasis or pneumonia.
- **Prevent postoperative dislocation or subluxation of the operated hip.**
  - Patient and caregiver education about motion restrictions, safe bed mobility, transfers, and precautions during ADLs (see Box 20.6).
  - Monitor the patient for signs and symptoms of joint dislocation, such as shortening of the operated lower extremity.
- **Achieve independent functional mobility prior to discharge.**
  - Bed mobility, rising from and sitting down in a chair, and transfer training, emphasizing proper trunk and lower extremity alignment and integrating weight-bearing and motion restrictions.

**CLINICAL TIP**

Rising from a low chair imposes particularly high-loads across the hip joint, producing loads approximately eight times the patient's body weight.<sup>120</sup> If the posterior capsule was incised during surgery, this places the involved hip at a high risk of posterior dislocation until soft tissues around the hip joint have healed sufficiently (at least 6 weeks) or until the surgeon indicates that unrestricted functional activities are permissible. Therefore, teach the patient the importance of sitting only on a chair with an elevated seat and to avoid sitting on soft, low furniture.

- Ambulation with an assistive device (initially a walker or two crutches) immediately after surgery, adhering to weight-bearing restrictions and gait-related ADL precautions. Emphasize a stable, symmetrical gait pattern. Progress to one crutch or a cane depending on pain, strength of hip abductors, and gait symmetry.
- Stair training with an assistive device, both ascending and descending, initially one step at a time.

**PRECAUTION:** Even if a patient is permitted to bear full weight on the operated extremity and discontinue crutch or cane use as tolerated, have the patient continue to use an ambulation aid when ascending and descending stairs during the first few weeks after surgery to reduce the risk of placing excessive torsional forces on the prosthetic hip joint.<sup>65</sup>

■ **Maintain a functional level of strength and muscular endurance in the upper extremities and nonoperated lower extremity.**

■ Active-resistive exercises in functional movement patterns, targeting muscle groups used during transfers and ambulation with assistive devices.

■ **Prevent reflex inhibition and atrophy of musculature in the operated limb.**

■ *Submaximal* muscle-setting exercises of the quadriceps, hip extensor, and hip abductor muscles—just enough to elicit a muscle contraction.

**PRECAUTION:** If a trochanteric osteotomy was performed, avoid even low-intensity isometric contractions of the hip abductors during the early postoperative phase unless initially approved by the surgeon and performed strictly at a minimum intensity. (See Box 20.6 for additional precautions after trochanteric osteotomy.)

■ **Regain active mobility and control of the operated extremity.**

■ While in bed, active-assistive ROM exercises of the hip within protected ranges.

■ Active knee flexion and extension exercises while seated in a chair, emphasizing terminal knee extension.

■ Active hip rotation, maintaining motion limitations based on the surgical approach.

■ If the status of the abductor muscles permits, active, gravity-eliminated hip abduction in the supine position by sliding the leg on a low-friction surface or active antigravity abduction combined with external rotation (clam exercise) in the side-lying position (with a pillow between the thighs to prevent hip adduction past neutral).

■ Active hip ROM (forward and backward pendular motions) in the standing position with the hands on a stable surface to maintain balance.

■ Bilateral, closed-chain, weight-shifting activities, heel raises, and mini-squats, while maintaining symmetrical alignment and weight-bearing limitations on the operated extremity.

■ **Prevent a flexion contracture of the operated hip.**

■ Avoid use of a pillow under the knee of the operated extremity while in supine.

**Criteria to progress.** The criteria to advance to the next phase of rehabilitation is highly dependent on weight-bearing and ROM restrictions; however, the following criteria typically must be met:

■ Well-healed incision; no signs of wound drainage or infection

■ Independent level-ground ambulation with one crutch or a cane or no assistive device if weight-bearing restrictions permit

■ Ability to bear full weight on the operated extremity without pain and with a fully extended knee

■ Functional ROM of the hip

■ Muscle strength of operated hip: at least 3/5

**Exercise: Moderate Protection Phase After Traditional THA**

After traditional THA, the intermediate phase of rehabilitation begins at about 4 to 6 weeks postoperatively. Full weight bearing may be permitted for some patients, but some degree of protection may be necessary for 12 weeks postoperatively for others. The extent of protection of the operated hip varies substantially based on the surgical approach, the type of fixation used, and the surgeon's preference. Full healing of soft tissue and bone continues for up to a year after surgery.

The exercises described for this phase may be carried out under therapist supervision or as part of a home program. Exercises and functional training focus on restoring muscle strength (particularly the hip abductors and extensors), postural stability and balance, a symmetrical gait pattern, muscular and cardiopulmonary endurance, and functional ROM. Exercises that target impairments in other body regions can also be included to improve overall function.

Postoperative precautions during ADL may continue for at least 12 weeks and sometimes considerably longer.<sup>94,112</sup> Patient education should focus on the return to anticipated activities in the home, workplace, or recreational setting.

**Goals and interventions.** The following are the goals and interventions for the intermediate (moderate protection) phase of rehabilitation:

■ **Regain strength and muscular endurance, emphasizing strength of hip abductors and extensors.**

**PRECAUTION:** The initiation and progression of resistance training to strengthen hip abductor muscles depends on the integrity of the abductor mechanism, which can be compromised during some surgical approaches. Likewise, progressing from bilateral to unilateral closed-chain training depends on when full weight bearing on the operated extremity is permitted.

■ While standing on the sound lower extremity, open-chain exercises within the permissible ranges in the operated leg against light resistance. Initially, emphasize increasing the number of repetitions rather than the resistance to improve muscular endurance.

■ Bilateral, closed-chain exercises to strengthen hip and knee extensors, such as mini-squats against light-grade elastic resistance or while holding light weights in both hands when unsupported standing, are permitted. Reinforce symmetrical alignment of the lower extremities during standing exercises.

■ Unilateral, closed-chain exercises, such as hip hiking or forward and lateral step-ups (to a low step) while standing on the operated extremity and partial lunges

with the involved foot forward when full weight bearing, are permitted on the operated lower extremity. During step-ups and lunges, apply elastic resistance around the lateral thigh of the operated extremity to simultaneously strengthen the hip abductors and hip extensors.

- **Improve cardiopulmonary endurance.**
  - Nonimpact aerobic conditioning program, such as progressive stationary cycling, swimming, or water aerobics.
- **Restore ROM while adhering to precautions.**
  - Gravity-assisted supine stretch to neutral in the Thomas test position. Pull the uninjured knee to the chest while relaxing the operated hip. (At least 10° of hip extension beyond neutral is needed for a normal gait pattern.)
  - Resting in a prone position for a prolonged passive stretch of the hip flexor muscles.
  - Integrate gained ROM into functional activities.

**PRECAUTION:** Check with the surgeon before initiating a stretch of the hip flexors to neutral or into hyperextension, particularly if an anterior or anterolateral approach was used during surgery. In addition, prone lying may not be permissible or comfortable for the patient at this time.

- **Improve postural stability, balance, and gait.**
  - Progressive balance activities in standing (see Chapters 8 and 23.)
  - Gait training, emphasizing an erect trunk, vertical alignment, equal step lengths, and a neutral symmetrical alignment of the pelvis and extremities.
  - If full weight bearing is not yet permitted, continue or progress to use of a cane (in the hand *contralateral* to the operated hip) and progress weight bearing on the operated limb. Practice walking on uneven and soft surfaces to challenge the balance system.
  - Continue cane use until weight-bearing restrictions are discontinued or if the patient exhibits gait deviations, such as a positive Trendelenburg sign on the operated lower extremity, indicating hip abductor weakness. Cane use is also recommended during extended periods of ambulation to decrease muscle fatigue.
  - For selected patients, consider treadmill walking to practice a symmetrical gait pattern.

### FOCUS ON EVIDENCE

Use of a cane in the contralateral hand by patients after a hip replacement has been shown to decrease electromyographic (EMG) activity in the hip abductor muscles to a significant degree regardless of whether moderate or near-maximum force is applied on the cane.<sup>116</sup> In the same study, ipsilateral cane use produced no significant decrease in EMG activity in the hip abductor muscles. The degree to which the decreases in EMG activity reflected a reduction in forces imposed on the prosthetic hip joint was not determined in this study. However, in single-subject studies of two patients with femoral endoprostheses, acetabular contact pressures were reduced by using a cane in the contralateral hand.<sup>53,79,80</sup>

**Criteria to progress.** The criteria to progress to advanced training during a final phase of rehabilitation include the following:

- Pain-free ambulation with or without a cane
- Functional ROM and strength of the operated hip
- Independence in ADL

### Exercise: Minimum Protection Phase and Resumption of Full Activity

After traditional THA, the final phase of rehabilitation begins when the patient has met the criteria to progress. This usually occurs around 12 weeks postoperatively. Continued training for restoration of strength, muscular and cardiopulmonary endurance, balance, and a symmetrical gait pattern should be the focus of this phase, coupled with a gradual resumption or modification of functional activities. Return to a full level of functional activities may take at least a year.<sup>132</sup>

### Extended rehabilitation and modification of activities.

Weakness of the hip abductors leading to pelvic obliquity and an asymmetrical gait pattern often presents preoperatively in patients with hip OA and has been shown to persist in some patients for months following THA.<sup>147</sup> With this in mind, patients, especially those wishing to return to an active lifestyle, may benefit from an extended strength training program that targets the hip musculature.

If ongoing rehabilitation services are available to a patient, the following activities should be considered:

- Integrate strength, endurance, and balance training into simulated functional activities to prepare for independence.
- To improve muscular and cardiopulmonary endurance, progressively increase the length of time and distance of a low-intensity walking program. Aim for a target frequency of 2 to 4 days a week for 30 minutes each session for the walking program.
- Through patient education, reinforce the importance of selecting or modifying activities to reduce or minimize the forces and demands placed on the prosthetic hip. When a patient's employment involves heavy labor, vocational retraining or an adjustment in work-related activities is advised.

### CLINICAL TIP

When walking and carrying a heavy object in one hand, suggest that the patient hold it on the same side as the operated hip. EMG studies have shown that under these circumstances the forces imposed on the abductor muscles of the operated hip are significantly lower than when the load is carried on the contralateral arm. This was found to hold true with and without cane usage.<sup>114,115</sup> Theoretically, this reduces the amount of stress imposed on the hip replacement over time.

**Return to sport activities.** The younger, active patient who has undergone THA usually has a desire to resume sport-related or fitness activities at some point following surgery.

Several factors, including the level of demand or degree of impact or twisting movements involved in the activity, the frequency of repetitive motions, and the potential for falls or contact, influence a surgeon's recommendation or approval for a patient to participate in various athletic activities. A patient's body weight, overall level of fitness, and his or her experience with the activity prior to surgery also affect whether or not an activity is allowable.<sup>34,61,75,97</sup>

To prolong the life of the hip replacement, a patient is routinely advised to refrain from high-impact sports and recreational activities. Activities that impose heavy rotational forces on the operated hip are of particular concern and could contribute to long-term loosening and wear of the prosthetic implants and eventual failure of the hip replacement. However, with a foundation of sufficient strength, endurance, balance, and use of proper biomechanics during functional activities, a patient can gradually and safely return to low- and moderate-impact sports and fitness activities following THA.

Table 20.4 lists the sports-related, recreational, and fitness activities highly recommended, recommended with caution, or not recommended based on a 2007 survey and the consensus of arthroplasty surgeons' opinions.<sup>75</sup> Ninety percent of the surgeons responding agreed that patients could return to selected activities by 6 months after undergoing THA.

### Outcomes

**Pain relief, patient satisfaction, and quality of life.** Most studies evaluating patient satisfaction, perceived levels of pain, function, and quality of life after THA reflect a marked decrease in pain and improvement in function.<sup>84,132</sup> However, patient's and surgeon's perceptions of satisfaction do not always agree. Lieberman and associates<sup>87</sup> demonstrated that when a patient reported little or no pain following THA, the patient's and surgeon's assessments of pain and level of satisfaction were similar. However, when patient's reported continuing pain after THA, there was less agreement between the patient's and surgeon's assessments of the level of patient satisfaction. This result explains

why there is a need for outcome assessments from both the patient and the health-care professional.

Several factors may contribute to unsatisfactory outcomes following THA. Fortin and colleagues<sup>48</sup> investigated the timing of THA and subsequent outcomes and determined that, not surprisingly, patients who had the worst physical function and pain before surgery had the poorest outcomes 2 years after surgery. Another long-term, prospective study (mean 3.6 years) of patients who had undergone unilateral THA for OA also confirmed that a higher preoperative level of pain predicted poorer outcomes.<sup>119</sup> This study also revealed that an older age at the time of surgery and the presence of postoperative low back pain were predictors of poor self-assessed outcomes.<sup>119</sup>

**Physical functioning.** Improvements in ROM, postural stability, strength, and functional mobility occur gradually after THA. Patients typically achieve 90% of their expected level of overall functional improvement by the end of the first post-surgical year. Over the next 1 to 2 years, patients report additional gains in strength and improved function, reaching a plateau at approximately 2 to 3 years after surgery.<sup>132</sup>

Trudelle-Jackson and colleagues<sup>161</sup> evaluated ROM, static muscle strength, and single-leg balance in a group of 15 patients with a mean age of 62 years (range, 51 to 77 years) 1 year after unilateral, primary THA. They found no significant differences in ROM between the operated and uninvolved hips and small—but not statistically significant—differences in the strength of hip and knee musculature. However, they did find substantial differences between the operated leg and the uninvolved leg for all parameters of balance measured during a one-leg stance. In addition, patients' self-assessed levels of physical function were moderately associated with muscle strength but only weakly with postural stability.

**Implant design, fixation, and surgical approach.** Several decades of studies indicate that both cemented and cementless THA result in equally positive postoperative outcomes in all

**TABLE 20.4** Guidelines for Participation in Sport, Recreational, and Fitness Activities Following THA<sup>75</sup>

areas of assessment, with the most consistent being pain reduction.<sup>85,135</sup> In-depth analyses and current information on outcomes of specific prosthetic designs, as well as outcome assessments of cemented, cementless, and hybrid procedures, can be found in the references previously cited in the operative overview of THA presented earlier in this chapter.

Woolson and colleagues<sup>170</sup> conducted a retrospective comparative study of 135 patients who had undergone primary, unilateral THA with either a standard posterior approach or a minimally invasive posterior approach. The participating surgeons determined which patients met the criteria for the minimally invasive procedure with regard to health history and body mass index. Consequently, the minimally invasive group was thinner and healthier than the conventional THA group. Despite this, there were no significant differences between the groups with respect to surgical outcomes (operating time, blood loss, need for transfusion) or in length of hospital stay or the percentage of patients discharged directly home. However, there was a higher rate of complications in the minimally invasive group, including wound complications, component malpositioning, and leg-length discrepancy. More recently, Goosen and colleagues reported no significant differences in perioperative blood loss or complications between subjects randomized to minimally invasive ( $n = 60$ ) and traditional ( $n = 60$ ) THA groups,<sup>56</sup> although mean operation times were shorter in the minimally invasive group. Similarly, Repantis and colleagues<sup>137</sup> noted no perioperative or immediate postoperative benefit to the minimally invasive approach over the traditional approach for THA. In this comparison, the same experienced surgeon performed either an anterior minimally invasive procedure ( $n = 45$ ) or an anterior traditional procedure ( $n = 45$ ). Although the minimally invasive group had lower pain intensity at 2 weeks postoperatively, there were no differences between groups for function or walking endurance.<sup>137</sup>

Ogonda and colleagues<sup>122</sup> conducted a randomized controlled trial comparing minimally invasive and traditional THA in 219 patients undergoing primary, unilateral, hybrid THA performed by the same surgeon. In both groups, a single incision, posterior approach was used, with the only differences being a shorter skin incision and less TFL disturbance during the minimally invasive approach. All patients participated in exercise and functional training after surgery. The only statistically significant group difference identified was less blood loss in the minimally invasive group, with no significant differences in postoperative pain and use of pain medication, ability to transfer and ambulate with an assistive device, length of hospital stay, or discharge to home or transitional facility. At 6 weeks postsurgery, there continued to be no significant differences between groups related to function or complications. Dorr and colleagues<sup>42</sup> reported similar in-hospital findings, with less pain on each postoperative day and a shorter hospital stay for a minimally invasive group compared with a traditional THA group.

A number of prospective, randomized studies have been conducted to compare improvements in gait following

minimally invasive versus traditional, unilateral THA. Results of a study by Mayr and coinvestigators<sup>96</sup> demonstrated significant improvement in several gait parameters at 6 weeks in the group that underwent minimally invasive THA but not in the traditional THA group. At 12 weeks, however, both groups showed significant improvements in gait, but the minimally invasive group improved in a larger number of the parameters measured. In contrast, another gait study reported no significant differences in gait characteristics between the minimally invasive and traditional THA groups at 10 days and 12 weeks after surgery.<sup>131</sup> Recently published analyses reported similar results, with no differences in walking speed, step length, cadence, or pelvic and thoracic motion between minimally invasive groups and traditional approach groups.<sup>109,136</sup> It is important to note that postoperative rehabilitation in these studies was uniform between groups, which may have contributed to the similarity of outcomes in the minimally invasive and traditional THA groups.

Lastly, Dorr and colleagues<sup>42</sup> also investigated improvements in functional mobility following THA and found that 87% of patients in the minimally invasive group used just one assistive device (crutch or cane) for ambulation at the time of discharge compared to 53% of the traditional THA group. However, there was no significant difference in walking distance at the time of discharge between the two groups. With the mixed findings from studies such as these, it is difficult to draw evidence-based conclusions about the impact of minimally invasive procedures versus traditional THA on early postoperative ambulation.

**Impact of rehabilitation.** Despite the number of sources in the literature that emphasize the importance of rehabilitation programs or, more specifically, a postoperative exercise and ambulation program after THA, the impact of postoperative interventions following THA has not been clearly established. Studies have demonstrated that access to inpatient physical therapy services does<sup>49,111</sup> and does not<sup>82</sup> decrease a patient's length of stay in an acute care facility after THA. It has also been shown that the use of physical therapy services after THA increases the probability of discharge to the home setting rather than to another healthcare facility.<sup>49</sup> The inclusion of exercise and gait training interventions provided by a physical therapist in addition to instruction given by a multidisciplinary hip group immediately after surgery resulted in greater hip ROM and strength and improved mobility than instruction alone at 15 days postsurgery.<sup>163</sup>

In a nonrandomized study of the effectiveness of a 6-week home exercise program with patients who were 6 to 48 months post THA, the two exercise groups (one performing ROM and hip muscle isometrics and the other performing ROM, isometric, and eccentric exercises) increased their walking speed, whereas a control group (no exercise program) did not. Interestingly, strength improvements were noted in all three groups.<sup>132</sup>

A randomized trial that enrolled subjects 3 months after posterolateral THA showed that participants who completed

12 sessions of training that was led by a physical therapist and emphasizing walking skills had significantly greater improvements on several performance-based and self-report outcome measures. When compared to a control group that did not have supervised therapy, greater improvements were noted at 5 months postsurgery in the intervention group for the 6-minute walk test, stair climbing time, figure-of-eight test, the Index of Muscle Function, hip extension ROM, the Harris Hip Score, and self-efficacy in the training group. Group differences in walking distance and stair climbing persisted at 12 months postsurgery, and there were fewer fall events reported in the walking skill training group.<sup>62</sup>

Mikkelsen and colleagues evaluated the effect of a twice-weekly progressive resistance training intervention following THA, comparing it to a home program of standard hip and knee resistance exercises. The intervention group (n = 32) performed 30 to 40 minutes of unilateral hip strengthening exercises on strength-training machines, using both concentric and eccentric contraction and loads that increased based on the repetition maximum, while the control group (n = 30) performed 10 repetitions of unloaded hip and knee movements twice a day for 4 weeks, followed by the same movements against elastic resistance for an additional 6 weeks. After 10 weeks of training, there were statistically significant group differences for maximal walking speed and stair climbing time in favor of the intervention group, but no other significant differences, including measures of hip strength and power.<sup>102</sup>

## Hemiarthroplasty of the Hip

### Indications for Surgery

The following are some of the main indications for prosthetic replacement of the proximal femur:<sup>54,76,78</sup>

- Acute, displaced intracapsular (subcapital, transcervical) fractures of the proximal femur in an elderly patient with poor bone quality and an anticipated low-demand level of activity after surgery<sup>54,76,101,126,127,155</sup>
- Failed internal fixation of intracapsular fractures associated with osteonecrosis of the head of the femur<sup>76,101,126</sup>
- Severe degeneration of the head of the femur associated with long-standing hip disease or deformity, resulting in disabling pain and loss of function that cannot be managed with nonoperative procedures<sup>76, 101,127</sup>

**NOTE:** Patients with preexisting degenerative hip disease who sustain a femoral fracture are candidates for primary THA rather than hemiarthroplasty.<sup>46,101</sup> Acute, severely comminuted intertrochanteric fractures are *infrequently* managed by primary hemiarthroplasty.<sup>101,156</sup>

### FOCUS ON EVIDENCE

A recent assessment of the American Board of Orthopaedic Surgery database regarding femoral neck fractures showed that between 1999 and 2011, the use of THA increased 7% while the use of hemiarthroplasty decreased 4%. Patients

younger than 65 years old were even more likely to have THA than arthroplasty.<sup>103</sup>

### Procedures

**Background.** Historically, acute displaced proximal femur fractures were treated with unipolar (fixed head), uncemented metal-stemmed endoprostheses. The primary complication associated with these single-component implants, regardless of design or fixation, was progressive erosion of the acetabular cartilage and subsequent pain.

To decrease acetabular wear, the bipolar hemiarthroplasty was developed. The bipolar design is composed of multiple components: a metal femoral ball-and-stem prosthesis that moves within a free-riding polyethylene shell, which in turn inserts into a metal cup that moves within the acetabulum. The purpose of the multiple-surface, load-bearing design is to dissipate the forces that previously acted directly on the acetabulum through the interposed components.<sup>70,101,126</sup> Contemporary versions of both unipolar and bipolar prostheses are in use today, with debate among surgeons regarding the advantages and disadvantages of one design versus the other.<sup>70,101,126</sup>

**Operative procedure.** A posterolateral approach is most commonly used for hemiarthroplasty. After visualizing the joint and removing the head of the femur, the metal-stemmed prosthesis is inserted into the shaft of the proximal femur. The femoral stem usually is cemented in place, although bio-ingrowth fixation is also used. Procedures for closure are consistent with THA.

### Postoperative Management

For the most part, the postoperative care and rehabilitation for hemiarthroplasty are similar to that described for THA. This includes the considerations and precautions for positioning and ADL, as well as the components and progression of the exercise and ambulation program. As with postoperative management after THA, the selection and progression of exercises and functional activities after hemiarthroplasty tend to reflect the opinions of surgeons and therapists and are based on the potential of specific exercises to remediate impairments and improve function. As a result, the effectiveness of exercise after hemiarthroplasty remains largely unreported. Only limited information on the impact of specific exercises and gait-related activities on the hip joint, per se, after hemiarthroplasty is available in the literature. Some findings from several single-subject studies of two patients with femoral endoprostheses have already been discussed in the previous section of this chapter on THA.<sup>53,79,80,152</sup>

**PRECAUTION:** Given the significant concerns for long-term erosion of acetabular cartilage after hemiarthroplasty, avoiding exercises that impose the greatest compressive or shearing forces across the hip joint is of critical importance. Exercises should be performed initially at a *submaximal* level and then progressed gradually. *Unassisted* heel slides and *maximum* effort gluteal setting exercises may need to be avoided during

the acute phase of postoperative rehabilitation.<sup>152</sup> In the post-acute rehabilitation period, manually resisted hip abduction should be progressed gradually because maximum-effort hip abduction is thought to generate greater forces across the hip joint than protected weight-bearing activities.<sup>53</sup>

### Outcomes

Present-day modular, unipolar, and bipolar hemiarthroplasty procedures appear to yield similar results in pain relief, functional outcomes, and type and rate of complications.<sup>76,101,126</sup> Although acetabular wear was identified as the primary concern after the unipolar replacement used several decades ago, the mechanical effectiveness of the bipolar prosthesis in preventing acetabular erosion has yet to be firmly established.<sup>76</sup> In a study of community-dwelling patients age 65 years or older (mean age 80 years) who had undergone hemiarthroplasty with either a bipolar implant or a modular unipolar implant, there were no significant differences between the two groups at 1 year and 4 to 5 years of follow-up with regard to functioning in daily activities or rates of dislocation, infection, or mortality.<sup>167</sup> Results of another study suggest that joint ROM may decrease over time after bipolar hemiarthroplasty, possibly due to the design of the implants. This decreased range was not associated with diminished functional abilities.<sup>70</sup>

Lastly, the use of hemiarthroplasty versus screw fixation for displaced femoral neck fractures in elderly patients was examined in a large (over 4,000 patients), retrospective study conducted in Norway.<sup>54</sup> Results of the study showed that the patients who had undergone hemiarthroplasty had significantly less postoperative pain, fewer secondary surgeries, and were more satisfied with the outcome of the surgery than the group who had undergone internal fixation (screw fixation) of the fracture site.

## Hip Fractures: Surgical and Postoperative Management

### Hip Fracture: Incidence, Risk Factors, and Impact on Function

A prevalent musculoskeletal occurrence in the elderly is fracture of the hip or, more correctly, fracture of the most proximal portion of the femur in the hip region. The acute signs and symptoms of hip fracture are pain in the groin or hip region, pain with active or passive motion of the hip, or pain with lower extremity weight bearing. The fractured lower extremity appears to be shorter by several centimeters and assumes a position of external rotation.<sup>76,127</sup>

In the United States, the vast majority of hip fractures occur in individuals between the ages of 75 to 85 years, with women accounting for 77.2% of the fractures in this age group.<sup>23</sup> Worldwide, the incidence of hip fracture has stabilized and appears to have decreased slightly in the United States between 1985 and 2005.<sup>23</sup> The total number of hip fractures per year is expected to increase, however, mainly because

of the higher proportion of elderly in the population.<sup>76,127</sup> Fewer than 3% of hip fractures are sustained by persons less than 50 years of age<sup>76,127</sup> and are usually associated with high-force, high-impact trauma or with repetitive microtrauma, such as from distance running.

Multiple risk factors, including those related to fall risk, contribute to the increased incidence of hip fracture with age.<sup>27</sup> Risk factors for falls and the potential for hip fractures in the elderly include age-related loss of muscle strength and flexibility, balance and gait deficits associated with musculoskeletal or neurological disorders, low vision, cognitive decline, and medication effects. Loss of bone density and strength associated with osteoporosis typically occurs in the proximal femur, distal radius, and spine, making these sites more susceptible to fracture.<sup>76,127</sup> A forceful rotational motion between the pelvis and lower extremity or the impact from a fall can both cause a fracture of the fragile proximal femur. Although 90% of all hip fractures in the elderly are associated with a fall,<sup>76</sup> it is not yet known if trauma from the fall caused the hip fracture or if a pathological fracture of the hip resulted in the fall.

In addition to the potential fracture mechanisms noted, the inability to absorb the impact of a fall also contributes to the risk of sustaining a fracture.<sup>127</sup> In addition, the characteristics of falling also change with age. As walking speed decreases with age, an older person usually drops and falls to the side, rather than falling forward on outstretched hands as occurs with faster walking speeds.<sup>76,127</sup>

Hip fracture in the elderly is associated with significant functional impairments and loss of independence. Many patients who survive for more than 1 year following hip fracture have limitations in ADLs and functional mobility and require assistance to transfer, dress, walk, and climb stairs.<sup>89,148</sup> The combination of limitations attributable to the hip fracture (not simply age), reduced activity and subsequent deconditioning during the recuperative period, and activity avoidance for fear of falling make it difficult to return to prefracture activity and functional levels.<sup>89,91</sup> Consequently, long-term nursing care or permanent placement in skilled nursing or assisted living facilities is often required.

Postfracture mortality rates in the United States declined from 1985 to 2005.<sup>23</sup> This decline may be the result of improved surgical techniques, which have reduced the need for prolonged immobilization or restricted weight bearing, thus decreasing postoperative complications such as pneumonia and thromboemboli.

### Sites and Types of Hip Fracture

Fractures of the proximal femur are broadly classified as *intra*capsular or *extra*capsular and then further subdivided by specific location (Fig. 20.7). Sites and specific types of hip fracture are noted in Box 20.7.<sup>76,98,101,155–157</sup> Of these sites, fractures in the intertrochanteric region are most common, accounting for approximately 50% of all proximal femur fractures.<sup>98</sup> Intracapsular fractures may compromise the vascular

**FIGURE 20.7** Fractures of the proximal femur are broadly divided into *intracapsular* and *extracapsular* sites. (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging*, ed. 4. Philadelphia: F.A. Davis, 2014, p 350, with permission.)

### BOX 20.7 Common Sites and Types of Hip Fracture

#### Intracapsular

- Fracture site proximal to the attachment of the hip joint capsule
- Further subdivided into *femoral head*, *subcapital* and *femoral neck* (*transcervical* or *basicervical* fractures)
- May be displaced, nondisplaced, or impacted
- May disturb the blood supply to the head of the femur resulting in avascular necrosis or nonunion

#### Extracapsular

- Fracture site distal to the capsule to a line 5 cm distal to the lesser trochanter
- Further subdivided into *intertrochanteric* (between the greater and lesser trochanters) or *subtrochanteric* and *stable* or *unstable* (comminuted)
- Does not disturb the blood supply to the head of the femur, but nonunion may occur as the result of fixation failure

supply to the head of the femur, which increases the risk of delayed healing, nonunion, or osteonecrosis (avascular necrosis) of the head of the femur. These complications occur far more frequently with displaced versus nondisplaced intracapsular fractures.<sup>76,101</sup> Intracapsular fractures are most often sustained by elderly women.<sup>76,101</sup>

In contrast, fracture-dislocation and acetabular trauma are most common in the young, active individual.<sup>76</sup> Most fracture-dislocations occur in a posterior direction, often causing traumatic disruption of the vascular supply to the head of the femur and damage to joint cartilage. Over time, osteonecrosis and posttraumatic arthritis may result from this type of trauma, necessitating prosthetic replacement of the hip joint.

## Nonoperative Management

In some situations, nonoperative management is the only treatment option after hip fracture. Traction is one appropriate alternative treatment for nonambulatory individuals or for medically unstable patients who cannot undergo a surgical procedure.<sup>76,127</sup> The patient remains in bed and the leg in traction just long enough for early healing to occur, followed by bed-to-chair mobilization. If weight bearing or ambulation is feasible, it is delayed until bone healing is sufficient, usually by 10 to 12 weeks or as long as 16 weeks after fracture.

## Open Reduction and Internal Fixation of Hip Fracture

### Indications for Surgery

Surgical intervention by means of open (or possibly closed) reduction followed by stabilization with internal fixation (Figs. 20.8 and 20.9) is indicated for the following types of proximal femur fracture:<sup>76,127,155–157</sup>

- Displaced or nondisplaced intracapsular femoral neck fractures
- Fracture-dislocations of the head of the femur
- Stable or unstable intertrochanteric fractures
- Subtrochanteric fractures

In the elderly patient, displaced intracapsular fractures often are managed with prosthetic replacement of the femoral

**FIGURE 20.8** Reduction and internal fixation of a complete fracture of the femoral neck. Restoration of alignment and good compression is obtained via fixation with three compression screws. The black arrows mark the extent of the fracture line. (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging*, ed. 4. Philadelphia: F.A. Davis, 2014, p 351, with permission.)

**FIGURE 20.9** Intertrochanteric fracture of the hip. This postoperative image shows fracture fixation via a side plate and screw combination device. The fracture line is evident, extending through the intertrochanteric region to the proximal femoral shaft. Some comminution is evident, and a large fragment on the medial shaft is noted. The imposed added densities of soft tissue are seen. (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging*, ed. 4. Philadelphia: F.A. Davis, 2014, p 353, with permission.)

head (hemiarthroplasty), rather than internal fixation, to avoid the relatively high incidence of nonunion.<sup>54,126</sup> There is, however, no definitive determination as to which procedure provides superior results.<sup>54</sup> Some severely comminuted (unstable) intertrochanteric fractures may also be managed with hemiarthroplasty.<sup>76,101,156</sup>

### Procedures

The goal of surgery is to achieve maximum stability and restore the bony alignment of the hip. Surgery is indicated during the first 24 to 48 hours after injury, particularly with intracapsular femoral neck fractures because the risk of disrupted vascular supply to the head of the femur is high. A variety of internal fixation devices are used to stabilize the many types of proximal femur fracture. The type and severity of the fracture, the associated injuries, and the patient's age and physical and cognitive status all influence the surgeon's choice of procedure.<sup>76,127</sup> The type of procedure performed, in turn, affects the progression of postoperative rehabilitation.

**Types of fixation and surgical approach.** The most common modern, internal fixation devices used include the following:<sup>2,76,127,155–157</sup>

- Intramedullary nail fixation that interlocks proximally in the femoral head or a sliding compression screw for intertrochanteric or subtrochanteric fractures.
- *In situ* fixation with multiple parallel cancellous lag screws or pins for nondisplaced or impacted femoral neck fractures and possibly for displaced femoral neck fractures in active patients less than 65 years of age.
- Dynamic extramedullary fixation with a sliding (compression) hip screw and lateral side plate for stable intertrochanteric fractures; may be combined with an osteotomy for unstable (comminuted) fractures. The dynamic hip screw allows sliding between the screw and plate and creates compression across the fracture site during early weight bearing.

An open surgical approach along the lateral aspect of the hip is used in these fixation procedures, although some aspects of the procedures may be performed percutaneously. The degree of soft tissue disruption differs with each procedure. The tensor fasciae latae, vastus lateralis, or gluteus medius may need to be incised parallel to the fibers and a capsulotomy is generally performed with femoral neck fractures.

### Postoperative Management

The ultimate goal of surgical intervention and postoperative care after hip fracture is to return the patient to their preferred living environment<sup>108</sup> at their pre-injury level of function.<sup>76,127</sup> It is generally agreed that rehabilitation services during recovery, including postoperative exercise and functional training across the continuum of care, are recommended and contribute to optimal outcomes.<sup>35,108</sup>

During the initial phase of postoperative rehabilitation in the acute care setting, the emphasis is on mobilization (getting the patient up and moving as quickly as possible) while protecting the stabilized fracture site. This prevents or minimizes the adverse effects of prolonged bed rest. In addition to helping the patient learn to move safely in bed, transfer, and ambulate independently with an assistive device, early postoperative rehabilitation typically includes patient or caregiver education, deep breathing and coughing exercises, lower extremity edema control (use of compressive stockings), proper positioning in bed to avoid contractures, and an exercise program.

After discharge from the hospital, postoperative functional training and a progression of exercises typically continue in a transitional, subacute rehabilitation or skilled nursing facility or at home. Despite consensus that rehabilitation after hospital discharge is an essential aspect of postoperative care,<sup>108</sup> there is little evidence that suggests one rehabilitation setting is superior to another for functional outcomes, and there is insufficient evidence to inform decisions about the optimal components of subacute rehabilitation.<sup>35</sup>

What is known, however, is that most patients are discharged from subacute rehabilitation services after achieving

independence in ambulation and necessary ADLs. On average, 85% to 95% of patients receiving physical therapy in the home setting are discharged from services by 7 to 9 weeks after hip fracture.<sup>92</sup> Often, services are discontinued despite persistent impairments and functional deficits and well before patients have attained a pre-injury level of function, which in turn increases the risk of future injury.<sup>19</sup>

### Weight-Bearing Considerations

The amount of weight bearing permissible during early ambulation and transfers is always determined by the surgeon for each patient on an individual basis. Factors that influence the decision are the patient's age and bone quality, the fracture location and pattern, the type of fixation used to stabilize the fracture site, and the degree of intraoperative stability achieved.<sup>76,78,127</sup> Recommendations range from nonweight bearing, toe-touch or touch-down weight bearing (< 10 lb), to weight bearing as tolerated. Current internal fixation methods have decreased the need for extended nonweight-bearing or toe-touch status after surgery.

Many fixation procedures used make early weight bearing possible. Some examples of fractures and fixation procedures in which weight bearing as tolerated is permissible immediately after surgery are:

- Nondisplaced, rigidly fixed, or impacted femoral neck fractures managed with *in situ* fixation.<sup>76,78,127,155</sup>
- Stable (noncomminuted) intertrochanteric fractures managed with a dynamic (sliding) compression screw and lateral side plate fixation.<sup>76,127,156</sup>
- Stable intertrochanteric and subtrochanteric fractures managed with interlocking intramedullary nailing and bone-to-bone fixation.<sup>2,76,127,157</sup>

Even when weight bearing is limited during ambulation and transfers, the fracture site is still subjected to significant forces through hip muscle activation. For example, moving in bed, sitting up at the edge of the bed, and active and resisted ROM exercises all generate forces across the hip that approach or even exceed those incurred during full weight-bearing ambulation.<sup>120</sup> Based on this, studies are investigating the risks associated with early weight bearing after open reduction and internal fixation of hip fractures.

### FOCUS ON EVIDENCE

In one study, elderly patients with stable as well as comminuted intertrochanteric fractures treated with dynamic compression screw and plate fixation were all allowed to bear weight as tolerated during ambulation with an assistive device immediately after surgery. One year postoperatively, there was no significant difference between the rate of implant failure and revision surgery in the patients with stable fractures and those with comminuted fractures. The investigators concluded that, at least in elderly patients with comminuted and noncomminuted intertrochanteric fractures that were stabilized intraoperatively, there was little

biomechanical justification for nonweight-bearing restrictions postoperatively.<sup>78</sup>

Excluded from this generalization were patients with complex fractures in whom satisfactory intraoperative stabilization could not be achieved, young patients with displaced femoral neck fractures with *in situ* fixation, and patients with severe bone disease (e.g., as the result of malignancy).

Despite the findings of this study and the recognized benefits of early ambulation and exercise, there is always a risk, albeit small, of failure of the internal fixation in some patients. Therefore, it is important to recognize the signs of possible displacement or loosening of the fracture stabilization device as summarized in Box 20.8. The presence of any of these signs or symptoms should be reported immediately to the surgeon.<sup>76,127</sup>

### Exercise and Functional Training

Decreased joint mobility, ROM, muscle performance, balance, and loss of functional mobility are the most common physical impairments after open reduction and internal fixation of hip fracture. Exercise and functional training continue to be the interventions routinely included throughout current-day postoperative rehabilitation to reduce impairments and improve functional outcomes.<sup>92</sup>

During the initial postoperative period, hip and even knee motions are quite painful, affecting ROM and strength of the involved lower extremity. In addition, some degree of tissue protection is necessary over the course of soft tissue healing (approximately 6 weeks) and bone healing (10 to 16 weeks).<sup>155–157</sup> These factors affect the progression of exercise and functional training, as do the location and stability of the fracture site, type of internal fixation used, and the soft tissues traumatized at the time of the injury and during surgery. Special considerations for exercise and ambulation after various types of hip fracture and with specific surgeries are noted in Box 20.9.<sup>76,127,155–157</sup>

The following sections outline a progression of exercises and functional training after open reduction and internal fixation of hip fractures.

#### BOX 20.8 Signs and Symptoms of Possible Failure of the Internal Fixation Mechanism

- Severe, persistent groin, thigh, or knee pain that increases with limb movement or weight bearing
- Progressive limb length inequality (shortening of the involved lower extremity) that was not present immediately after surgery
- Persistent external rotation of the operated limb
- A positive Trendelenburg sign during weight bearing on the involved limb that does not resolve with strengthening exercises

### BOX 20.9 Special Considerations for Exercise and Gait After Internal Fixation of Fractures of the Proximal Femur

- Multiple hip muscles are traumatized by fracture of the hip, leading to postoperative pain, reflex inhibition, and weakness. Fractures at these sites may cause damage to the following muscles.
  - Greater trochanter: gluteus medius
  - Lesser trochanter: iliopsoas
  - Subtrochanteric region: gluteus maximus
- The tensor fasciae latae (TFL) and vastus lateralis (VL) are usually incised during surgery, causing postoperative pain, inhibition, and weakness during hip abduction and knee flexion.
- Adhesion formation between the incised TFL and VL may develop and restrict motion. Hip adduction and internal rotation and knee flexion place a stretch on the TFL and VL, respectively, during ROM exercises and therefore are often painful.
- If there is shortening of the involved limb after fracture and internal fixation, the distance between the distal insertion of the gluteus medius on the greater trochanter and the center of axis of hip motion is often decreased, thus diminishing the mechanical advantage of the muscle and causing weakness and a positive Trendelenburg sign during ambulation.
- Intracapsular fractures typically traumatize the capsule, and internal fixation requires an incision into the capsule (capsulotomy). Both predispose the capsule to postoperative restriction.

#### Exercise: Maximum Protection Phase

Exercises begin on the first postoperative day to prevent complications and to restore a patient's control of the involved hip during functional activities. Initially, exercises are directed toward restoring ROM of the involved hip and developing balance and strength in the upper extremities and uninvolved lower extremity to facilitate ambulation with an assistive device. It is reasonable to expect to achieve 80° to 90° of active hip flexion (with the knee flexed) by 2 to 4 weeks postoperatively.<sup>76</sup>

There is lack of consensus about the appropriate time to begin resistance exercises with the involved lower extremity. Low-intensity resistance exercises of the operated hip may be delayed until 4 to 6 weeks postoperatively to allow time for any surgically incised hip muscles to heal. However, resistance exercises of knee and ankle musculature may be initiated as soon as tolerable.

#### FOCUS ON EVIDENCE

Mitchell and colleagues<sup>105</sup> conducted a randomized, controlled trial to determine the effects of 6 weeks of quadriceps

resistance exercises during the early phase of postoperative rehabilitation after hip fracture. The study included 80 patients described as “frail elderly” (all > 65 years of age, mean 80 years). All subjects performed a standard therapy program of ROM exercises and functional training after surgery. Half of the patients also performed bilateral resisted knee extension exercises at 16 days postoperatively, beginning with 3 sets of 12 repetitions at the 50% 1-RM intensity twice a week, and progressing to 80% intensity by the fifth week.

After 6 weeks of resistance training, the bilateral quadriceps strength of the intervention group increased to a significantly greater extent than that of the control group. Based on a functional mobility test, the intervention group also demonstrated a significantly greater reduction in functional impairments and activity limitations than the control group. However, there were no significant differences in improvement between groups regarding gait velocity or test scores measuring independence in ADL. There were no training-related adverse events during the study.

The authors concluded that moderate- to high-intensity postoperative quadriceps resistance training during early recovery after hip fracture was functionally beneficial and well tolerated by the participants despite their age and frailty.

**Goals and interventions.** The following are goals, exercises, and functional training interventions typically initiated in the hospital setting and continued following discharge from the hospital.<sup>11,12,72,92</sup> Patient education occurs throughout this phase of rehabilitation emphasizing progressive use of the operated extremity, safety, the prevention of postoperative complications, and reducing the risk of a future fall.

- **Prevent vascular and pulmonary complications.**
  - Ankle pumping exercises performed regularly throughout the day to maintain circulation and reduce the risk of DVTs and thromboemboli.
  - Deep breathing exercises and airway clearance to prevent pulmonary complications.
- **Improve strength in the upper and sound lower extremities.**
  - Exercises against progressive levels of resistance targeting key muscle groups used to lift body weight during bed mobility, standing transfers, and ambulation with assistive devices.
  - Emphasis on closed-chain training with most weight on the sound extremity, such as bridging exercises, to simulate the movement patterns used during these activities.
- **Re-establish balance, postural stability, and safe and independent functional mobility within weight-bearing restrictions.**
  - Weight-shifting activities in bilateral stance.
  - Heel and toes raises in bilateral stance.
  - Stabilization exercises in bilateral stance (alternating isometrics/rhythmic stabilization).

- Balance activities with self-initiated perturbations by reaching in various directions.
- Bed mobility, transfers, and gait training with an assistive device.
- **Prevent postoperative reflex inhibition of hip and knee musculature.**
  - Low-intensity isometric (setting) exercises of the hip and knee musculature of the operated extremity. Depending on the fracture site and its stability, perform submaximal gluteal, abductor, adductor, and quadriceps and hamstring setting exercises.
- **Restore mobility and control of the operated hip and adjacent joints.**
  - Assisted, progressing to active ROM of the involved hip and knee in progressively more challenging positions as pain and fracture healing permit. For example, in the supine position, perform heel slides before straight leg raises (SLRs). When the knee is flexed, the shorter moment arm places lower rotational loads on the fracture site than a long moment arm.
  - Pelvic tilts and knee-to-chest movements with the *uninvolved* leg to prevent stiffness in the low back region.
  - Unassisted hip flexion, abduction, and extension while standing on the sound leg and holding onto a stable surface for balance before progressing to SLRs in a horizontal position.
  - Low-intensity, dynamic resistance exercises in weight-bearing and nonweight-bearing positions as the stability of the fracture site allows.

**PRECAUTION:** When initiating setting and dynamic exercises of the involved hip after comminuted subtrochanteric fractures that required medial cortex reconstruction, postpone contractions of the abductor and adductor muscles for 4 to 6 weeks to avoid stresses across the fracture site.<sup>157</sup>

### Exercise: Moderate and Minimum Protection Phases

By 6 weeks, soft tissues are healed; by 8 to 12 weeks, depending on the age and health of the patient, some degree

of bone healing has occurred. By 6 weeks of rehabilitation, except in unusual situations, at least partial weight bearing or full weight bearing as tolerated is now permissible. By 8 to 12 weeks, although a patient gradually can be weaned from use of an assistive device during ambulation, most continue to use at least a cane well beyond this time frame.

During the intermediate and final phases of rehabilitation, the emphasis is on increasing strength and functional control of the involved lower extremity and gradually increasing the patient's level of functional activities. However, patients often are discharged from supervised therapy by 7 to 9 weeks or no later than 12 weeks postoperatively.

**Extended exercise programs after surgery for hip fracture.** Several studies have demonstrated that after a standard course of postoperative rehabilitation and with clearance from the patient's surgeon, an extended program of properly supervised, carefully progressed resistance exercises for strength training, begun as early as 6 weeks or as late as 5 to 7 months postoperatively (depending on the intensity of the exercise program), is safe and effective.<sup>19,60,67,91,145,146</sup>

The intensity, frequency, and duration of the extended exercise program varied in these studies, and the equipment used for resistance training ranged from elastic resistance products to weight machines. Features of the exercise programs implemented in three of the studies are summarized in Table 20.5. Additional details and outcomes of these studies are addressed at the conclusion of this section on postoperative management after hip fracture.

### CLINICAL TIP

After hip fracture surgery, mildly to moderately frail elderly individuals who complete a standard course of postoperative therapy followed by 6 months of an extended exercise program that includes progressive resistance exercise training can expect that their fractured extremity will achieve a level of strength at least equivalent to that of their nonfractured extremity.<sup>67</sup>

**TABLE 20.5** Summary of Studies of Extended Exercise Programs Following Surgery for Hip Fracture

First Author and Type of Study	Subjects: (n) and Mean Age	Setting, Format, and Timing of Intervention	Frequency, Duration, and Types of Exercise	Features of PRE Training

First Author and Type of Study	Subjects: (n) and Mean Age	Setting, Format, and Timing of Intervention	Frequency, Duration, and Types of Exercise	Features of PRE Training
			Phase 2: Moderate- to high-intensity PRE added to shortened phase 1 program <i>Control group:</i> A portion of phase 1 exercises, no PRE	leg press, seated bench press, biceps curl, seated rowing
Hauer <sup>60</sup> RCT with two groups Mangione <sup>91</sup> RCT with three groups	<i>N</i> = 28; all at least 75 years Intervention group: <i>n</i> = 15; 81.7 years Control group: <i>n</i> = 13; 80.8 years	Facility based; group format; begun 6–8 weeks postfracture	<i>Intervention group:</i> Three weekly sessions for 3 months; PRE, balance, and functional training <i>Control group:</i> Stretching, seated calisthenics, memory tasks.	Two sets at 70%–90% of 1-RM intensity Weight machines and body weight resistance Exercises: leg press, hip/knee extension, plantarflexion
Mangione <sup>91</sup> RCT with three groups	<i>N</i> = 33 Resistance group: <i>n</i> = 11; 77.9 years Aerobic group: <i>n</i> = 12; 79.8 years Control group: <i>n</i> = 10; 77.8 years	Home based; individual format; begun 19.4, 19.7, and 12.6 weeks after surgery, respectively, for resistance, aerobic, and control groups	Total of 3 months: two sessions weekly for 2 months, followed by 1 session weekly for 1 month	Three sets of eight reps at the 8-RM intensity Portable resistance unit or body weight resistance Exercises: supine hip and knee extension, hip abduction, standing hip extension; standing plantarflexion (heel raises)
Latham <sup>83</sup> RCT with two groups	<i>N</i> = 232; Intervention: <i>n</i> = 120 (Age 77.2) Control: <i>n</i> = 112 (Age 78.9)	Home based; individual format after traditional rehab; time since fracture 9.5 months for intervention group, 8.6 months for control group	6-month program: Three sessions per week <i>Intervention Group:</i> Functional tasks and standing exercises. <i>Control Group:</i> Nutrition education for cardiovascular health.	Functional tasks with elastic resistance; Standing exercises with weighted vests and varying step heights
Singh <sup>150</sup> RCT with two groups	<i>N</i> = 124; Intervention: <i>n</i> = 62 (Age 80.1) Control: <i>n</i> = 62 (Age 78.4)	Clinic based, individually prescribed; training began 6 to 8 weeks after fracture	12-month program: Twice per week <i>Intervention Group:</i> High-intensity PRE <i>Control Group:</i> Usual multidisciplinary care	Whole-body PRE (80% of peak upper and lower body strength); Progressive balance training

**Goals and interventions.** The following goals and exercises are appropriate during the intermediate and advanced phases of rehabilitation.

- **Increase flexibility of any chronically shortened muscles.** Muscles typically involved include the ankle plantarflexors,

hip flexors, and hamstrings. Suggested stretching techniques include:

- Heel cord stretching with a towel or with the assistance of a caregiver while sitting on a bed with the knee extended and later while standing.

- Hip flexor stretching in the supine (Thomas test) position.
- Hamstring stretching by sitting on the edge of a table with one leg supported in hip flexion and knee extension and the other in extension over the side of the support surface (see Fig. 20.18).
- **Improve strength and muscular endurance in the lower extremities for functional activities.** Refer to the section on exercise interventions later in the chapter for descriptions of the following exercises.
  - Bilateral, closed-chain active exercises, such as mini-squats and heel raises using body weight as the source of resistance and a table or walker for support and balance as soon as partial weight bearing on the operated lower extremity is permissible.
  - Lunges and forward and lateral step-ups when weight bearing to tolerance is allowable.
  - Open-chain hip and knee exercises initially against light to moderate resistance (up to 5 lb) with elastic resistance or cuff weights. Emphasize hip extension and abduction for a positive impact on ambulation.
  - Task-specific training, such as stair-climbing or carrying small loads while ambulating.
- **Improve postural stability, neuromuscular responses, standing balance, and functional mobility.**
  - A progression of balance activities appropriate for the patient's age and desired activity level (refer to Chapters 8 and 23).
  - Progressive ambulation on various surfaces and at varying speeds.
- **Increase aerobic capacity/cardiopulmonary endurance.**
  - Stationary bicycling, upper body ergometry, or treadmill walking.
  - Aerobic conditioning activities, possibly in an age-appropriate, community-based exercise class, to increase walking distance and velocity.

### FOCUS ON EVIDENCE

A *CPG for hip fracture management in the elderly*<sup>1</sup> notes moderate support that supervised occupational and physical therapy across the continuum of care improves functional outcomes and prevents falls and strong support for intensive physical therapy after discharge following a femur fracture.

### Outcomes

**General outcomes.** The true measure of success of surgical intervention and postoperative rehabilitation after hip fracture is the extent to which a patient can return to his or her prefracture level of function. The level of pre-injury functional mobility in patients with femoral neck fractures has been shown to be a critical factor in postoperative survival.<sup>66</sup> In one follow-up study of patients after hip fracture, only 33% had regained their pre-injury level of function in basic ADL and instrumental ADL (IADL) 1 year postoperatively.<sup>72</sup> Given

the advanced age and health status of the typical patient who sustains a hip fracture, it is not surprising that 1 year postoperative mortality rates are high, ranging from 12% to 36% depending on the mean age, general health status, and severity of the fracture.<sup>76</sup> Beyond 1 year of recovery, mortality rates are equal to age-matched subjects who have not sustained a hip fracture.<sup>76</sup>

Among patients who survive 1 year postoperatively, 83% demonstrated the ability to ambulate independently (50 feet on an uncarpeted surface) in one study.<sup>11</sup> In another study, 92% of patients returned to independent ambulation, but only 41% regained their prefracture level of ambulation.<sup>77</sup> In a study of community-dwelling older adults (mean age 83.4 years) 6 months after discharge from the hospital following a fall-related hip fracture, 53.3% (48/90) had experienced one or more falls.<sup>148</sup> The need for an assistive device during ambulation after hip fracture and the patient's prefracture fall history were predictors of a fall after hospital discharge.

**Impact of rehabilitation.** According to a report of the National Center for Medical Rehabilitation Research, the use of therapeutic exercise is one of the least examined factors affecting outcomes after hip fracture.<sup>168</sup> The minimal evidence that does exist indicates that rehabilitation is associated with positive outcomes. For example, in one study, the number of visits to physical therapy has been positively associated with the ability to ambulate independently.<sup>11</sup> Another study indicated that the frequency of physical therapy visits increased the likelihood of regaining functional independence and going directly home from an acute care setting after hip fracture surgery.<sup>58</sup>

In a randomized, controlled study, subjects who participated in a 1-month home exercise program increased their knee extensor strength and increased their walking velocity to a greater extent than the control group.<sup>145</sup> Another randomized, controlled study that evaluated a 6-month home exercise program of functional tasks and strengthening exercises demonstrated significant improvements in performance-based and subjective outcome measures for the intervention group relative to the control group.<sup>83</sup> Another study compared the effects of a 2-week program of weight-bearing versus non-weight-bearing exercises initiated during inpatient rehabilitation and found that both groups demonstrated substantial improvements in lower extremity muscle strength, balance, gait, and other functional tasks. However, there were no significant differences between groups.<sup>146</sup> This study supports the value of both types of exercise during early rehabilitation.

In the studies summarized in this section (see Table 20.6), muscle strength and performance on a variety of functional mobility and ADL tests improved to a significantly greater extent in the groups who participated in resistance training than in the groups who participated in low-intensity or no resistance training.<sup>19,60,91</sup> The resistance training group in the study by Binder and colleagues<sup>19</sup> also reported a significant decrease in the perceived levels of disability, whereas the

control group, who performed only low-intensity exercises, did not. The resistance training group in the investigation by Hauer and associates<sup>60</sup> noted improved perception of walking steadiness but no change in fear of falling.

Moderate- to high-intensity resistance training after discharge from a “standard” postoperative program appears to be not only feasible, but also safe. Other than reports of mild muscle soreness during the early weeks of resistance exercise programs, training-related adverse events were reported in only one study, and these events were not specific to the involved hip.<sup>19</sup> A more recent study evaluating a multidisciplinary intervention that included high-intensity exercises showed reductions in risk of death and nursing home admissions, plus lower reliance on assistive devices.<sup>150</sup> However, not all extended rehabilitation programs after hip fracture have been shown to be effective. The results of a study of individuals enrolled in a long-term, home-based, multifaceted rehabilitation program (including extensive ADL and IADL training) in comparison to a traditional postoperative exercise and ambulation program for 6 months postoperatively demonstrated no significant between group differences.<sup>158</sup>

## Painful Hip Syndromes: Nonoperative Management

### Related Pathologies and Etiology of Symptoms

Painful symptoms in the hip region other than arthritis may be caused by pathologies involving the muscles, tendons, bursae, or the acetabular labrum. Often, symptoms occur as a result of overuse or repetitive trauma to the tissues and may have underlying structural or faulty mechanical predisposing factors.

#### FOCUS ON EVIDENCE

The *CPG for Nonarthritic Hip Joint Pain linked to the International Classification of Functioning, Disability and Health*<sup>45</sup> identifies intra-articular structures as potential sources of nonarthritic hip pain, including femoroacetabular impingement, structural instability, labral tears, chondral lesions, loose bodies, and ligamentous tears, as well as acknowledging extra-articular structural impairments in the musculoskeletal system.

#### Musculotendinous Factors

Overuse or trauma to any of the musculotendinous units in the hip region can result from excessive strain during a muscle contraction or from repetitive use with inadequate time allowed for the injured tissue to heal between activities.

**Tendinopathies and muscle strains.** Commonly strained muscles include the hip flexors, adductors, and hamstrings. Decreased flexibility and muscle fatigue may predispose an individual to strains and/or injury during an activity or sporting event; sudden falls, such as slipping on ice, may also cause a muscle strain.

**Repetitive trauma.** Strength and flexibility imbalances among agonist/antagonist muscle pairs or among synergistic muscles may result in overuse injuries related to repetitive or high-intensity activities. Common overuse syndromes at the hip may reflect dominance of the tensor fasciae latae and rectus femoris as hip flexors, abductors, and internal rotators with apparent weak gluteus medius and gluteus minimus muscles or dominance of the hamstrings over the gluteus maximus.<sup>142</sup> Overuse of the piriformis muscle with apparent weakness of the gluteus maximus and medius muscles has also been reported.<sup>159</sup> Because of the relationship of these muscles with the pelvis and knee as well as the effect of faulty mechanics on weight-bearing function, patients with these muscle imbalances may also present with low back or knee symptoms.

#### Bursitis

**Trochanteric bursitis.** With inflammation of the trochanteric bursa, pain is experienced over the lateral hip and possibly down the lateral thigh to the knee when the iliotibial band rubs over the greater trochanter. Discomfort may be experienced after standing asymmetrically for long periods with the affected hip elevated and adducted and the pelvis dropped on the opposite side. Ambulation and climbing stairs aggravate the condition. Muscle flexibility, strength imbalances, and the resulting faulty pelvic motion may be the predisposing factors leading to bursal irritation.

**Psoas bursitis.** Pain is experienced in the groin or anterior thigh and possibly into the patellar area when there is inflammation of the psoas bursa. Activities requiring excessive, repetitive hip flexion aggravate the condition.

**Ischiogluteal bursitis (Tailor’s or Weaver’s Bottom).** When there is inflammation of the ischiogluteal bursa, pain is experienced around the ischial tuberosity, especially when sitting. If the adjacent sciatic nerve is irritated from the swelling, symptoms of sciatica may occur.

#### Femoroacetabular Impingement

Trauma, acetabular labral impingement, capsular laxity, dysplasia, and degeneration are causative factors for tears in the acetabular labrum leading to anterior hip or groin pain.<sup>6,57,86,164</sup> There may be associated structural abnormalities in the acetabulum or femur.<sup>6</sup> Acetabular labral pathology is associated with hip OA in older patients.<sup>57</sup> Patients usually present with pain that is activity dependent and describe mechanical symptoms such as clicking, locking, catching, or giving way.<sup>86</sup> Groin pain is most often related to an anterior tear, and buttock pain is most often related to a posterior tear. With an anterior lesion, positive tests typically include pain with the impingement test

(combined flexion, adduction, and internal rotation) and with the scour test.<sup>6</sup> The log roll test may elicit pain or clicking when rolling the femur into internal rotation, and there may be restricted mobility and groin pain with the FABER (flexion, abduction, external rotation) test. Muscle flexibility and strength imbalances have been reported, including tightness of hip flexors and lumbar extensors and weak, inhibited gluteal and abdominal muscles.<sup>57</sup> Radiographic imaging and MRI (using gadolinium contrast) are usually performed to diagnose labral pathology.

### CLINICAL TIP

Although FAI is often treated surgically, a period of conservative management is advocated that addresses any biomechanical impairment. Emphasize alignment of the hip joint, reduce anteriorly directed forces on the joint, and develop a length/strength balance in the muscles of the hip. Strengthen the hip abductors, gluteus maximus, iliopsoas, and external rotators and develop flexibility in the hamstring muscles. Avoid hip rotation under loads (pivoting) and correct faulty gait, such as knee hyperextension, which causes hip hyperextension during stance.<sup>86</sup> No exercise should cause pain.

## Common Impairments of Structure and Function

**Pain.** With musculotendinous strains, symptoms occur when the involved muscle is contracted or stretched or when the provoking activity is repeated, often restricting participation in daily activities, community mobility, or sports activities. With impingement (bursa or labral tears), symptoms typically occur when the involved tissue is pinched between opposing structures.

**Gait deviations.** Slightly shorter stance occurs on the painful side. There may be a slight lurch or shift in the gait to minimize forces on the impaired structures.

**Imbalance in muscle flexibility and neuromuscular control.** Flexibility or altered patterns of activation in synergistic muscles may be precipitating factors in many painful hip syndromes. Imbalances are described in the introductory section of this chapter and summarized in the descriptions of painful hip syndromes.

**Decreased muscular endurance.** Muscle fatigue may lead to altered joint posture, stress, and imbalanced muscle use as described previously.

## Management: Protection Phase

### Patient Education

Advise the patient on the importance of modifying activities. Tailor the modifications to the patient's impairments, such as avoiding the impinged position; altering the sitting, standing,

or sleeping positions that provoke symptoms; using an assistive device temporarily to reduce stress; or avoiding exercises that aggravate the patient.<sup>45</sup>

### Control Inflammation and Promote Healing

When there is chronic irritation or inflammation from an acute injury, follow the guidelines as described in Chapter 10, with emphasis on resting the involved tissue by not stressing or putting pressure on it.

### Develop Support in Related Areas

Initiate exercises to maximize neuromuscular control and alignment of the pelvis and hip and to develop strength in weak muscles. Avoid stressing the inflamed tissue during exercise. Patient education and cooperation are necessary to reduce repetitive trauma.

## Management: Controlled Motion Phase

When acute symptoms have decreased, initiate a progressive exercise program within the tolerance of the involved tissues to improve muscle performance. The program should emphasize regaining a balance in length; neuromuscular control; strength; and endurance in the muscles of the hip, trunk, and the rest of the lower extremity.

### Develop a Strong Mobile Scar and Regain Flexibility

Remodel the scar in muscle or tendon, if suspected, by applying cross-fiber massage to the site of the lesion (if accessible) followed by multiple-angle submaximal isometrics in pain-free positions.

### Develop a Balance in Hip Muscle Length and Strength

Specific exercises are described in the exercise sections of this chapter.

- Stretch any muscles that are restricting motion with gentle, progressive techniques. Instruct the patient to do self-stretching with proper stabilization to ensure that the stretches are performed safely and effectively.
- Begin developing neuromuscular control to train muscles to optimally align the femur with emphasis on hip external rotation, external rotation combined with abduction, and hip extension with emphasis on the gluteus maximus.
- When the patient is aware of proper muscle control and is able to maintain segment alignment, progress to strengthening the weakened muscles through the range of joint motion.
- Initiate controlled weight-bearing exercises when tolerated. Because the individual is probably standing and walking during daily activities, they may not tolerate additional closed-chain activities than those initiated during the healing stage, so proceed with caution. Carefully observe the exercises so proper movement patterns are used.

### CLINICAL TIP

With the common faulty pattern of increased hip adduction and internal rotation when bearing weight, valgus collapse at the knee is also likely. Increase the patient's awareness of knee alignment by having them focus on maintaining the knee in line vertically over the foot when descending stairs or sitting down.

- Muscles not directly involved in the pathology should be stretched and strengthened if they are contributing to asymmetrical forces. The patient may not have sufficient trunk coordination or strength, which may also contribute to the underlying problem if hip muscles must overcompensate. (See Chapter 16 for suggestions for developing control and stabilizing function in the trunk muscles.)
- Use exercises that encourage symmetrical muscle activation, such as biking or partial weight-bearing and weight-shifting activities in the parallel bars. Observe the coordination and movement patterns between the trunk, hip, knee, and ankle.
- Stop exercise with the onset of fatigue, when substitute motions appear, or if pain develops in the weakest segment in the chain.

### Develop Muscle and Cardiopulmonary Endurance

- For muscle endurance, have the patient perform each exercise safely for 1 to 3 minutes before progressing to the next level of difficulty.
- Determine aerobic activities that do not exacerbate the patient's symptoms. It may be that the patient simply needs to modify the intensity of the activities used in their current aerobic program.

### Patient Education

Initiate a home exercise program as soon as the patient has demonstrated correct neuromuscular control and safety and independence with stretching, strengthening, and aerobic activities. Provide regular follow-up instruction for modification and progression of the program.

### Management: Return to Function Phase

- Progress closed-chain and functional training to include balance, neuromuscular control, and muscular endurance.
- Use specificity principles; increase eccentric resistance and demand for controlled speed if necessary for return to work, activities, or sporting events.
- Progress to patterns of motion consistent with the desired outcome. Use acceleration/deceleration drills and plyometric training.
- Assess total body functioning while the patient performs the desired activity. Facilitate the proper timing and sequencing of events during functional movements.

- Prior to returning to the desired function, have the patient practice the activity in a controlled environment and for an abbreviated time period. As tolerated, introduce variability in the environment and increase the intensity and duration of activities.

### FOCUS ON EVIDENCE

*The CPGs for Nonarthritic Hip Joint Pain*<sup>45</sup> support interventions that include patient education and counseling that minimize aggravating factors and manage pain; joint and soft tissue mobilization procedures for hip joint capsular and fascial restrictions; therapeutic exercise for flexibility, strengthening, and conditioning; and neuromuscular re-education for coordination.

## Exercise Interventions for the Hip Region

No matter what the cause, muscle strength or flexibility imbalance in the hip can lead to abnormal lumbopelvic and hip mechanics, which can contribute to low back, sacroiliac, or hip pain (see Chapters 14 through 16). Abnormal hip mechanics from muscle flexibility and strength imbalances may also affect the knee and ankle during weight-bearing activities, potentially causing overuse syndromes or increased stress in these regions (see Chapters 21 and 22).

## Exercise Techniques to Increase Flexibility and Range of Motion

The exercise techniques in this section are suggestions for correcting limited flexibility of the musculature and periarticular tissues crossing the hip. Principles and techniques of passive stretching and neuromuscular inhibition are presented in Chapter 4 and those of joint mobilization/manipulation in Chapter 5. Specific manual and self-stretching techniques are described in this section.

Flexibility (self-stretching) exercises, chosen according to the degree of limitation and ability of the patient to participate, can be valuable for reinforcing therapeutic interventions performed by the therapist. Not all of the following exercises are appropriate for every patient. Consequently, the therapist should select exercises and their intensity appropriate for each patient's level of function and progress each exercise as indicated. Recall that when the patient is able to contract the muscle opposite the range-limiting muscle, not only is the agonist being trained, but there is the added benefit of reciprocal inhibition of the shortened

(antagonist) muscles. This principle is key to achieving effective joint control in the newly gained ROM.

## Techniques to Stretch Range-Limiting Hip Structures

**NOTE:** Two-joint muscles can restrict full ROM of the hip when simultaneously lengthened at the knee joint. This first section describes stretches to increase hip motions only. Therefore, the two-joint muscles must be kept on slack across the knee during these stretches. Techniques to stretch specific two-joint muscles are described in the second section.

### To Increase Hip Extension

#### Prone Press-Up

**Patient position and procedure:** Prone with hands on a table at shoulder level. Have the patient press the thorax upward and allow the pelvis to sag (see Fig. 15.4B).

**PRECAUTION:** This exercise also moves the lumbar spine into extension; if it causes pain to radiate into the patient's leg rather than providing just a stretch sensation in the anterior trunk, hip, and thigh, it must not be performed.

#### “Thomas Test” Stretch

**Patient position and procedure:** Supine with the hips near the end of the treatment table, both hips and knees flexed, and the contralateral thigh held against the chest with the arms. Have the patient slowly lower the thigh to be stretched toward the table in a controlled manner and allow the knee to extend, so the two-joint rectus femoris does not limit the range. Do not allow the thigh to externally rotate or abduct. Direct the patient to let the weight of the leg produce the stretch force and to relax the tight muscles at the end of the range (Fig. 20.10). The therapist may apply a passive stretch force manually, or a hold-relax technique may be used by applying a force to the distal thigh (see Fig. 4.26).

#### Modified Fencer Stretch

**Patient position and procedure:** Stand in a fencer's lunge-like posture with the involved leg in back (extended) and uninvolved leg forward. Position the back leg in the same plane as the front leg and the foot pointing forward. Have the patient first do a posterior pelvic tilt and then shift the body weight onto the anterior leg until a stretch sensation is felt in the anterior hip region of the back leg (Fig. 20.11). If the heel of the back foot is kept on the floor, this exercise may also stretch the gastrocnemius muscle.

#### Kneeling Fencer Stretch

**Patient position and procedure:** Kneel on the side to be stretched, with the uninvolved leg forward in hip/knee flexion and the foot on the ground. Have the patient first do a posterior pelvic tilt and then shift the body weight onto the anterior leg until a stretch sensation is felt in the anterior hip region

**FIGURE 20.10** Self-stretching to increase hip extension. The pelvis is stabilized by holding the opposite hip in flexion. The weight of the thigh provides a stretch force as the patient relaxes. Allowing the knee to extend emphasizes the one-joint hip flexors (iliopsoas), whereas maintaining the knee in flexion and hip neutral to rotation as the thigh is lowered emphasizes the two-joint rectus femoris and tensor fasciae latae muscles.

**FIGURE 20.11** Self-stretching of the hip flexor muscles and soft tissue anterior to the hip using a modified fencer's squat posture.

of the back leg. Positioning the involved hip in internal rotation may enhance this stretch.

### To Increase Hip Flexion

#### Bilateral Knee to Chest Stretch

**Patient position and procedure:** Supine. Have the patient bring both knees toward the chest and grasp the thighs firmly until a stretch sensation is felt in the posterior hip region. Monitor the position carefully, because if the pelvis lifts up off the mat, the lumbar spine flexes and the stretch force is transmitted there instead of to the hips.

### Unilateral Knee to Chest Stretch

**Patient position and procedure:** Supine. Have the patient bring one knee to the chest and grasp the thigh firmly against the chest while keeping the other lower extremity extended on the mat. This position isolates the stretch force to the hip being flexed and helps stabilize the pelvis.

To emphasize a stretch of the gluteus maximus muscle, have the patient pull the knee toward the opposite shoulder.

### Quadruped (All Fours) Stretch

**Patient position and procedure:** On hands and knees. Have the patient rock the pelvis into an anterior tilt, causing lumbar extension (Fig. 20.12 A); then maintain the lumbar extension and shift the buttocks back in an attempt to sit on the heels. The hands remain forward (Fig. 20.12 B). It is important not to let the lumbar spine flex while holding the stretch position, so the stretch affects the hip.

**FIGURE 20.12** Gluteus maximus self-stretch with lumbar spine stabilization. (A) The patient on all fours rocks into an anterior pelvic tilt, causing lumbar extension. (B) While maintaining lumbar extension, the patient shifts the buttocks back, attempting to sit on the heels. When lordosis can no longer be maintained, the end-range of hip flexion is reached; this position is held for the stretch.

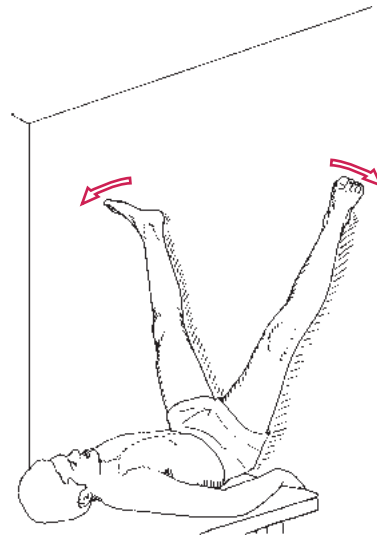

### Short-Sitting Stretch

**Patient position and procedure:** Sitting in a chair or at edge of elevated exercise mat (so that the hips are positioned in 90° of flexion) with the pelvis rotated anteriorly and the low back extended to stabilize the spine. Have the patient grasp the front of the chair seat (or mat) and lean or pull the trunk forward, keeping the back arched, so the motion occurs only at the hips.

### To Increase Hip Abduction

**Patient position and procedure:** Supine with both hips flexed 90°, knees extended, and legs and buttocks against the

wall. Have the patient abduct both hips as far as possible with gravity causing the stretch force (Fig. 20.13).

**FIGURE 20.13** Self-stretching of the adductor muscles with the hips at 90° of flexion.

### To Increase Hip Abduction and External Rotation Simultaneously

■ **Patient position and procedure:** Sitting or supine with soles of feet together and hands on the inner surface of the knees. Have the patient push the knees down toward the floor with a sustained stretch. The stretch can be increased by pulling the feet closer to the trunk.

**NOTE:** When this stretch is performed supine, teach the patient to stabilize the pelvis and lumbar spine by actively contracting the abdominal muscles and maintaining a neutral spinal position.

■ **Patient position and procedure:** Sitting or supine hook-lying, with ankle of extremity to be stretched placed on the opposite thigh (FABER or figure-4 position) (Fig. 20.14).

**FIGURE 20.14** Self-stretching to increase hip abduction and external rotation using the figure-4 position.

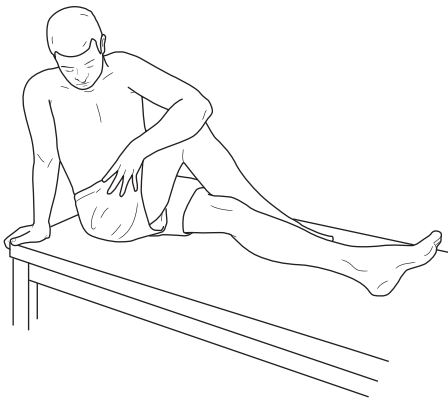

Have the patient push the knee down with one hand while stabilizing the ankle on the thigh with the other hand.

To increase the stretch on the posterior hip musculature, have the patient bend forward at the hips (or bring the flexed knee toward the chest if in hook-lying) while maintaining the lumbar spine in extension and pelvis in midline (not tipping to one side).

- **Patient position and procedure:** Standing in a fencer's position but with the back leg externally rotated. Have the patient shift the weight onto the front leg until a stretch sensation is felt along the medial thigh in the hind leg.

### To Increase Hip Internal Rotation

**Patient position and procedure:** Long-sitting position on a mat with the leg of the hip to be stretched flexed and crossed over the opposite leg (Fig. 20.15). Keep the foot planted and adduct and internally rotate the hip by moving the knee medially.

**FIGURE 20.15** Self-stretching to increase internal rotation of the hip.

## Techniques to Stretch Range-Limiting, Two-Joint Muscles

### Rectus Femoris Stretches

**NOTE:** The rectus femoris is the only 2-joint component of the quadriceps femoris muscle group. It is elongated using hip extension while maintaining the knee in flexion.

#### “Thomas Test” Stretch

**Patient position and procedure:** Supine with the hips near the end of the treatment table, both hips and knees flexed, and the thigh on the side opposite the tight hip held against the chest with the arms. While keeping the knee flexed, have the patient lower the thigh to be stretched toward the table in a controlled manner. Do not allow the thigh to externally rotate or abduct. Direct the patient to let the weight of the leg produce the stretch force and to relax the tight muscles at the end of the range. The patient can attempt to further extend the hip by contracting the extensor muscles (see Fig. 20.10 but with the knee flexed).

**NOTE:** This is the same stretch used to increase hip extension—except to stretch the rectus femoris, the knee is kept flexed so the range for hip extension is less.

#### Prone Stretch

**Patient position and procedure:** Prone with the knee flexed on the side to be stretched. Have the patient grasp the ankle on that side (or place a towel or strap around the ankle to pull on) and flex the knee. As the muscle increases in flexibility, place a small folded towel under the distal thigh to further extend the hip.

**NOTE:** Do not allow the hip to abduct or externally rotate or allow the spine to hyperextend.

#### Standing Stretch

**Patient position and procedure:** Standing with the hip extended and knee flexed and grasping the ankle. Instruct the patient to maintain a posterior pelvic tilt and neutral hip abduction/adduction and not allow the back to arch or side bend during this stretch (Fig. 20.16).

**FIGURE 20.16** Self-stretching of the rectus femoris while standing. The femur is kept in line with the trunk. Care must be taken to maintain a posterior PT and not arch or twist the back.

**NOTE:** If the rectus femoris is too tight to stretch safely in this manner, the patient may place his or her foot on a chair or bench located behind the body rather than grasping the ankle.

### Hamstrings Stretches

**NOTE:** The two-joint hamstring muscle group is stretched by flexing the hip while maintaining the knee in extension.

#### Straight Leg Raising

**Patient position and procedure:** Supine with a towel behind the thigh. Have the patient perform an SLR of the

restricted extremity by maintaining the knee in extension and flexing the hip, and pulling on the towel to move the hip into more flexion.

### Hamstrings Stretch in Doorway

**Patient position and procedure:** Supine, on the floor, with one leg through a doorway and the other leg (the one to be stretched) propped up against the door frame. For an effective stretch, the pelvis and opposite leg must remain on the floor with the knee extended.

- To increase the stretch when the patient is able, have the patient move the buttock closer to the doorframe, keeping the knee extended (Fig. 20.17 A).
- Teach the patient to perform the hold-relax/agonist contraction technique by pressing the heel of the leg being stretched against the doorframe, causing an isometric contraction, relaxing it, then lifting the leg away from the frame (Fig. 20.17 B).

**FIGURE 20.17** Self-stretching of the hamstring muscles. Additional stretch can occur if the person either (A) moves the buttock closer to the door frame or (B) lifts the leg away from the doorframe.

### Hamstrings Stretch on Chair or Table

- **Patient position and procedure:** Sitting with the leg to be stretched extended to another chair, or sitting at the edge

of a treatment table, with the leg to be stretched on the table and the opposite foot on the floor. Have the patient lean the trunk forward toward the thigh, maintaining the back in neutral so there is motion only at the hip joint (Fig. 20.18).

**FIGURE 20.18** Self-stretching the hamstring muscles by leaning the trunk toward the extended knee, flexing at the hips.

- **Alternate position:** Standing with the extremity to be stretched on a stool or the seat of a chair. Have the patient lean the trunk forward toward the thigh, keeping the back stabilized in neutral so that motion is only at the hip joint.

### Bilateral Toe Touching

**NOTE:** Bilateral toe touching exercises are often used to stretch the hamstring muscles in exercise classes. It is important to recognize that having the patient reach for the toes does not selectively stretch the hamstrings but stretches the low back and mid-back as well. Toe touching is considered a general flexibility exercise and tends to mask shortening of soft tissues in one region and overstretch areas already flexible. Whether a person can touch the toes depends on many factors (e.g., body type; arm, trunk, and leg length; flexibility in the thoracic and lumbar regions; and hamstring and gastrocnemius length).

**Patient position and procedure:** Standing. To discourage the “toe touch” idea, teach the patient to place the hands on the hips when bending forward. To specifically stretch the hamstrings using the forward-bend method while standing, teach the patient to first do an anterior pelvic tilt to extend the lumbar spine; then maintain the back position and bend only at the hips (“hinge at the hips”) moving only through the range of forward bending in which the spine can be maintained in extension. The stretch sensation should be felt in the hamstring region.

**PRECAUTION:** This stretching technique should not be used when the patient has low-back impairments because forward bending greatly increases muscle activation and mechanical stress to the tissues of the low back.

## Tensor Fasciae Latae and Iliotibial Band Stretches

**NOTE:** The tensor fasciae latae (TFL) inserts into the iliotibial (IT) band, which inserts into the extensor mechanism and lateral fascia of the knee. The TFL is a hip flexor, abductor, and internal rotator; for an effective stretch, all *three* components must be addressed. In addition, for an effective stretch of the muscle, the IT band must be positioned across the greater trochanter and the knee must be flexed. Adding knee flexion at later stages is a more aggressive technique that may also enhance the effectiveness of TFL stretches.

### Supine Stretch

**Patient position and procedure:** Supine with two pillows under the hips and back to position the hips in extension. Instruct the patient to cross the uninvolved extremity over the top of the involved extremity, so the involved thigh has room to move into adduction and internal rotation. The foot of the uninvolved extremity is placed lateral to the knee of the adducted thigh and assists in holding the stretch position (Fig. 20.19).

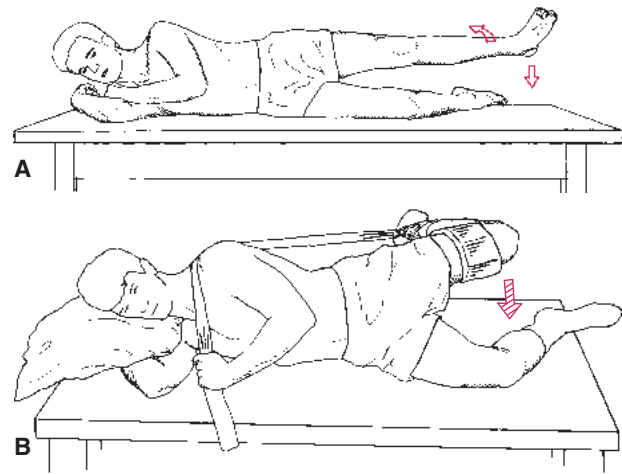

**FIGURE 20.19** Self-stretching of the tensor fasciae latae: supine. Pillows support the spine and pelvis, allowing the hips to extend. The crossed-over foot stabilizes the femur in adduction and external rotation.

### Side-Lying Stretch

■ **Patient position and procedure:** Side-lying, with the leg to be stretched uppermost. The bottom extremity is flexed for support, and the pelvis is tilted laterally, so the waist is against the mat or floor. Abduct the top leg and align it in the plane of the body (in extension). While maintaining this position, have the patient externally rotate the hip and then gradually lower (adduct) the thigh to the point of stretch (Fig. 20.20 A).

**NOTE:** It is critical to keep the trunk aligned and not allow it to roll backward. If the trunk rolled backward, the hip would then flex, and the iliotibial tract would slip in front of the greater trochanter, preventing an effective stretch.

■ **Progression:** Secure a belt or sheet around the ankle of the involved leg and have the patient hold onto the other end placed over the shoulder (Fig. 20.20 B). Instruct the patient to first flex the knee and abduct the hip and then extend

**FIGURE 20.20** Self-stretching of the tensor fasciae latae: side-lying. **(A)** The thigh is abducted in the plane of the body; then it is extended and externally rotated, then slowly lowered. Additional stretch occurs by flexing the knee. **(B)** Progress the intensity of a sustained stretch by pulling the hip into extension with a strap and adding a weight.

the hip. (This ensures that the IT band is positioned over the greater trochanter.) Then have the patient adduct the hip in slight external rotation until tension is felt along the lateral aspect of the knee. If tolerated, a 2- to 5-lb weight is placed distally over the lateral thigh for added stretch, and the position maintained for 20 to 30 minutes (also see manual stretching Fig. 4.29).

■ **Fascial release procedure for the IT band in side-lying.** Refer to the description and illustration of the foam roller release in Chapter 21 (see Fig. 21.22).

### Standing Stretch

**Patient position and procedure:** Standing with the side to be stretched toward a wall and the hand on that side placed on the wall. Have the patient extend, adduct, and externally rotate the extremity to be stretched and cross it behind the other extremity. With both feet on the floor, have the patient shift his or her pelvis toward the wall and allow the normal knee to bend slightly (Fig. 20.21). There is a slight side-bending of the trunk away from the side being stretched.

## Exercises to Develop and Improve Muscle Performance and Functional Control

During the controlled motion and return to function phases of intervention, when only moderate or minimum protection of healing tissues is necessary, the patient must learn to develop control of hip movement while using good trunk stability. For a muscle that has not been functioning normally

**FIGURE 20.21** Self-stretching of the tensor fasciae latae: standing. The pelvis shifts toward the tight side with a slight side bend of the trunk away from the tight side. Increased stretch occurs when the extremity is positioned in external rotation prior to the stretch.

because other muscles are more active, exercises begin with developing patient awareness of muscle contractions and movements through graded isometrics and controlled ROM exercises. If muscle shortening has prevented full ROM, development of muscle control in any newly gained range must immediately follow stretching activities. Principles for improving muscle performance as well as techniques for manual resistance exercise and methods of mechanical resistance are described in Chapter 6. Manually applied resistance should be used when muscles are weak or when helping the patient focus on activating specific muscles.

Exercises described in the following sections may be adapted for home exercise programs and progressed by integrating advanced function training exercises described in Chapter 23. Choose exercises that challenge the patient to progress toward the functional goals established in the plan of care.

## Open-Chain (Nonweight-Bearing) Exercises

Even though weight-bearing activities dominate lower extremity function, when a patient is weak or has poor control of specific muscles or movement patterns, it is advantageous to begin exercises in nonweight-bearing positions, so the individual can learn to isolate muscle activity and control specific motions. In addition, many functional activities have a nonweight-bearing component, such as the swing phase in gait, lifting the leg up to a step when going upstairs, and lifting the lower extremity into a car or onto a bed.

## To Develop Control and Strength of Hip Abduction (Gluteus Medius, Gluteus Minimus, and Tensor Fasciae Latae)

**NOTE:** When a patient is observed to flex and internally rotate the thigh when abducting the hip, there may be a muscle activation imbalance between the TFL and gluteus medius. Most often, the TFL is dominant and the stabilizing forces from the gluteus medius are poorly controlled with this movement pattern.<sup>142</sup> To manage this, the posterior fibers of the gluteus medius and minimus must be trained to contract and control external rotation while the TFL relaxes. If there is sufficient control of rotation, abduction is performed utilizing the optimum synergy between these muscles. Techniques to address this imbalance are described in the following sections.

### Supine Abduction

**Patient position and procedure:** Supine with the hips and knees extended. Have the patient concentrate on isolated hip abduction while keeping the trunk still. Do not let the femur roll outward into external rotation. Supine abduction is the easiest position in which to initiate motion, because the influence of gravity on the abductors is eliminated.

- For very weak abductors (< 3/5 manual muscle test grade), provide assistance or place a skate or towel under the leg to minimize the effects of friction.
- If the abductors are not strong enough to progress to antigravity training in the side-lying position, place a weight, such as a sandbag, along the lateral aspect of the thigh or ankle and have the patient push the weight outward.

### Side-Lying Abduction

**NOTE:** If the TFL is tight, the range into extension or adduction may be limited. It is important to stretch this muscle (see Figs. 20.19, 20.20, and 20.21) prior to performing hip abduction to strengthen the gluteus medius. Be certain that the patient does not let the hip flex or internally rotate during these exercises to minimize action of the TFL. If the patient has difficulty controlling hip rotation while abducting in the side-lying position, first develop strength in the external rotators as described later in this section.

**Patient position and procedure:** Side-lying with the bottom hip and knee flexed for stability. Have the patient lift the top leg into abduction, keeping the hip neutral to rotation and in slight extension. Do not allow the hip to flex or the trunk to roll backward.

- Add ankle weights to provide resistance as the patient's strength improves.

### Standing Abduction

**Patient position and procedure:** In single-leg stance, have the patient move the nonweight-bearing lower extremity out to the side. Instruct the patient to maintain the trunk upright

in neutral alignment and avoid hiking the pelvis and flexing or rotating the abducting hip.

- Add resistance by applying an ankle weight on the moving leg or by using pulleys or elastic resistance applied at right angles to the moving extremity.
- The abductors on the weight-bearing lower extremity contract isometrically to stabilize the pelvis (see Fig. 20.26 B).

### To Develop Control and Strength of Hip Extension (Gluteus Maximus)

#### Gluteal Muscle Setting

**Patient position and procedure:** Supine or prone. Use gluteal setting exercises to increase awareness of the contracting muscle; teach the patient to “squeeze” (contract) the buttocks.

#### Standing Leg Lifts With Trunk Support

**Patient position and procedure:** Standing at the edge of a treatment table with the trunk flexed and supported on the table. Have the patient alternately extend one hip, then the other. This is done with the knee flexed to train the gluteus maximus while relaxing the hamstrings. To progress, add weights or elastic resistance to the distal thigh.

#### CLINICAL TIP

When attempting hip extension with the knee flexed, if the hamstrings cramp from active insufficiency, the patient is using the hamstrings rather than the gluteus maximus and should learn to alter this contraction pattern. Help them refocus on the maximus by using isometrics in various positions before progressing with this exercise.

#### Quadruped Leg Lifts

**Patient position and procedure:** In the quadruped position or lying prone over a large gym ball, have the patient alternately extend each hip while keeping the knee flexed (Fig. 20.22). Combine this exercise with trunk stabilization

**FIGURE 20.22** Isolated training and strengthening of the gluteus maximus. Starting in the quadruped position, extend the hip while keeping the knee flexed to rule out use of the hamstring muscles. Do not to extend the hip beyond the available ROM to avoid causing stress to the sacroiliac or lumbar spinal joints.

by first having the patient find the neutral pelvic position, drawing in the abdominal muscles, then extending the hip (see Chapter 16).

#### CLINICAL TIP

When instructing a patient in hip extension exercises, care is taken not to extend the hip beyond the available range of hip extension; otherwise, the motion causes stress in the sacroiliac joint or lumbar spine. Emphasize spinal stabilization when performing hip extension.

#### Standing Extension

**Patient position and procedure:** In single-leg stance, have the patient extend the opposite hip (see Fig. 20.26 A). Instruct the patient to maintain the trunk upright in neutral alignment and not allow the moving hip to extend beyond the normal range.

- To add resistance, apply an ankle weight on the moving leg or by using pulleys or elastic resistance applied at right angles to the moving extremity.
- The hip musculature on the weight-bearing lower extremity must contract isometrically to stabilize the pelvis.

### To Develop Control and Strength of Hip External Rotation

#### Prone Isometrics

**Patient position and procedure:** Prone with knees flexed and about 10 inches apart. Have the patient press the medial aspect of the heels together, causing an isometric contraction of the external rotators. This also may be done with the knees extended; emphasize the sensation of the thighs rolling outward, not adducting.

#### Clam Shell Exercise

**NOTE:** Clam shell exercises combine hip external rotation with abduction.

**Patient position and procedure:** With the patient side-lying, lower extremities partially flexed at the hips and knees, and the heel of the top leg resting on the heel of the bottom leg, have the patient lift the knee of the top leg, keeping the heels together. Add resistance by tying an elastic band around the thighs or by placing a cuff weight around the distal thigh of the top leg (Fig. 20.23).

- Variations of the clam shell exercise include beginning with the patient supine in the hook-lying position with an elastic band around the distal thigh for resistance and progressing to a modified bridge position or side plank position using the elastic band around the knee for resistance. These last two positions require good trunk stabilization while moving the hips through the abduction/external rotation motion.

**FIGURE 20.23** Clam exercises to develop control and initiate antigravity strengthening of the external rotators. Wrap an exercise band around the thighs or add a weight to top leg to increase resistance.

### Side-Lying External Rotation: Progression

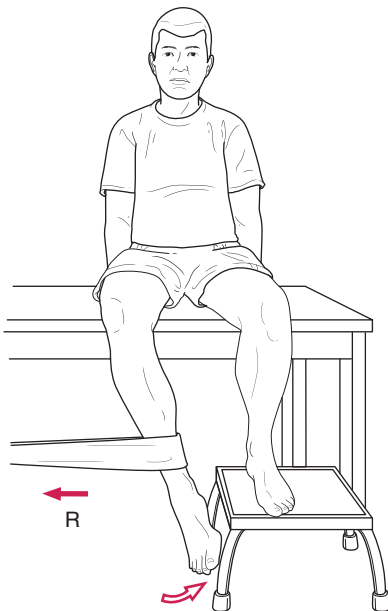

**Patient position and procedure:** Hip and knee of top leg extended and aligned with the trunk. First, have the patient roll the leg outward. Then progress to lifting the lower extremity into abduction with the hip externally rotated. Apply elastic resistance or a cuff weight around the thigh when resistance is tolerated.

**NOTE:** Do not allow the patient to roll the trunk backward or flex the hip, as this exercise is done to minimize substitution with the tensor fasciae latae.

### Sitting: External Rotation

**Patient position and procedure:** Sitting with knees flexed over the edge of a treatment table. Secure an elastic band or tubing around the patient's ankle and the table leg on the same side. For resisted external rotation have the patient move the foot toward the opposite leg, pulling against the resistance (Fig. 20.24).

**NOTE:** Do not allow substitution with knee flexion or extension or hip abduction.

**FIGURE 20.24** Strengthening the external rotators in a sitting position with elastic resistance.

## To Develop Control and Strength of Hip Flexion (Iliopsoas and Rectus Femoris)

### Supine Heel Slides

**Patient position and procedure:** Begin in hip and knee extension and have the patient flex the hip and knee by sliding the heel toward the buttock.

### Hip and Knee Flexion

**Patient position and procedure:** Standing in front of a step or stool and holding onto a stable object for balance if necessary. Have the patient lift the leg (flex the hip and knee) and place the foot on the step and then return the foot to the floor. Alternate with the other leg for bilateral strengthening.

- To progress resistance add an ankle weight and/or the height of the step.
- Variations include having the patient perform alternating hip/knee flexion (high-step marching) or climbing a flight of stairs.

### Straight-Leg Hip Flexion

**Patient position and procedure:** Supine, or standing and holding on to a stable structure for balance if necessary. Have the patient flex the hip while maintaining the knee in extension. For resistance when supine, add cuff weights; when standing, secure elastic resistance around the patient's distal thigh or leg.

## To Develop Control and Strength of Hip Adduction

### Side-Lying Adduction

**Patient position and procedure:** With the bottom leg aligned in the plane of the trunk (hip extension) and the top leg flexed forward with the foot on the floor or with the thigh resting on a pillow, have the patient lift the bottom leg upward into adduction. Weights can be added to the ankle to progress strengthening (Fig. 20.25 A). A more difficult position is to have the patient hold the top leg in abduction and adduct the bottom leg upward to meet it (Fig. 20.25 B).

### Standing Adduction

**Patient position and procedure:** Have the patient adduct the leg across the front of the weight-bearing leg. Add ankle weights to provide resistance, or fasten elastic resistance or a pulley at right angles to the moving leg.

## Closed-Chain (Weight-Bearing) Exercises

Weight-bearing exercises in the lower extremity involve all of the joints in the chain and are therefore not limited to hip muscles. Most activities bring into play antagonistic, two-joint muscles in which each muscle is being lengthened across one joint while it is shortening across another, thus maintaining an optimal length-tension relationship. In addition to causing motion, a prime function of the muscles in weight bearing is to control the forces of gravity and momentum for balance

**FIGURE 20.25** Training and strengthening the hip adductors. **(A)** The top leg is stabilized by flexing the hip and resting the foot on the mat while the bottom leg is adducted against gravity. **(B)** The top leg is isometrically held in abduction while the bottom leg is adducted against gravity.

and stability. Therefore, the exercises for the hip described in this section include balance and stabilization training as well as strengthening and functional exercises. More advanced balance and functional exercises are described in Chapter 23.

A number of EMG studies have analyzed lower extremity exercises used to strengthen hip musculature in both non-weight-bearing and weight-bearing positions. Two such studies, primarily of weight-bearing exercises, are summarized in Box 20.10.<sup>7,41</sup>

Exercises performed in weight-bearing postures described in the following section are closely related and are progressed concurrently as the patient is able. If the patient does not tolerate or is not permitted to be full weight bearing, begin exercises with upper extremity assistance, such as parallel bars,

or utilize a therapeutic pool if one is available and the patient has no open wounds (see Chapter 9).

### Closed-Chain Isometric Exercises

#### Alternating Isometrics and Rhythmic Stabilization

**Patient position and procedure:** Standing; begin with bilateral standing and progress the patient to unilateral standing. Alternating isometrics and rhythmic stabilization develop postural adjustments to applied forces.

- Apply manual resistance against the pelvis in alternating directions and ask the patient to hold (with isometric contractions). There should be little or no movement.
- Vary the force and direction of resistance; also vary where the force is applied by shifting the resistance from the pelvis to the shoulders and eventually against outstretched arms (see Fig. 22.15).
- At first, use verbal cueing. Then, as the patient learns control, apply the varying forces without warning.

#### Stabilization in Single-Leg Stance

**Patient position and procedure:** Standing on the involved leg with elastic resistance placed around the thigh of the opposite extremity and secured to a stable upright structure. If the uninvolved knee is stable, the resistance can be applied around the ankle. Have the patient maintain alignment and stability of the trunk and the weight-bearing extremity while moving the opposite extremity forward, backward, and to the side.

- To resist *hip flexion of the moving thigh*, have the patient face away from where the resistance is secured. This requires stabilization by the posterior muscles on the stance side.
- To resist *extension of the moving thigh*, have the patient face toward where the resistance is secured (Fig. 20.26 A). This requires stabilization by the anterior muscles on the stance side.

### BOX 20.10 EMG Analysis of Selected Weight-Bearing Exercises Used to Strengthen Lower Extremity Musculature\*

*Gluteus maximus*: > 40% MVC (strong contraction)

- Single-limb wall slide,<sup>7</sup> single-limb squat, and single-limb deadlift<sup>41</sup>
- Single-limb mini-squat<sup>7</sup>
- Step-ups (forward, lateral, retro)<sup>7</sup>
- Lunges (transverse, forward, sideways)<sup>41</sup>

*Gluteus maximus*: < 40% MVC

- Side-lying hip abduction, clam with 60° hip flexion<sup>41</sup>
- Transverse hop, forward hop, and clam with 30° hip flexion<sup>41</sup>

*Gluteus medius*: > 40% MVC (strong contraction)

- Side-lying hip abduction<sup>41</sup>
- Single-limb wall slide<sup>7</sup>
- Lateral band walk, single-limb deadlift, sideways hop<sup>41</sup>
- Forward step up<sup>7</sup>

- Sideways hop, transverse hop, transverse lunge, forward hop, forward lunge, clam with 30° hip flexion<sup>41</sup>

*Gluteus medius*: < 40% MVC

- Sideways lunges and clam exercise (in the side-lying position) with 60° hip flexion<sup>41</sup>

*Biceps femoris*: < 40% MVC

- Single-leg wall squat, mini-squat, and forward step-up<sup>7</sup>
- Retro step-up and lateral step-up are 10% and 9% MVC, respectively<sup>7</sup>

\*The clam exercise was performed in a nonweight-bearing position. The exercises are listed from most effective to least effective for activating each muscle as normalized to its own maximum voluntary contractions (MVC).

- To resist *abduction* and *adduction*, have the patient face so the band is directed toward one side and then the other (Fig. 20.26 B).

**FIGURE 20.26** Closed-chain stabilization and strengthening exercises with elastic resistance around the opposite leg. **(A)** Resisting extension on the right requires stabilization of the anterior muscles of the left side. **(B)** Resisting abduction on the right requires stabilization by the left frontal plane muscles. To increase difficulty, the resistance is moved distally onto the leg.

**NOTE:** Although the nonweight-bearing extremity is moving against resistance, the emphasis of the exercise is to develop stability and strengthen the weight-bearing side. Therefore, fatigue is determined when the patient can no longer hold the weight-bearing extremity or pelvis stable.

These stabilization exercises can be used for balance training by having the patient vary the speed of the moving leg.

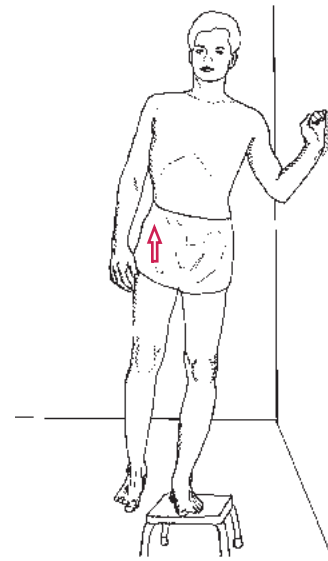

## Closed-Chain Dynamic Exercises

### Hip Hiking/Pelvic Drop

**Patient position and procedure:** Standing with one leg on a 2- to 4-inch block and using a wall or stable surface for balance if necessary. Alternately lower and elevate the pelvis on the side of the unsupported leg (Fig. 20.27). This develops control of the abductors of the stance leg and hip hikers on the unsupported side.

## FOCUS ON EVIDENCE

In an EMG study by Bolgla and Uhl,<sup>21</sup> a series of 16 healthy subjects performed 6 different abductor exercises using a constant weight. The authors documented significantly greater maximum voluntary contraction of the gluteus medius in the stance leg (weight-bearing leg) during the pelvic drop exercise than during other hip abduction exercises. In addition, standing hip abduction showed significantly greater hip abductor activity on the weight-bearing side than on the moving (open-chain) side;

**FIGURE 20.27** Training the hip abductor and hiker muscles for frontal plane strengthening and stability.

the activity on the weight-bearing side had a comparable maximum voluntary contraction as side-lying hip abduction.

## Bridging

**Patient position and procedure:** Begin in the hook-lying position. Have the patient press the upper back and feet into the mat, elevate the pelvis, and extend the hips. This strengthens the hip extensors in coordination with the trunk stabilizers (Fig. 20.28).

**FIGURE 20.28** Training and strengthening the hip extensor muscles using bridging exercises. Resistance can be added against the pelvis.

- **Progressions:** Apply resistance against the anterior pelvis manually or by strapping a weighted belt around the pelvis. Have the patient hold the bridge position and alternately extend the knees. To challenge proprioception and balance, perform bridging exercises using a large gym ball positioned either under the back with feet on the floor or under the feet while lying on the floor.
- **Variation:** Apply elastic resistance around the thighs. While maintaining the bridge position, have the patient abduct and externally rotate the thighs to coordinate strengthening of the gluteus maximus, medius, and external rotators.

### Wall Slides

**Patient position and procedure:** Standing and resting the back against a wall with feet forward and a shoulder-width apart. Have the patient slide the back down the wall by flexing the hips and knees, then slide up the wall by extending the hips and knees (Fig. 20.29 A). This strengthens the hip and knee extensors eccentrically and concentrically. If sliding the back directly against the wall causes excessive friction, place a towel behind the patient's back.

- **Progressions:** Place a large exercise ball behind the back. This requires additional control because the surface is less stable (Fig. 20.29 B). Add arm motions and weights to develop coordination and increase strength. To develop isometric strength, have the patient hold the flexed position and superimpose arm motions with weights. Tie these exercises in with the functional activity of sit-to-stand (with arm assistance if necessary) to and from various chair heights.

**FIGURE 20.29** Wall slides/partial squats to develop eccentric control of body weight. (A) The back sliding down a wall, superimposing bilateral arm motion for added resistance. (B) The back rolling a gym ball down the wall, superimposing antagonistic arm motion to develop coordination.

### Partial Squats/Mini-Squats VIDEO 20.1

**Patient position and procedure:** In bilateral stance, have the patient lower the body by flexing the hips and knees as if sitting on a chair. Add resistance by having the patient hold weights in the hands, or use elastic resistance secured under the feet (see Fig. 21.27). Progress to safe lifting techniques that involve squatting.

**NOTE:** If there is need to protect the ACL following ACL reconstruction, limit knee flexion range from 0° to 60° (see Box 21.10 in Chapter 21). Have the patient lower the hips as if preparing to sit on a chair so the knees do not move anterior to the toes. To reduce patellofemoral compression, instruct the patient to squat only through pain-free ranges and avoid deep knee bends.

- **Variations:** Apply elastic resistance around the thighs. While abducting and externally rotating the thighs against the

resistance, have the patient perform partial squats (Fig. 20.30) or side-step in one direction and then the other (hips slightly flexed) to coordinate strengthening of the gluteus maximus, medius, and external rotators.

**FIGURE 20.30** Elastic resistance around thighs is used to activate the hip external rotators and abductors while performing partial squats to develop strength of the hip and knee extensors.

### Single-Limb Deadlift VIDEO 20.1

**Patient position and procedure:** In unilateral stance with the weight-bearing hip and knee in 30° flexion. Have the patient bend forward at the hips and reach for the toes of the stance leg with the contralateral hand while extending the hip and knee of the nonweight-bearing leg behind (Fig. 20.31). Then return to the upright starting position. This strengthens the hip extensors of the weight-bearing extremity eccentrically and concentrically.

**FIGURE 20.31** Single-limb deadlift to strengthen the hip extensors and develop control in the knee.

### Step-Ups and Step-Downs

**Patient position and procedure:** Begin with a low step, 2 to 3 inches in height; increase the height as the patient is

able. Have the patient step up and down, forward, laterally, or backward.

- Be sure the patient places the entire foot on the step and lifts and lowers the body with smooth motion. When stepping up, be certain the patient avoids a lurching motion of the trunk or pushing off with the trailing extremity.
- Make sure the patient keeps the trunk upright and the knee aligned vertically over the foot to prevent hip adduction and internal rotation and subsequent valgus collapse. If valgus positioning occurs, reinforce activation of the gluteus medius with manual resistance applied to the lateral thigh of the stepping leg (see Fig. 21.28 A).
- *Progression:* In addition to increasing the step height, add resistance with a weight belt, elastic resistance around the waist (see Fig. 21.28 B), weights in the hands, or a weight around the ankle of the nonweight-bearing leg.

### Partial and Full Lunges

**Patient position and procedure:** After assuming a forward stride position, have the patient flex the hip and knee of the forward extremity and then return upright. Repeat with the same leg or alternate legs. Begin by flexing the knee within a small range, progressing to 90° knee flexion. Instruct the patient to keep the knee in alignment with the forward foot and not bend the knee forward of the foot.

- Use a cane or rod for balance, or hold on to a stable surface for support (parallel bars, treatment table, countertop) if the patient has difficulty controlling the movement (Fig. 20.32).
- It is important to keep the toes pointing forward, bend the knee in the same plane as the feet, and keep the back upright.

**FIGURE 20.32** Partial lunge with cane assistance to develop balance and control for lowering body weight.

- *Progressions:* Hold weights in the hands for additional resistance, take a longer stride, or lunge forward onto a small step. Integrate a function into this exercise by lunging and picking up objects from the floor.

**NOTE:** A patient with an ACL-deficient knee or a surgically repaired ACL should not flex the knee forward beyond the toes when performing lunges, because this increases the shear force and stress to the ACL. An individual with patellofemoral pain typically experiences increased pain under these circumstances because the external torque generated by the force of gravity acting on the body is greater when the mass is posterior to the knee flexion/extension axis. Adapt the position of the knee or body based on the patient's symptoms and presenting pathology.

### Resisted Side Stepping

**Patient position and procedure:** Patient standing upright or in a partial squat position with an elastic band secured around the knees or distal legs (or the two ends of the band can be held in each hand with the band under both feet). Have the patient step sideways and return, or walk sideways with additional side steps 8 to 10 times then return by leading with the other leg.

### FOCUS ON EVIDENCE

In an EMG study by Berry et al,<sup>16</sup> 24 healthy adults performed resisted side stepping with an elastic band around the ankles in both the upright and partial squat positions. The authors consistently recorded significantly greater muscle activation levels in the gluteus maximus, gluteus medius, and tensor fascia latae of the stationary limb compared to the moving limb in both positions. The gluteus medius and maximus had greater activation in the squat position, whereas the tensor had higher values in the upright position.

### Resisted Side Sliding

**Patient position and procedure:** Standing upright or in a partial squat position with an elastic band secured around the ankles. Place a towel under the moving foot and have the patient slide that foot along the floor into hip abduction and return with hip adduction while maintaining stability in the stationary leg (Fig. 20.33).

## Functional Progression for the Hip

For a patient to return to full function, the level of challenge from the exercise program must meet the demands that will be imposed during ADL, IADL, work, or sports-related

**FIGURE 20.33** Standing side slides with elastic resistance; the stationary leg provides stability and control of the body weight while the moving leg slides along the floor into abduction and adduction.

tasks. An outcome may be simply learning how to ambulate forward, backward, and around obstacles safely, or it may involve developing a high level of strength, endurance, coordination, balance, and skill.

The progression of exercises typically begins with isolated activation, control, endurance, and strengthening of the impaired muscles and advances to a variety of open- and closed-chain exercises in combined movement patterns that simulate functional activities to further improve strength, power, and muscular endurance. Balance, coordination, skill, and aerobic conditioning are also integrated into the exercise program as weight-bearing tolerance improves.

Key components of functional exercise progressions for the hip incorporate the entire lower extremity as well as the trunk and upper extremities. Suggestions are summarized in Box 20.11. Details of progressions of exercises for advanced training are described in Chapter 23. Also, refer to Chapter 16 for progressions of spinal exercises and safe body mechanics, Chapter 7 for principles of aerobic exercise, and Chapter 8 for principles of balance training.

### BOX 20.11 Summary of Functional Progressions for the Hip

For each activity, adapt the exercise to challenge the patient, but avoid unsafe stresses to the tissues.

- **Balance activities.** Initiate balance activities at the level of weight bearing allowed and progress from bilateral to unilateral activities. Add sagittal and frontal plane arm movements; progress to transverse and diagonal planes. Advance balance/perturbation training activities from stable to unstable surfaces.
- **Ambulation activities.** Increase challenges for ambulation, such as having the patient walk on uneven surfaces, turn, maneuver backward, and walk up and down ramps first under supervision and then unassisted. As soon as the patient is able, have him or her practice rising up and sitting down from chairs of various heights and climbing and descending flights of stairs. Add resistance and speed as tolerated.
- **Safe body mechanics.** Incorporate exercises that prepare the patient for use of safe body mechanics, such as repetitive squats and lunges. Progress the exercises by having the patient lift and carry or push and pull various loads as part of the exercise routine. Utilize safe patterns of motion that replicate functional requirements.
- **Aerobic training.** Cardiopulmonary endurance exercises that replicate functional demands are introduced early in the rehabilitation program and progressed as the patient tolerates.
- **Agility drills.** Use agility drills such as maneuvering around and stepping over obstacles. Incorporate running, jumping, hopping, skipping, and side-shuffle drills.
- **Advanced strength training.** Incorporate maximum eccentric loading into a weight training progression. Any of the previously described exercises can be adapted, but it is critical to assist the patient through the concentric phase of the exercise and guard him or her through the eccentric phase as the resistance is greater than what the muscle can control concentrically. Also include isokinetic training, particularly at medium and fast speeds (velocity spectrum training), if equipment is available.
- **Plyometric training.** If the patient is returning to activities that require strength and power, incorporate plyometric drills. For example, have the patient jump from a box or step; flex the hips, knees, and ankles to absorb the impact of landing; and immediately jump back up to the box or step.

## Independent Learning Activities

### Critical Thinking and Discussion

- Describe the function of the primary muscle groups of the hip joint in open- and closed-chain situations. Include their role in stabilizing the pelvis during single-leg stance and the effects on the spine when the pelvis is moved by the hip musculature.
- Describe the role of the hip during the gait cycle. Include hip muscle activity, hip and pelvic motions needed, and pathological gait patterns that may be related to muscle weakness or restricted motion.
- Analyze the type of gait deviations a patient might exhibit after internal fixation of a fracture of the proximal femur, THA, or hip hemiarthroplasty.
- After THA or internal fixation of a hip fracture, what are the signs that dislocation of the hip or loss of fracture stabilization has occurred?

### Laboratory Practice

- Identify and practice the techniques you would use to treat a mobility impairment if the results of your examination included decreased joint play versus restricted flexibility in the hip musculature. Include exercises that could be used in a home exercise program.
- Demonstrate a progression of exercises to develop control and strength in the gluteus medius muscle after total hip replacement.
- Develop an exercise routine and progression for an individual with hip muscle weakness who wants to return to work that requires walking, lifting objects that weigh up to 45 lb, and climbing ladders with 45-lb weights.

### Case Studies

- Mr. C, 57 years of age, is a mail carrier; he has walked his mail route for 32 years. Over the past year, he has noticed that his hip hurts after sitting for more than 1 hour and that there is a marked increase in pain when first getting up out of a chair and walking. He also has noticed that there is increased discomfort in his hip and knees near the end of each workday. The medical diagnosis is OA. Strength testing reveals generally 4/5 on manual muscle tests except the gluteus medius, which is 3+/5. There is mild tightness in the hip flexors, including the rectus femoris and tensor fasciae latae. Mr C wants to avoid being a “candidate for total hip replacement surgery.”
  - Explain why the patient’s job would perpetuate these symptoms.
  - Outline a plan to manage the symptoms; identify measurable goals and interventions you would use to reach the goals.
  - What can the patient do to protect his hip joints?
- Ms. J, a 31-year-old mother, recreational tennis player, and bowler, is recovering from multiple femoral fractures she sustained in an automobile accident 3 months ago. There is radiological healing of all the fracture sites, and she is now allowed full weight bearing and no restrictions in activities. She has significant hip mobility impairments from joint restrictions and muscle weakness.
  - What joint ranges and muscle strength levels are needed for her to return to her functional and recreational activities?
  - Outline a plan to manage the symptoms; identify measurable goals and interventions you would use to reach the goals. Using the taxonomy or motor skills described in Chapter 1, develop a series of progressively more challenging motor tasks under varying environmental conditions.
- Mr. P is a 32-year-old firefighter who strained his right hamstring muscles near the ischial tuberosity while pulling a heavy individual out of a burning building 4 days ago. Currently, he is experiencing considerable pain, especially when rising from or lowering himself into a chair and climbing or descending stairs, and is unable to sit on hard surfaces (because of pressure as well as flexing the hip). Hip flexion is limited to 90° and SLR to 45°. He tolerates minimal resistance to hip extension or knee flexion. This individual must be able to climb a ladder while wearing his gear (40 lb) and air pack (40 lb) and carrying a 20-lb hand tool; in addition, he must be able to carry a 175-lb individual across his shoulder, drag a heavy body across the floor, climb five flights of stairs while wearing full gear, and run a half mile in 5 minutes to be able to return to work.
  - Explain why this patient has impaired function in bio-mechanical terms.
  - Establish goals that reflect treatment of the impairments and desired functional outcomes.
  - Design a program of intervention at each stage of tissue healing.
  - Design a series of exercises that can be used to prepare Mr. P for return to function once the muscle has healed.
- A 78-year-old woman who lives at home with her husband has been referred to you for home-based physical therapy. Ten days ago she underwent cemented THA with a posterolateral approach for late-stage posttraumatic arthritis associated with injuries sustained in a horseback riding accident 30 years ago. She has been home from the hospital for 5 days. She is ambulating with a walker on level surfaces, and weight bearing is tolerated. The patient’s long-term goals are to be able to participate in a community-based fitness program for older adults and resume travel with her husband.
  - Continue progressing her exercise program that was initiated in the hospital.

- Review the precautions she must take for the next 6 to 12 weeks during ADLs.
- Make suggestions on how she or her husband might adapt the home environment to help her adhere to the precautions.
- To help her meet her long-term goals, design a sequence of progressively more demanding functional activities, integrating the taxonomy of motor tasks (addressed in Chapter 1) and the principles of aerobic conditioning (discussed in Chapter 5).

### Independent Learning Activities 840

The knee joint is designed for mobility and stability; it functionally lengthens and shortens the lower extremity to raise and lower the body or to move the foot in space. Along with the hip and ankle, it supports the body when standing, and it is a primary functional unit in walking, climbing, running, and sitting activities.

As in the other regional chapters of the text, this chapter is divided into three primary sections. Highlights of the anatomy and function of the knee complex are reviewed in the first section of the chapter, followed by material on the management of knee disorders and surgeries. The third section includes exercise interventions for the knee region. Chapters 10 through 13 present general information on principles of management. The reader should be familiar with the material in these chapters as well as have a background in examination and evaluation in order to effectively design a therapeutic exercise program to improve knee function in patients with impairments due to injury or pathology or following surgery.

## Structure and Function of the Knee

The bones of the knee joint consist of the distal femur with its two condyles, the proximal tibia with its two tibial plateaus, and the large sesamoid bone in the quadriceps tendon, the patella. It is a complex joint both anatomically and biomechanically (Fig. 21.1).<sup>108</sup> The proximal tibiofibular joint is anatomically close to the knee but is enclosed in a separate joint capsule and functions with the ankle. Therefore, the proximal tibiofibular joint is discussed in Chapter 22.

**FIGURE 21.1** Bones and joints of the knee and leg.

## Joints of the Knee Complex

A lax joint capsule encloses two articulations: the tibiofemoral and the patellofemoral joints. Recesses from the capsule form the suprapatellar, subpopliteal, and gastrocnemius bursae.

Folds or thickenings in the synovium persist from embryologic tissue in as many as 60% of individuals and may become symptomatic with microtrauma or macrotrauma.<sup>24,136</sup>

## Tibiofemoral Joint

**Characteristics.** The knee joint is a biaxial, modified hinge joint with two interposed menisci supported by ligaments and muscles. Anteroposterior stability is provided by the cruciate ligaments; mediolateral stability is provided by the medial (tibial) and lateral (fibular) collateral ligaments (MCL and LCL), respectively (Fig. 21.2).<sup>37,108</sup>

**FIGURE 21.2** The medial meniscus is attached to the medial collateral, anterior cruciate, and posterior cruciate ligaments. The lateral meniscus is also attached to the posterior cruciate ligament. (Joint capsule removed for visualization). (From Hartigan, E, Lewek, M, and Snyder-Mackler, L: *The knee*. In Levangie, PK, and Norkin, CC (eds): *Joint Structure and Function: A Comprehensive Analysis*, ed. 5. Philadelphia: F.A. Davis, 2011, with permission.)

- The convex bony partner is composed of two asymmetrical condyles on the distal end of the femur. The medial condyle has a longer surface than the lateral condyle, which contributes to the locking mechanism at the knee.
- The concave bony partner is composed of two tibial plateaus on the proximal tibia with their respective fibrocartilaginous menisci. The medial plateau is larger than the lateral plateau.
- The menisci improve the congruency of the articulating surfaces. They are connected to the tibial condyles and capsule by the coronary ligaments, to each other by the transverse ligament, and to the patella via the patellomeniscal ligaments.<sup>108</sup> Anterior and posterior menisiofemoral ligaments connecting the lateral meniscus to the femur may also be present.<sup>104</sup> The medial meniscus is firmly attached to the joint capsule as well

as to the MCL, anterior and posterior cruciate ligaments (ACL and PCL), and semimembranosus muscle. The lateral meniscus attaches to the PCL and the tendon of the popliteus muscle through capsular connections.<sup>108</sup> Because the medial meniscus has more extensive attachments than the lateral meniscus (see Fig. 21.2), it has a greater chance of sustaining a tear when there is trauma to the knee.

**Arthrokinematics.** Joint mechanics are affected by open and closed-chain positions of the extremity, and are summarized in ONLINE Box 21.1 available on the FA Davis web site.

- With motions of the tibia while in a nonweight-bearing, open kinematic chain, the concave plateaus slide in the same direction as the bone motion.
- With motions of the femur on a fixed tibia while in a weight-bearing, closed kinematic chain, the convex condyles slide in the direction opposite to the bone motion.
- Axial rotation occurs between the tibia and femur as the knee flexes and extends due to the asymmetrical condyles. In nonweight bearing extension the tibia rotates laterally on the femur, and with flexion it rotates medially.

**Screw-home mechanism.** The axial rotation that occurs between the femoral condyles and the tibia during the final degrees of extension is called the locking, or screw-home, mechanism. When the tibia is fixed with the foot weight bearing on the ground, terminal extension results in the femur rotating internally (the medial condyle slides farther posteriorly than the lateral condyle). Concurrently, the hip moves into extension. Tension in the iliofemoral ligament, which occurs with hip extension, reinforces the medial rotation of the femur to lock the knee. As the knee is unlocked, the femur rotates laterally. Unlocking of the knee occurs indirectly with hip flexion and directly from action of the popliteus muscle. Individuals who cannot lock their knee into extension because they lack full hip extension (hip flexion contracture) are unable to benefit from this passive stabilizing function during standing.

## Patellofemoral Joint

**Characteristics.** The patella is a sesamoid bone in the quadriceps tendon. It articulates with the intercondylar (trochlear) groove on the anterior aspect of the distal femur. Its articulating surface is covered with smooth hyaline cartilage. The patella is embedded in the anterior portion of the joint capsule and is connected to the tibia by the ligamentum patellae. Many bursae surround the patella.<sup>108</sup>

**Mechanics.** As the knee flexes, the patella first contacts the intercondylar groove with its inferior margin and maintains contact with the groove as flexion increases. With extension, the patella remains seated in the groove until near full knee extension, when there is a small amount of superior patellar translation in the proximal intercondylar groove.<sup>154</sup> If patellar movement is restricted, it interferes with the range of knee flexion and may contribute to an extensor lag with active knee extension.<sup>289</sup>

## Patellar Function

The primary function of the patella is to increase the moment arm of the quadriceps muscle in its function to extend the knee. The cartilaginous surface of the patella also reduces friction and dissipates forces between the patella and the femoral condyles.<sup>108</sup>

## Patellar Alignment

The alignment of the patella in the frontal plane is influenced by the direction of the quadriceps muscle group composite force vector and by its attachment to the tibial tubercle via the patellar tendon. The result of these opposing forces is a bowstring effect on the patella that produces a lateral pull. The bowstring effect can be estimated by measuring the Q-angle. The Q-angle is the angle formed by two intersecting lines: one from the anterior superior iliac spine to the midpatella and the other from the tibial tubercle through the midpatella (Fig. 21.3).<sup>108,178</sup> A normal Q-angle, which tends to be greater in women than men, is 10° to 15°. A higher Q-angle suggests greater lateral bowstring forces on the patella.

**FIGURE 21.3** The Q-angle is the angle formed by the intersection of a line drawn from the center of the patella to the anterosuperior iliac spine and a line drawn from the center of the patella to the tibial tuberosity. These two lines represent forces that create a bowstring effect on the patella. An increased Q-angle is a factor contributing to excessive lateral tracking of the patella. (From McKinnis, LN: Fundamentals of Musculoskeletal Imaging, ed. 4. Philadelphia: F.A. Davis, 2014, p 375, with permission.)

## Forces Maintaining Alignment

In addition to the bony restraints of the trochlear groove (femoral sulcus), the patella is stabilized by passive and dynamic restraints. The superficial portion of the extensor retinaculum, to which the vastus medialis (VM) and vastus lateralis (VL) muscles attach, provides dynamic stability to the patella in the transverse plane. The medial and lateral patellofemoral ligaments, which attach to the adductor tubercle medially and iliotibial (IT) band laterally, provide passive restraints to the patella in the transverse plane.<sup>108</sup> The medial and lateral patellotibial ligaments and patellar tendon combine to stabilize the patella against the superiorly directed pull of the quadriceps muscle group (Fig. 21.4).

## Patellar Malalignment and Tracking Problems

Malalignment and tracking problems of the patella may be caused by several factors that may or may not be interrelated.<sup>99</sup>

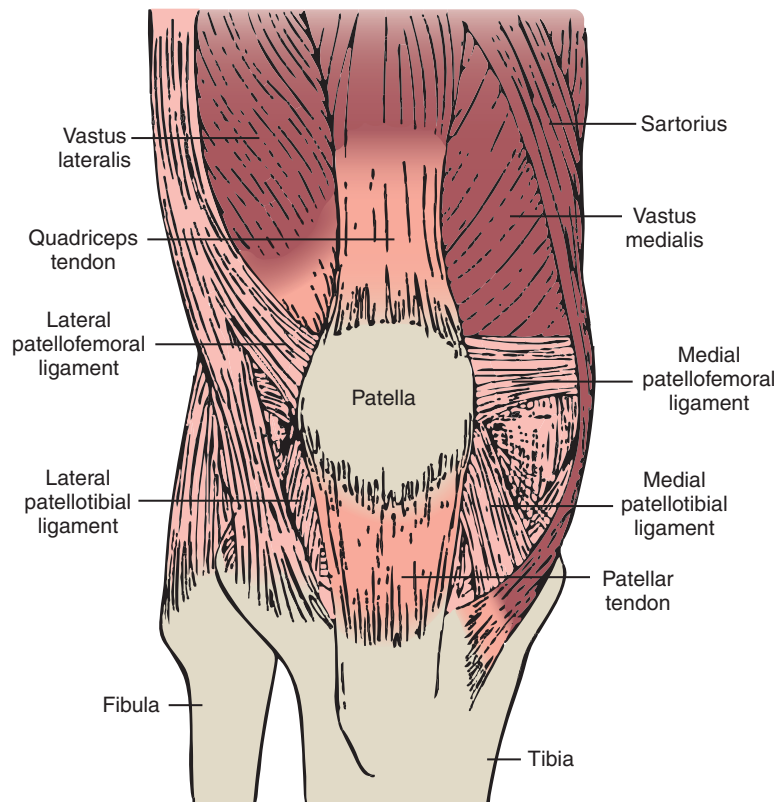

**Increased Q-angle.** With an increased Q-angle, there may be increased force between the lateral patellar facet and lateral femoral condyle when the knee flexes during weight bearing. Structurally, an increased Q-angle may occur with a wide pelvis, femoral anteversion, coxa vara, genu valgum, and/or laterally displaced tibial tuberosity. Lower extremity motions in the transverse plane that may increase the Q-angle are external tibial rotation, internal femoral rotation, and a pronated

subtalar joint. Dynamic knee valgus (see Fig. 21.9), where the knee joint center moves medially relative to the foot during weight-bearing activities, also increases the Q-angle.<sup>233,234</sup>

## FOCUS ON EVIDENCE

A recent MRI study<sup>277</sup> comparing femoral and patellar orientation at multiple knee angles during weight bearing in females with ( $n = 15$ ) and without ( $n = 15$ ) patellofemoral pain showed significant group-by-angle interactions for three of four outcome variables (femoral medial rotation, lateral patellar displacement, and patellar tilt, but not patellar rotation). Subjects in the patellofemoral pain group demonstrated significantly altered joint kinematics compared to the control group, with the greatest differences between groups at 0° knee flexion. The authors propose that increased femoral medial rotation is the main mechanism responsible for these kinematic differences.

**Muscle and fascial tightness.** A tight IT band and lateral retinaculum prevent medial translation of the patella. Tight ankle plantarflexors result in pronation of the foot when the ankle dorsiflexes, causing lateral torsion of the tibia and functional lateral displacement of the tibial tuberosity promoting an increased lateral force on the patella.<sup>166</sup> Tight rectus

**FIGURE 21.4** The extensor retinaculum is reinforced medially by the transversely oriented medial patellofemoral ligament and the longitudinally oriented medial patellotibial ligament. The lateral patellofemoral ligament and lateral patellotibial ligament help resist an excessive medial glide of the patella. (From Hartigan, E, Lewek, M, and Snyder-Mackler, L: *The knee*. In Levangie, PK, and Norkin, CC (eds): *Joint Structure and Function: A Comprehensive Analysis*, ed. 5. Philadelphia: F.A. Davis, 2011, p 403, with permission.)

femoris and hamstring muscles may affect knee mechanics and lead to compensations.<sup>172</sup>

**Hip muscle weakness.** Hip abductor and external rotator weakness may result in femur adduction and knee valgus and contribute to increased medial rotation of the femur observed under weight bearing in subjects with patellofemoral pain syndrome.<sup>125,194</sup>

## Patellar Compression

**Patellar contact.** The posterior surface of the patella has several facets and is not completely congruent with the trochlear groove on the femur. When the knee is in complete extension (0°), the patella is superior to the trochlear groove. By 15° of flexion, the inferior border of the patella begins to articulate with the superior aspect of the groove. As knee flexion increases, the patella slides distally in the groove, and surface contact area increases. Beyond 60° of flexion the contact area either continues to increase, levels off, or decreases, depending on the source.<sup>98,99</sup> As the knee flexes past 90°, the quadriceps tendon comes in contact with the trochlear groove as the patella slides inferiorly.

**Compression forces.** In full extension, because there is minimal to no contact of the patella with the trochlear groove, there is no compression of the articular surfaces. Furthermore, the nearly parallel alignment of the femur and tibia creates minimal compressive loading through a small sagittal plane bowstring effect. The resultant force from this quadriceps and patellar tendon bowstring effect causes increased compressive forces as the knee flexes, but there is also greater joint surface contact area to dissipate these higher forces. Patellofemoral joint reaction forces rise rapidly between 30° and 60°, but there is controversy regarding the extent of joint reaction forces at higher flexion angles.

- During squatting, the joint reaction force continues to rise until 90° and then levels off or decreases because the quadriceps tendon begins making contact with the trochlear groove and dissipates some of the force.<sup>98</sup>
- In an open-chain, nonweight-bearing exercise with a free weight on the distal leg, the greatest joint reaction force in the patellofemoral articulation occurs at around 30° of flexion.<sup>98</sup> This is more likely due to the changing moment arm of the weight rather than the resultant force of the quadriceps and patellar tendons.
- An increased Q-angle causes increased lateral facet compression as the knee flexes.<sup>234</sup>

## Muscle Function

### Knee Extensor Muscle Function

The quadriceps femoris muscle group is the only muscle crossing anterior to the flexion/extension axis of the knee and is the prime mover (agonist) for knee extension. Other muscles that can act to extend the knee require the foot to be fixed, creating a closed chain. In this situation, the hamstrings and

the soleus muscles can cause or control knee extension by pulling the proximal tibia posteriorly.

**Closed-chain function.** During standing and the stance phase of gait, the knee is an intermediate joint in a closed chain. The quadriceps muscle controls the amount of knee flexion and also extends the knee through reverse muscle pull on the femur. In the erect standing posture when the knee is locked in extension, the quadriceps need not function when the gravity line falls anterior to the flexion/extension axis. In this case, tension in the hamstring and gastrocnemius tendons support the posterior capsule of the knee.

**Patella.** The patella improves the mechanical advantage of the knee extensors by increasing the moment arm between the extensor force vector and the knee joint flexion/extension axis. Its greatest effect on the leverage of the quadriceps is during knee extension from 60° to 30° and the effect rapidly diminishes from 15° to 0° of extension.<sup>101,108</sup>

**Torque.** The peak extension torque produced by the quadriceps muscle occurs between 70° and 50°.<sup>34</sup> The physiological advantage of the quadriceps rapidly decreases during the last 15° of knee extension because of its shortened length. This, combined with its decreased mechanical advantage in the last 15°, requires the muscle to significantly increase its contractile force when large demands are placed on the muscle during terminal extension.<sup>101</sup>

- During standing closed-chain activities, assistance for knee extension is provided by the hamstring and soleus muscles. In addition, the ACL and the hamstring muscle group contractile force counter the anterior translation force produced by quadriceps muscle contractions.<sup>75,171</sup>
- During open-chain knee extension exercises in the sitting or supine position, when the resistive torque is maximum in terminal extension because of the resistance moment arm, a relatively strong contraction of the quadriceps muscle is required to overcome the physiological and mechanical disadvantages of the muscle to complete the final 15° of motion.<sup>101</sup> However, recall that the compressive loads on the patella also decrease in terminal extension because of its superior location with respect to the trochlear groove and the relatively small sagittal plane bowstring effect of the quadriceps and patellar tendon.

### CLINICAL TIP

Be aware of the effect of the external resistance and how the muscle is challenged differently through the range of motion. During open-chain exercises with fixed resistance such as an ankle weight, the resistance torque is most challenging for the quadriceps in terminal extension, while there is minimal challenge midrange where the muscle is capable of generating greater tension. This paradox will impact the effectiveness of the exercises performed by the patient, their comfort during the exercise, and the joint loading that occurs across the range of motion.

## Knee Flexor Muscle Function

The hamstring muscles are the primary knee flexors and also influence rotation of the tibia on the femur. Because the hamstrings are two-joint muscles, they contract more efficiently when the decrease in length during knee flexion is offset by increased length through hip flexion. During closed-chain weight-bearing activities, the hamstring muscles can assist with knee extension by pulling the tibia posteriorly.

- The gastrocnemius muscle also can function as a knee flexor, but its prime function at the knee during weight bearing is to support the posterior capsule against hyperextension forces.
- The popliteus muscle supports the posterior capsule and acts to unlock the extended knee.
- The pes anserinus muscle group (sartorius, gracilis, and semitendinosus) provides medial stability to the knee and affects rotation of the tibia in a closed chain.

## Dynamic Stability of the Knee

Because of the incongruity between the rounded femoral condyles and nearly flat tibial plateaus, there is minimal knee stability provided by the bony architecture. The cruciate and collateral ligaments provide significant passive stability to the knee throughout joint motion. Dynamic stability is the ability of a joint to remain stable in the presence of rapidly shifting loads during motion.<sup>122</sup> Dynamic stability requires motor control of the neuromuscular system to coordinate muscle activity around the joint. The complex feedforward and feedback responses mediated by the central nervous system modulate muscle stiffness and are important for providing dynamic knee stability under varying loads and stresses imposed on the joint structures.<sup>309</sup> As summarized in a clinical commentary by Williams,<sup>309</sup> clinical and scientific evidence is accumulating to substantiate exercise programs designed for the purpose of developing dynamic stability of the knee—that is, to improve dynamic control of the knee via neuromuscular responses in order to reduce knee ligament stress and minimize the risk of injury during high-intensity activities.

## The Knee and Gait

During the normal gait cycle, the knee goes through a range of 60° (0° extension at initial contact or heel strike to 60° at the end of initial swing). There is also some medial rotation of the femur as the knee extends at initial contact and just prior to heel-off.<sup>108,212,228</sup>

## Muscle Control of the Knee During Gait

Stability during the gait cycle is efficiently controlled by the normal function of the muscles that cross the knee joint.<sup>212,228</sup>

**Quadriceps.** The quadriceps muscle controls the amount of knee flexion during initial contact and loading response and then extends the knee toward midstance. It again controls the amount of flexion during preswing (heel-off to toe-off) and prevents excessive knee flexion (heel rise) during initial swing. With loss of quadriceps function, the patient lurches the trunk anteriorly during initial contact to stabilize the joint by moving the trunk center of gravity anterior to the knee flexion/extension axis.<sup>283</sup>

**Hamstrings.** The hamstring muscles primarily decelerate and control knee extension during terminal swing. Loss of function may result in the knee snapping into extension prior to initial contact. The hamstrings also provide posterior support to the knee capsule when the knee is extended during stance, and loss of this function results in progressive genu recurvatum.<sup>283</sup>

**Soleus.** The single joint ankle plantarflexor muscles (primarily the soleus) help limit the amount of knee flexion during preswing by controlling the forward movement of the tibia over the fixed foot. Loss of function results in compensatory hyperextension of the knee during preswing. Loss of heel rise during the preswing phase resulting in a lag or slight dropping of the pelvis on that side may also occur with soleus dysfunction.

**Gastrocnemius.** The gastrocnemius muscle provides posterior support to the extended knee at the end of loading response or foot flat and just prior to preswing or heel-off. Loss of gastrocnemius function results in hyperextension of the knee during these periods as well as loss of propulsion from plantarflexion during preswing or push-off.

## Hip and Ankle Impairments

Because the knee is the intermediate joint between the hip and foot, problems in these two areas can interfere with knee function during gait. Examples include the following.

**Hip flexion contractures.** Inability to extend the hip prevents the knee from extending just before terminal stance (heel-off).

**Length/strength imbalances.** With asymmetry of length, strength, or neuromuscular control of hip and knee muscles, unbalanced forces may stress structures of the knee, giving rise to pain during walking or running. For example, a tight tensor fasciae latae or gluteus maximus muscle may increase stress on the IT band and lead to lateral knee pain, or it could affect patellofemoral joint kinematics and lead to anterior knee pain. Weak hip external rotators and abductors result in femoral internal rotation, which can create a relative lateral displacement of the patella and subsequent patellofemoral pain.<sup>277</sup> Overuse of the hamstring muscle group may result in compensatory increases in quadriceps femoris muscle activation and result in anterior knee pain (see Chapter 20 for discussion of muscle imbalances in hip).

**Foot impairments.** The position and function of the foot and ankle affect the stresses transmitted to the knee. For example, with pes planus or pes valgus, there is an overall medial rotation of the lower extremity, with increased Q-angle and an increased bowstring effect on the patella.<sup>166</sup>

## Referred Pain and Nerve Injuries

For a detailed description of referred pain patterns and peripheral nerve injuries in the knee region, see Chapter 13.

### Major Nerves Subject to Injury at the Knee

The sciatic nerve divides into the tibial and common peroneal nerves just proximal to the popliteal fossa. These nerves are relatively well protected deep in the fossa.

- The *common fibular (peroneal) nerve* (L2–L4) becomes superficial where it winds around the fibula just below the fibular head, a common site for injury. Symptoms of sensory loss and muscle weakness are distal to that site.
- The *saphenous nerve* (L2–L4) is a sensory nerve that innervates the skin along the medial side of the knee and leg. It may be injured with trauma or surgery in that region, resulting in chronic pain syndromes.

### Common Sources of Referred Pain

Nerve roots and tissues derived from spinal segments L3 refer to the anterior aspect, and those from S1 and S2 refer to the posterior aspect of the knee.<sup>50</sup> The hip joint, which is primarily innervated by L3, may refer symptoms to the anterior thigh and knee. In cases of referred pain, therapeutic exercise for the knee is beneficial only for preventing disuse of the knee musculature; primary treatment must be directed to the source of the nerve irritation.

## Management of Knee Disorders and Surgeries

To make sound clinical decisions when treating patients with knee disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and to identify the structural and functional impairments, activity limitations, and participation restrictions. In this section, common pathologies and surgical procedures are presented and conservative and postoperative management of these conditions is described.

## Joint Hypomobility: Nonoperative Management

### Common Joint Pathologies and Associated Impairments

Osteoarthritis (OA) and rheumatoid arthritis (RA), as well as acute trauma, can all affect the knee joints. In addition, decreased flexibility and adhesions can develop in the joints and surrounding tissues any time the knee joint is immobilized following an injury, surgery, or fracture. The etiology of arthritic and joint symptoms and general management guidelines are described in Chapter 11; this section applies that information to management of the knee joint.

#### Osteoarthritis (Degenerative Joint Disease)

OA, often referred to as degenerative joint disease, is the most common disease affecting weight-bearing joints. In the knee, articular cartilage destruction is more often apparent on the medial joint compartment than the lateral compartment (Fig. 21.5).

**FIGURE 21.5** Advanced bilateral, medial compartment degenerative joint disease in the knees of a 52-year-old computer programmer/analyst who subsequently underwent right total knee arthroplasty.

One-third of individuals older than age 65 have radiographic evidence of knee OA.<sup>16</sup> Pain, muscle weakness, medial compartment laxity, and motion limitations affect function and lead to disability. Deformity such as genu varum commonly develops in the knees in the presence of OA, although genu valgum may occur in some individuals. Knee instability (the sensation of knee buckling or shifting) is frequently reported by individuals with knee OA and significantly contributes to impaired physical function.<sup>77</sup> Factors such as excess weight, joint trauma, developmental deformities, quadriceps weakness, and

abnormal tibial rotation are risk factors for developing OA of the knee.<sup>6,16</sup>

### FOCUS ON EVIDENCE

An investigation of 52 patients with medial compartment knee OA by Schmitt and associates<sup>255</sup> found that self-reported knee instability contributed to limited function during daily living. However, the study showed no direct relationship between the severity of reported knee instability and the amount of medial joint laxity, varus alignment of the knee, or quadriceps muscle strength.

In a study of 220 patients with OA, 95% of the subjects reported lack of knee confidence during gait; pain during gait and fear of movement being high correlates with lack of confidence.<sup>272</sup>

### Posttraumatic Arthritis

*Posttraumatic arthritis* of the knee occurs in response to any injury that affects the joint structures, particularly following traumatic ligament and meniscal tears. With these injuries, joint swelling may be immediate, indicating bleeding within the joint, or progressive (more than 4 hours to develop), indicating serous effusion. Acute symptoms include pain, limited motion, and muscle guarding. Trauma, including repetitive microtrauma, is a common cause of degenerative changes in the knee joint.

### Rheumatoid Arthritis

Early-stage RA usually manifests first in the hands and feet but with progression of the disease process, the knees may also become involved. With RA, the joints become warm and swollen and limited motion develops. In addition, a genu valgum deformity commonly develops during the advanced stages of the disease.

### Postimmobilization Hypomobility

When the knee has been immobilized for several weeks or longer, such as during healing of a fracture or after surgery, the capsule, muscles, and soft tissue develop contractures and motion becomes restricted. Tissue adhesions may restrict caudal gliding of the patella, which limits knee flexion, and may cause pain if the tissue tightness results in increased patellofemoral joint compression forces. If proximal gliding of the patella is restricted when the quadriceps muscle contracts, an extensor lag may occur with active knee extension.<sup>281</sup> This usually occurs after operative repairs of some knee ligaments, when the knee is immobilized in flexion for a prolonged period.

### Common Structural Impairments

- With joint involvement, the pattern of restriction at the knee is usually more loss of flexion than extension.
- When there is effusion (swelling within the joint), a joint position near 25° of flexion is often most comfortable for

the patient because this position has the greatest capsule distensibility. Minimal joint motion is possible in the presence of effusion.

- Reflex inhibition and resulting weakness of the quadriceps femoris muscle occurs because of joint distention.<sup>279</sup> Symptoms such as joint distention from effusion, stiffness, pain, and reflex quadriceps inhibition may cause an extensor (quadriceps) lag in which the active range of knee extension is less than the passive range available.<sup>281</sup>
- Impaired balance responses such as increased body sway under both static and dynamic conditions have been reported in patients with knee arthritis.<sup>300</sup>

### Common Impairments, Activity Limitations, and Participation Restrictions

- With acute symptoms and in advanced stages of joint degeneration, there is pain during motion, weight bearing, and gait that may interfere with work or routine household and community activities.
- There is limitation of, or difficulty controlling, weight-bearing activities that involve knee flexion, such as sitting down and rising from a chair or a commode, descending or ascending stairs, stooping, squatting, or rising from the floor.<sup>74</sup>
- With end-stage arthritis, physical activity is markedly curtailed with less participation in leisure and household activities.<sup>291</sup>

## Joint Hypomobility: Management—Protection Phase

See Chapter 11 for general guidelines for the management of acute joint lesions and specific guidelines for OA and RA.

### Control Pain and Protect the Joint

**Patient education.** It is important to teach the patient methods to protect the joint including bed positioning, use of orthotics to avoid deforming contractures, range of motion (ROM) and muscle-setting exercises to maintain mobility and promote blood flow, and safe functional activities that reduce stresses on the knee.

**Functional adaptations.** Instruct the patient to minimize stair-climbing, use elevated seats on commodes, and avoid deep-seated or low chairs in order to minimize the high muscle forces required in these knee flexion ranges while bearing weight. If necessary during an acute flare of arthritis, have the patient use crutches, canes, or a walker to distribute forces through the upper extremities while walking.

### Maintain Soft Tissue and Joint Mobility

**Passive, active-assistive, or active ROM.** Use ROM techniques within the limits of pain and available motion. The patient may be able to perform active ROM in the gravity-eliminated, side-lying position, or self-assisted ROM.

**Grade I or II joint distraction and anterior/posterior glides.** Apply gentle manual techniques, if tolerated, with the

joint in or near resting position (25° flexion). These techniques are used to inhibit pain as well as maintain joint mobility. Stretching is contraindicated at this stage.

### Maintain Muscle Function and Prevent Patellar Adhesions

**Setting exercises.** Perform pain-free quadriceps (“quad sets”) and hamstring muscle-setting exercises with the knee in pain-free positions, quad sets with leg raises, and submaximal closed-chain muscle setting exercises. Muscle-setting exercises are described in detail in the last section of this chapter. Quad sets may help maintain mobility of the patella when the tibiofemoral joint is immobilized and therefore are routinely taught following surgery or when the joint is immobilized.

### Joint Hypomobility: Management—Controlled Motion and Return to Function Phases

As joint effusion decreases and tissues are able to tolerate increased stresses, the goals of treatment change to deal with the impairments interfering with function. The patient is progressed through controlled motion exercises and activities that focus on safely returning to desired functional activities.

#### Educate the Patient

- Inform the patient about his or her condition, what to expect regarding recovery, and how to protect the joints.
- Teach the patient safe exercises to do at home, how to progress them, and how to modify them if symptoms are exacerbated by the disease, overuse, or the exercises. Exercises that include specifically designed strengthening, stretching, ROM, and use of a stationary bicycle have been shown to improve functional outcomes in patients with OA in a home exercise program.<sup>59</sup> It is important to emphasize that maintaining strength in the supporting muscles helps protect and stabilize the joint and that balance exercises help reduce the incidence of falls.
- Instruct the patient to perform active ROM and muscle-setting techniques frequently during the day, especially prior to bearing weight, in order to reduce the painful symptoms that occur with initial weight bearing.<sup>74</sup>
- The patient with OA or RA should be cautioned to alternate activity with rest.

#### FOCUS ON EVIDENCE

In a randomized, controlled study<sup>59</sup> of 134 patients with knee OA, a clinic treatment group ( $n = 66$ ) received supervised exercise, manual therapy, and home exercises for 4 weeks. A home exercise group ( $n = 68$ ) performed home exercises only. Outcomes consisted of the distance walked in 6 minutes and the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC). Both groups improved at 4 weeks; the clinic treatment group improved 52% on the WOMAC,

whereas the home exercise group improved 26%. Both groups improved 10% on the 6-minute walk distances. At 1 year, there was no difference between the groups, and both groups demonstrated improvement over baseline measurements. However, the clinic treatment group was less likely to be taking medication for the arthritis and was more satisfied with the outcome of their rehabilitation. The lack of long-term maintenance highlights the importance of patient education and adherence to a prescriptive long-term home exercise program.

#### Decrease Pain From Mechanical Stress

Continue use of assistive devices for ambulation if necessary. The patient may progress by using less assistance or may ambulate for periods without assistance. Continue use of elevated seats on commodes and chairs, if needed, to reduce the mechanical stresses imposed when attempting to stand.<sup>74</sup>

#### Increase Joint Play and Range of Motion

**PRECAUTION:** Do not increase ROM unless the patient has sufficient strength to control the motion already available. A mobile weight-bearing joint with inadequate muscle control causes impaired stability and makes lower extremity weight-bearing function difficult.

**Joint mobilization.** When there is loss of joint play and decreased mobility, joint mobilization techniques should be used. Apply grade III or IV sustained or oscillatory techniques to the tibiofemoral and patellofemoral articulations with the joint positioned at the end of its available range. (See Figs. 5.49 through 5.54 and their descriptions in Chapter 5.) As ROM increases, integrate the rotational accessory motions that accompany flexion and extension.<sup>134</sup>

- To increase *flexion*, position the tibia in medial rotation and apply the posterior glide against the anterior aspect of the medial tibial plateau.
- To increase *extension*, position the tibia in lateral rotation and apply the anterior glide against the posterior aspect of the lateral tibial plateau.
- Medial and lateral gliding of the tibia on the femur may also be done to regain mobility for flexion and extension.

**Stretching techniques.** Passive and proprioceptive neuromuscular facilitation (PNF) stretching techniques are used to increase extensibility of the muscles and extracapsular noncontractile soft tissues that are restricting knee motion. Specific techniques are described in the last section of this chapter.

**PRECAUTIONS:** Techniques that force the knee into flexion by using the tibia as a lever or by using strong quadriceps contractions (during a hold-relax maneuver) may exacerbate joint symptoms.

Incorporate the following to minimize joint trauma from stretching.

- Mobilize the patellofemoral and tibiofemoral joints before stretching in order to facilitate the natural joint arthrokinematics during the stretch maneuvers.

- Apply soft tissue or friction massage to loosen adhesions or contractures prior to stretching. Include deep massage around the patellar borders.
- Modify the intensity of the contractions used during PNF stretching techniques to decrease the effects of joint compression. If activating the quadriceps for a hold-relax technique to increase knee flexion aggravates anterior knee pain, an agonist contraction technique with the hamstring muscles can be used instead.
- Use low-intensity, long-duration stretches within the patient's tolerance.

**Mobilization with movement.** Mobilization with movement (MWM) may be applied to increase ROM and/or decrease the pain associated with movement by facilitating joint arthrokinematics. Mulligan<sup>195</sup> states that MWM is more effective with loss of knee flexion than extension. The principles of MWM are described in Chapter 5.

#### MWM: Lateral or Medial Glides

**Patient position and procedure:** Supine for extension or prone for flexion. Apply a pain-free medial or lateral glide to the tibial plateau manually or with a mobilization belt. The direction of glide is often in the direction of the pain (i.e., lateral knee pain responds best to a lateral glide of the tibia and medial knee pain to a medial glide).<sup>195</sup>

- While sustaining the mobilization, ask the patient to actively move to the end of the available pain-free range of flexion or extension.
- Add pain-free overpressure to achieve the benefit of end-range loading.

#### MWM: Internal Tibial Rotation for Flexion—Manual Technique

**Patient position and procedure:** Supine with the knee flexed to the end of its available pain-free range. Apply internal rotation mobilization to the tibia with manual pressure from one hand on the anteromedial tibial plateau simultaneously with pressure from the other hand on the posterolateral tibial plateau, posterior to the fibular head.

- Sustain the internal rotation mobilization and ask the patient to flex the knee using a mobilization belt looped around the foot. Hold the position at the end of the available pain-free range for several seconds (Fig. 21.6).

**FIGURE 21.6** MWM with internal tibial rotation to increase knee flexion.

#### MWM: Internal Rotation for Flexion—Self-Treatment

**Patient position and procedure:** Standing with the foot of the involved leg on a chair and knee flexed. Position the foot such that the tibia is internally rotated. Have the patient apply internal rotation pressure against the anteromedial and posterolateral tibial plateaus and shift the weight forward to flex the knee to the end of the available pain-free range (Fig. 21.7).

**FIGURE 21.7** Self-treatment using MWM with internal tibial rotation to increase knee flexion.

#### Improve Muscle Performance in Supporting Muscles

Exercises identified in this section are described in detail in the last section of this chapter.

**Progressive strengthening.** Begin with multiple-angle isometrics to both knee flexors and extensors and active ROM exercises in open- and closed-chain positions using a moderate progression of repetitions and resistance through arcs of pain-free motion. Exercise intensity should be within the tolerance of the joint and should not exacerbate symptoms.

- When performing open-chain exercises, patients experience less pain with faster speeds and light resistance compared to slow speeds with heavy resistance.
- Resistance to knee extension through the mid-ROM (45° to 90°) tends to exacerbate patellofemoral pain because of the increased joint compressive forces on the patella. Apply resistance in arcs of motion that are pain free on either side of the symptomatic range. This can be done using manual or mechanical resistance.
- Strengthen both hip and ankle musculature using open- and closed-chain exercises to balance forces throughout the lower extremities and progress the patient toward functional independence. (See Chapters 20 and 22 for hip and ankle exercises.)

**Muscular endurance training.** Increase repetitions at each resistance level before increasing resistance.

**Functional training.** Climbing steps, sitting down and rising up from chairs and commodes, and using safe body mechanics to lift objects from the floor are often difficult in individuals with knee arthritis. It is imperative to strengthen the knee musculature using modifications of functional activities, gradually removing the modifications and progressing the difficulty as strength improves.

- **Step-up and step-down exercises (forward, backward, lateral).** Begin with a low step height, and progress to the step height the patient requires for home and community mobility. Progress to functional activities, such as climbing stairs or ladders, depending on the desired outcomes.
- **Wall slides and minisquats to 90°, if tolerated.** Stay within a range that does not exacerbate symptoms. Tie these exercises in with the functional activities of sitting down and sit-to-stand (with arm assistance if necessary) to and from various chair heights. Determine if chair adaptation is needed for safe function. Teach proper lower extremity alignment and posterior weight shift to activate and strengthen the gluteus maximus.
- **Partial lunges.** Concentrate on trunk control and keeping the knee over the stance foot during the motion. Have the patient activate the lumbopelvic musculature to stabilize the pelvis during the lunge activity. Progress by gradually increasing the depth of the lunge and by picking up small objects from the floor to simulate effective body mechanics.
- **Balance activities.** Balance activities are initiated at the level the patient can control. Detailed suggestions are outlined in Chapters 8 and 23.
- **Ambulation.** Decrease use of assistive devices as quadriceps strength improves to a manual muscle test level of 4/5 and as joint motion during gait becomes normalized and symmetrical. Practice walking on a variety of terrains and inclines, and include changes of direction, first with assistance and then independently.

### Improve Cardiopulmonary Endurance

Select and adapt activities to minimize irritating stresses on the knee.

- **Swimming, water aerobics, and aquatic exercises** provide an environment for improving muscular and cardiopulmonary function with minimal joint loading.
- **Bicycling** is a low-impact form of exercise. Adjust the seat height so the knee goes into complete extension (but not hyperextension) when the pedal is at the lowest point of its arc. If using a stationary bike, begin with low resistance and progress as tolerated.
- **High impact activities—with caution.** For some patients, progression to running or jumping rope and other high-impact, faster-paced, or more intense activities can be undertaken so long as the joint remains asymptomatic. If joint deformity is present and proper biomechanics cannot be restored, the patient should be discouraged from progressing to these activities to prevent further joint damage.

### Outcomes

Two systematic reviews of studies designed to examine the effects of exercise in the management of hip and knee OA support aerobic exercise and strengthening exercises to reduce pain and disability.<sup>248,249</sup> The consensus of expert opinion cited by Roddy<sup>248</sup> is that (1) there are few contraindications and (2) exercise is relatively safe in patients with OA but should be individualized and patient-centered with consideration for age, comorbidity, and general mobility. Similarly, the Cochrane Database of Systematic Reviews;<sup>80</sup> the Philadelphia Panel Evidence-Based Clinical Practice Guidelines;<sup>229</sup> and, more recently, a summary of systematic reviews of studies on physical therapy interventions for patients with knee OA<sup>127</sup> indicated that there is evidence to support strengthening, stretching, and functional exercises as interventions for the management of knee pain as the result of OA and to improve physical function.

Another study followed 285 patients with knee OA for 3 years and found that factors that protected the individuals from poor functional outcomes included strength and activity level, as well as mental health, self-efficacy, and social support.<sup>264</sup>

An outcome review<sup>57</sup> summarized that moderate- or high-intensity exercises for patients with RA have minimal effect on the disease activity but that there is insufficient radiological evidence regarding the effect of exercise on large joints. The review also indicated that long-term moderate- or high-intensity exercises that are individualized to protect radiologically damaged joints improve aerobic capacity, muscle strength, functional ability, and psychological well-being of patients with RA. Subjects with RA who participated in a combined aerobic, strength, and functional activity program and continued that program through an 18-month follow-up maintained knee extensor muscle strength while those who did not continue exercising lost strength. Aerobic fitness declined and functional ability was maintained from baseline in both groups at the 18-month follow-up.<sup>56</sup>

Finally, a recent systematic review by the Osteoarthritis Research Society International recommended referral to physical therapy services as a nonpharmacological intervention to improve functional capacity of patients with symptomatic OA.<sup>318</sup>

## Joint Surgery and Postoperative Management

A range of surgical options for management of knee arthritis is available when joint pain and synovitis cannot be controlled with conservative therapy and appropriate medical management, or when destruction of articular surfaces, deformity, or motion restriction have progressed to the point that functional abilities are significantly impaired.

The surgical procedure selected depends on the patient's signs and symptoms, activity level and age, type of disease, severity of articular damage or joint deformity, and involvement of other joints. *Arthroscopic débridement* and *lavage* are

used to remove loose bodies that may cause symptoms such as swelling and intermittent locking of the knee.<sup>17,260</sup> Several procedures to repair damaged articular cartilage have been developed, with mixed results. *Abrasion arthroplasty*, a procedure designed to smooth worn articular surfaces and stimulate growth of replacement cartilage has had only limited success.<sup>17,260</sup> More recently developed procedures to repair small, localized articular cartilage defects of the knee, such as *microfracture*,<sup>94,262</sup> *osteochondral autograft transplantation (mosaicplasty)*,<sup>13,106,143</sup> and *autologous chondrocyte implantation*,<sup>44,95,303</sup> appear to hold promise.

*Synovectomy* had been the procedure of choice for the young patient with unremitting joint effusion, synovial proliferation, and/or pain as the result of RA or juvenile RA and minimal articular surface destruction, but it is now used infrequently.<sup>35,223,260</sup> *Osteotomy* of the distal femur or proximal tibia (an extra-articular procedure) redistributes weight-bearing forces between the tibia and femur in an attempt to reduce joint pain during activities and delay the need for knee arthroplasty.<sup>17,35,260</sup> In the past, high tibial osteotomy was considered a surgical option for the active patient younger than age 50 to 55 years without active systemic disease, significant motion limitations, or joint deformity. However, advancements in arthroplasty have meant that joint replacement is now performed more frequently in younger patients, making osteotomy a less common surgical option.<sup>39</sup>

When erosion of articular surfaces becomes severe and pain is unremitting, *total knee arthroplasty (total knee replacement)* is the surgical procedure of choice to reduce pain, correct deformity, and improve functional movement.<sup>123,167,258</sup> Only in highly selective situations is *arthrodesis* (fusion) of the knee used as a salvage procedure to provide a patient with a stable and pain-free knee.

Regardless of the type of surgery, the goals of surgery and postoperative management are to (1) reduce pain, (2) correct deformity or instability, and (3) restore lower extremity function. Carefully progressed postoperative rehabilitation is essential for optimal functional outcomes.

## Repair of Articular Cartilage Defects

Injuries of the ligaments or menisci of the knee and acute or chronic patellofemoral dysfunction are often associated with articular surface damage. Surgical management of chondral defects has proved challenging because of the limited capacity of articular cartilage to heal.<sup>44,153</sup> However, several surgical procedures are available to repair cartilage lesions when non-operative management or palliative arthroscopic débridement and lavage have been unsuccessful. The strategies for these surgical procedures focus on either repair or restoration.<sup>242</sup>

Cartilage repair procedures include microfracture or bone drilling,<sup>94,153,242,262,282</sup> while restoration procedures range from osteochondral autograft transfer (OAT), osteochondral allograft transplant,<sup>13,18,106,143</sup> and autologous chondrocyte implantation.<sup>95,153,242,303</sup> These procedures are designed to stimulate growth of hyaline cartilage within focal articular

cartilage defects and to prevent progressive deterioration of joint cartilage leading to OA.<sup>44,153</sup>

Descriptions of procedures specific to the knee are presented in this section. Regardless of the cartilage procedure selected, each requires the patient's ability and willingness to adhere to a lengthy rehabilitation process.

## Indications for Surgery

The primary indication for repair or restoration of an articular cartilage defect is a symptomatic knee caused by a small to relatively large focal lesion of the tibiofemoral or patellofemoral joint surfaces. Lesions are most commonly located on the weight-bearing portions of the medial or lateral femoral condyles, the trochlear groove, and the patellar facets.

Selection criteria when choosing the procedure include the size of the chondral lesion, the depth and location of the lesion, the elapsed time since the occurrence of the defect, and the patient's age and intended activity level. In general, defects greater than 1 to 2 cm<sup>2</sup> but no more than 4 cm<sup>2</sup> are considered suitable for repair. Defects larger than 4 cm<sup>2</sup> are more appropriate for restoration techniques.<sup>242</sup> Most patients who undergo articular cartilage repair are young and active.<sup>44,153</sup>

### CLINICAL TIP

A system for classification of cartilage lesions developed by the International Cartilage Repair Society is based on a five-point grading scale. Lesions range from grade 0 (normal cartilage without notable defects) to grade 4 (severely abnormal, full-thickness osteochondral defects).<sup>32</sup>

## Procedures

**Microfracture.** Microfracture is indicated for repair of small defects, usually of the medial or lateral femoral condyle or the patella. The procedure is performed arthroscopically and uses a nonmotorized awl to systematically penetrate the subchondral bone and expose the bone marrow. This first-option treatment is designed to stimulate a marrow-based repair response leading to local ingrowth of cartilaginous repair tissue (fibrocartilage) to mend the lesion.<sup>44,94,153,262,282</sup> Autologous matrix-induced chondrogenesis is a newer technique that combines microfracture with the application of a bilayer collagen membrane to stabilize the ingrowth and guide the repair.<sup>242</sup>

**Osteochondral autograft transfer.** For focal lesions involving chondral or subchondral tissue of the weight-bearing surfaces of the knee, osteochondral graft transplantation may be selected. This is an arthroscopic or mini open procedure that transplants intact mature articular cartilage along with some underlying bone, resulting in a bone-to-bone graft.<sup>13,18,106,143</sup> *Mosaicplasty* is a similar technique that uses multiple small-diameter osteochondral plugs that are harvested and press-fit into the chondral defect, instead of the single piece of tissue that is used in the OAT procedure.<sup>13,18,106,143</sup>

Donor sites are most often nonweight-bearing, nonarticulating portions of the supracondylar ridge of the lateral femoral articulating surfaces.<sup>13</sup>

**Autologous chondrocyte implantation.** This procedure, also referred to as chondrocyte transplantation, is used in younger patients with a single, larger (2- to 4-cm<sup>2</sup>) full-thickness chondral and osteochondral defect of the femoral condyle or patella.<sup>44,95,303</sup> The procedure occurs in two stages. First, healthy articular cartilage is harvested arthroscopically from the patient. Then chondrocytes are extracted from the articular cartilage, cultured for several weeks, and processed in a laboratory to increase the volume of healthy tissue. The second stage involves the implantation of the chondrocytes during an arthrotomy (open procedure). After debriding the chondral defect sites, they are covered with a periosteal patch harvested from the proximal medial tibia, and the patch is secured with fibrin glue. Millions of autologous chondrocytes are then injected under the patch into the articular defects.

Patient positioning during the first 4 hours after surgery is critical. Patients are positioned so the effect of gravity distributes the chondrocytes evenly along the base of the defect.<sup>240</sup> For example, after a patellar surface repair, the patient is positioned in prone.

Maturation of the implanted chondrocytes is a lengthy process. It may take as long 6 months for the graft site to become firm and as long as 9 months for the graft to become as durable as the healthy tissue surrounding the graft.<sup>95</sup>

**Osteochondral allograft transplant.** For defects larger than 4 cm<sup>2</sup>, the only option for repair—although used infrequently—is an osteochondral allograft of intact articular cartilage from a cadaveric donor. Intact grafts are harvested and stored for up to 4 weeks before implantation in the defect.<sup>55</sup> Frozen allografts have also been used in some patients with good long-term results,<sup>22,226</sup> although freezing the graft material may kill articular chondrocytes and lead to graft failure.<sup>44,153</sup>

**Other procedures.** If coexisting ligament or meniscus pathology or tibiofemoral or patellofemoral malalignment is identified prior to or concomitant with surgical repair, reconstruction or realignment must be carried out for the articular cartilage repair to be successful. The most common procedures are ACL reconstruction and meniscus repair for tibiofemoral articular defects and lateral retinacular release for patellar defects.<sup>13,95</sup>

## Postoperative Management

A cautiously progressed and closely monitored rehabilitation program is critical for a successful outcome after articular cartilage repair procedures. The components and progression of a rehabilitation program, including exercise, ambulation, and functional activities, must be carefully graded to protect the repair or graft and prevent further articular damage while applying controlled stresses to stimulate the healing process.

There are many common elements to the progression of postoperative exercises and functional activities after microfracture, osteochondral autologous transplantation, and autologous chondrocyte implantation, yet they also vary to

some degree. Detailed postoperative protocols, as well as comprehensive clinical practice guidelines for each of these procedures, have been published.<sup>13,95,143,142,240</sup> In addition to the type of repair, the rehabilitation progression is based on the size, depth, and location of the articular defect, the concomitant surgical procedures, and patient-related factors such as age, body mass index, health history, and preoperative activity level.

The goals during rehabilitation after articular cartilage repair are similar to those for most knee rehabilitation programs presented in this chapter. Protected weight bearing over an extended period of time and early motion are essential after articular cartilage repair to promote maturation and maintain the health of the repaired or implanted cartilage. Special considerations for exercise and weight bearing associated with the various articular cartilage procedures are summarized in Box 21.1.<sup>13,95,143,142,240,303</sup>

## Total Knee Arthroplasty

Total knee arthroplasty (TKA), also called total knee replacement, is a widely performed procedure for advanced arthritis of the knee. TKA is primarily performed in older patients ( $\geq 70$  years of age), but over the past few decades the proportion of younger patients undergoing TKA has increased significantly.<sup>146</sup> The overarching goals of TKA are to relieve pain and improve a patient's physical function and quality of life.<sup>189,258</sup>

### Indications for Surgery

The following are common indications for TKA:<sup>123,167,258</sup>

- Severe joint pain with weight bearing or motion that compromises functional abilities
- Extensive destruction of knee articular cartilage secondary to advanced arthritis
- Marked deformity of the knee such as genu varum or valgum
- Gross instability or motion limitation
- Failure of nonoperative management or a previous surgical procedure

## Procedure

### Background

Prosthetic replacement of one or more surfaces of the knee joint was developed during the 1960s. To address problems with early prosthetic designs, semiconstrained, two-component designs were created, and design innovations continue to this day. For the patient with severe anterior knee pain resulting from advanced patellofemoral deterioration, a three-component, total condylar design that includes patellofemoral joint resurfacing was developed. For advanced arthritis of only the medial or lateral aspect of the knee, the unicompartmental (unicondylar) knee arthroplasty (UKA) was developed as an alternative to TKA.<sup>197,217,252,290</sup>

A therapist's knowledge of the different types of TKA and UKA used today enhances communication between the therapist and surgeon and provides a foundation for rehabilitation decisions.

**BOX 21.1 Special Considerations and Precautions for Rehabilitation After Articular Cartilage Repair\***

- The larger the lesion, the slower and more cautious the rehabilitation progression.
- Early but controlled ROM is advocated to facilitate the healing process and begins immediately or within a day or two after surgery (CPM, passive or assisted exercise).
- Controlled (protected) weight bearing initiated as early as possible is beneficial to the healing process, but adherence to weight-bearing restrictions is critical.
- Duration and degree of weight-bearing restrictions vary with the defect size and the type and location of the repair.\*
  - Longer period of protected weight bearing for osteochondral transplantation/mosaicplasty and autologous chondrocyte implantation than after microfracture
  - Longer period of protected weight bearing for a femoral condyle repair (up to 8 to 12 weeks) than for a patellar defect (up to 4 weeks)
  - Full weight bearing is delayed for as long as 8 to 12 weeks
- Protective bracing may be used postoperatively.
  - Typically locked in extension, except during exercise
  - Worn during weight-bearing activities 4 to 6 weeks
- Worn during sleep for as many as 4 weeks
- An unloading brace may be used after repair of a femoral condyle defect during the period of protected weight bearing to shift the weight away from the repair
- Return to functional activity.<sup>142</sup>
  - In general, low-impact sports such as swimming, skating, rollerblading, and cycling are permitted at about 6 months
  - High-impact sports, such as jogging, running, and aerobics are usually permitted at:
    - 8–9 months for small lesions
    - 9–12 months for larger lesions
  - Higher-impact sports such as tennis, basketball, football, and baseball are usually permitted by 12–18 months.

\*Considerations and precautions vary with the size, depth, and location of the articular defect, type of surgical repair and concomitant procedures, and patient-related factors (e.g., age, body mass index, health history, and preoperative activity level).

**Types of knee arthroplasty.** Contemporary knee replacement procedures can be divided into several categories based on component design, surgical approach, and type of fixation (Box 21.2).<sup>124,167,194,197,258,290</sup> One category is based on the number of components implanted or articulating surfaces replaced. Another is based on the degree of constraint or amount of inherent congruency/stability built into the design. Most TKA procedures today involve a two-component (bicompartamental), semiconstrained prosthetic system that replaces the proximal tibia and distal femur (Fig. 21.8). These systems are typically composed of a modular or nonmodular femoral component with a metal articulating surface paired with a single

all-polyethylene or metal-backed modular or nonmodular tibial component with a polyethylene articulating surface.<sup>124,167,258</sup>

Occasionally, a tricompartmental design, which also resurfaces the posterior aspect of the patella with a polyethylene component, is selected if the patellofemoral joint is symptomatic.<sup>123,167,258</sup> For the younger patient (< 55 years of age) with advanced disease of only the medial or lateral compartment of the knee joint, a unicompartmental design is often selected to replace just one tibial plateau and one femoral condyle.<sup>197,217,252,258,290</sup>

Intact MCL and LCL are necessary prerequisites for semi-constrained and unconstrained TKA.<sup>123,167,258</sup> Fully constrained

**BOX 21.2 Total Knee Arthroplasty: Design, Surgical Approach, and Fixation****Number of Compartments Replaced**

- Unicompartmental: only the medial or lateral joint surface is replaced
- Bicompartamental: entire femoral and tibial surfaces are replaced
- Tricompartmental: femoral, tibial, and patellar surfaces are replaced

**Implant Design**

- Degree of constraint
  - Unconstrained: no inherent stability in the implant design; used primarily with unicompartmental arthroplasty
  - Semiconstrained: provides some degree of stability with little compromise of mobility; most common design used for total knee arthroplasty

- Fully constrained: significant congruency of components; most inherent stability but motion is considerably limited
- Fixed-bearing or mobile-bearing design
- Cruciate-retaining or cruciate-excising/substituting

**Surgical Approach**

- Standard/traditional versus minimally invasive
- Quadriceps-splitting versus quadriceps-sparing

**Implant Fixation**

- Cemented
- Uncemented
- Hybrid

**FIGURE 21.8** Posterior cruciate-retaining total knee arthroplasty of the right knee with cemented fixation. **(A)** Anteroposterior view. **(B)** Lateral view.

designs, now used infrequently, are reserved for the low-demand patient who has marked instability of the knee, extensive bone loss, severe deformity, or who has had previous TKA revisions.<sup>123,167</sup> Contemporary fully constrained designs are not hinged but have inherent medial-lateral (ML) and anterior-posterior (AP) stability, with some degree of rotation of the tibia on the femur allowed to lessen the problem of progressive loosening of the prosthetic components over time.<sup>123,167</sup>

TKA designs are also classified as mobile-bearing or fixed-bearing. The most recent development in the evolution of TKA is the introduction of the mobile-bearing, bicompartamental prosthetic knee. A mobile-bearing knee has a rotating platform inserted between the femoral and tibial components whose top surface is congruent with the femoral implant (round-on-round articulation) but whose undersurface is flat for rotation and sliding of the tibial component (flat-on-flat articulation).<sup>38,194,258</sup> A fixed-bearing knee does not have such an insert.<sup>60,258</sup> The purpose of the mobile-bearing insert is to decrease long-term wear of the polyethylene tibial component. A mobile-bearing knee design is recommended for the active patient, younger than 55 to 65 years of age.<sup>258</sup>

Another way to classify TKA design is based on the status of the PCL. Designs are described as cruciate-retaining or cruciate-excising/substituting.<sup>123,167,213,216,258</sup> Although the ACL is routinely excised during knee replacement—except with UKA—the PCL can be preserved or sacrificed. If the

PCL is intact to provide posterior stability to the knee, one of several cruciate-retaining designs that require less congruency and allow some degree of AP glide can be used. If the PCL is irreparably deficient, a cruciate-excising/substituting prosthesis is selected. This type of design has inherent posterior stability from the congruency of the components, a posterior prominence in the tibial component, or a cam-post mechanism built into the design. Cruciate-retaining and cruciate-excising designs can be either fixed-bearing or mobile-bearing.<sup>258</sup>

**Surgical approach.** TKA and UKA procedures are also described in terms of the surgical approach employed.<sup>28,41,197,258</sup> Since the inception of knee arthroplasty, an open approach requiring a relatively long anterior incision has been employed to provide sufficient exposure of the knee joint during the procedure. A recent advance is the development of *minimally invasive* knee arthroplasty.<sup>28,197</sup> As with traditional joint arthroplasty, minimally invasive arthroplasty is an open procedure. However, minimally invasive TKA involves a smaller incision and less soft tissue disruption to reduce postoperative pain and increase the rate of postoperative recovery. Standard (traditional) and minimally invasive surgical approaches are described later in this section.

**Fixation.** The method of fixation—cemented, uncemented, or “hybrid”—is another way to classify TKA procedures—that is, implants are held in place with acrylic cement, bone

ingrowth (uncemented), or a combination of these two methods.<sup>167,215,239,302</sup> Initially, almost all total knee replacements relied on cemented fixation. However, a long-term complication associated with early designs of cemented prostheses was biomechanical loosening, primarily of the tibial component at the bone-cement interface, with young, active patients at highest risk for component loosening.<sup>302</sup>

To address the problem of loosening, cementless (biological) fixation relying on rapid growth of bone into the surfaces of a porous-coated or beaded prosthesis was introduced and recommended primarily for the young, active patient.<sup>123,167,215,258,302</sup> In addition, a hydroxyapatite coating on the prosthesis can be used to enhance the ingrowth of bone.<sup>260</sup> However, long-term follow-up demonstrated that although the femoral component reliably achieved fixation to bone, tibial component loosening occurred at an even higher rate with all-cementless fixation compared with cemented fixation.<sup>215,302</sup> This finding gave rise to the “hybrid” TKA, which combines cemented fixation of the tibial component and cementless fixation of the femoral component.

Currently, all-cemented fixation is used most often, and all-cementless is used least often. A surgeon’s decision whether to employ hybrid fixation is based on the patient’s age, bone quality, and expected activity level and the tightness of fit of the femoral component achieved during surgery.<sup>258</sup> Design modifications to augment fixation of the tibial component (e.g., with pegs or screws) continue, although the long-term value of these designs has yet to be determined.<sup>123,316</sup>

In summary, research and development continue on TKA biomechanics, prosthetic designs, fixation methods, materials with better wear qualities, and surgical techniques using sophisticated instrumentation for alignment and placement of the components.

### Operative Overview

An incision along the midline or anteromedial aspect of the knee can be used with either the standard or minimally invasive approach. Key features of these two types of approaches are compared in Table 21.1.<sup>28,41,197,258</sup> A quadriceps-splitting or a quadriceps-sparing approach is used to reach the capsule for

an arthrotomy. The knee is flexed, and osteophytes, menisci, and the ACL are resected. If a posterior cruciate-substituting prosthesis is to be implanted, the PCL is also excised.

A series of surgical techniques are performed prior to inserting the implants.<sup>124,258</sup> Contemporary TKA usually employs either computer-assisted navigation during surgery or custom-made cutting blocks based on presurgical images to ensure precise placement and alignment of the components. Small portions of the distal femur and proximal tibia are removed and prepared for the implants. If a patellar implant is indicated, the patellar surface also is prepared and the prosthesis inserted. After trial components are inserted, soft tissue tension, collateral ligament balance, ROM, and patellar tracking are assessed. The lateral retinaculum may be released to improve patellar tracking.<sup>144,258</sup> Permanent components are inserted, and the capsule and other soft tissues are repaired. The area is thoroughly irrigated, and the wound is closed with a small suction drain in place and the knee positioned in extension. A sterile dressing is placed over the incision, and the area is covered from foot to thigh with a compression wrap.

### Complications

The incidence of complications after TKA is low. Intraoperative complications, such as an intercondylar fracture or damage to a peripheral nerve, are uncommon. Because minimally invasive TKA is considered more technically challenging than conventional TKA, the rate of intraoperative complications, such as fracture or malpositioning of an implant, is higher with a minimally invasive than a standard approach.<sup>28,87</sup> An increased incidence of intraoperative technical errors is associated with patient obesity.<sup>129</sup>

Early and late postoperative complications include infection, joint instability, polyethylene wear, and component loosening. As with arthroplasty of other joints, there is a risk of wound-healing problems and deep vein thrombosis (DVT) during the first few months after surgery. Although the incidence of deep periprosthetic infection is low, it is the most common reason for early failure and the need for revision arthroplasty. In contrast, polyethylene wear of the patellar and tibial components is the most common late complication

**TABLE 21.1** Features of Standard and Minimally Invasive Surgical Approaches for Total Knee Arthroplasty

Standard Traditional Approach	Minimally Invasive Approach
<ul style="list-style-type: none"> <li>■ Anteromedial parapatellar vertical or curved incision from the distal aspect of the femoral shaft, running medial of the patella to just medial of the tibial tubercle, ranging from 8–12 cm<sup>28</sup> or 13–15 cm<sup>258</sup> in length</li> <li>■ Necessary soft tissue releases prior to eversion of the patella</li> <li>■ Anterior capsule release</li> <li>■ Dislocation of the tibiofemoral joint prior to bone cuts and implantation of components</li> </ul>	<ul style="list-style-type: none"> <li>■ Reduced length of anteromedial skin incision 6–9 cm in length<sup>28</sup></li> <li>■ No patellar eversion</li> <li>■ Anterior capsule release</li> <li>■ No tibiofemoral dislocation</li> <li>■ <i>In situ</i> bone cuts</li> <li>■ <i>In situ</i> implantation of components</li> </ul>

requiring revision.<sup>52,196</sup> The incidence of biomechanical loosening has been reduced significantly with the newer prosthetic designs and improved surgical techniques.<sup>196,259</sup> If mechanical loosening develops over time, it occurs most often at the tibial component and with cementless or hybrid TKAs rather than fully cemented replacements.<sup>215</sup>

Other postoperative complications that can compromise a patient's functional recovery include limited knee flexion, joint instability leading to subluxation,<sup>52,258</sup> and patellar instability or tracking problems leading to impaired function of the extensor mechanism (most often an extensor lag).<sup>144,258</sup>

Additionally, obesity has been shown to limit mobility outcomes after TKA compared to nonobese patients.<sup>129</sup>

### Postoperative Management

Goals and interventions during progressive phases of postoperative rehabilitation after TKA are summarized in Table 21.2. Guidelines are similar for management after UKA. Interventions also may include preoperative patient education on an individual or group basis.<sup>260</sup> Following surgery, patients routinely receive gait training and exercise instruction while hospitalized and in a subacute rehabilitation facility. Many patients also

receive home-based or outpatient therapy after discharge from inpatient care.

A patient is advanced from one phase of rehabilitation to the next based on an evaluation of their signs and symptoms and responses to selected interventions rather than solely at designated time periods. Accordingly, the timelines noted in Table 21.2 and described in the following sections are intended to serve only as general guidelines.

**NOTE:** The postoperative guidelines in Table 21.2 and the following sections reflect recommendations for patients who have undergone *primary* TKA in which a *standard* surgical approach was used. The suggested timelines for the progression of exercises and weight bearing tend to be more rapid after UKA than TKA and after minimally invasive compared with traditional arthroplasty, but slower after complex revision arthroplasty versus primary arthroplasty.

### Immobilization and Early Motion

After primary TKA, the knee is either immobilized in a bulky compression dressing for a day, or subjected to mechanical continuous passive motion (CPM). The position of immobilization after primary TKA is usually extension.<sup>258</sup> Although uncommon, an alternative approach is to immobilize the knee in a 90° flexion splint immediately after surgery and for brief intervals during the next day or two to achieve knee flexion as soon as possible while maintaining knee extension with

exercises.<sup>117</sup> With a complicated revision arthroplasty, an extended period of immobilization may be required.

During the initial postoperative period, it may be advisable for the patient to wear a posterior extension orthosis during ambulation until quadriceps control is reestablished. An extension orthosis is also indicated at night for the patient who is having difficulty achieving full knee extension or who had a significant preoperative knee flexion contracture.<sup>39,258</sup>

After first being introduced, CPM was used routinely following TKA during the patient's hospitalization.<sup>97</sup> Early studies demonstrated benefits of CPM, including decreased need for postoperative pain medication, decreased incidence of deep vein thrombosis, and increased or more rapid recovery of ROM.<sup>131,161,176</sup> Over time, however, this practice has decreased as early mobility has been shown to be equally effective in realizing these benefits.<sup>109</sup>

Customary practice for the past 2 decades has been to initiate early postoperative exercise following TKA except in some instances of complex revision arthroplasty.<sup>66</sup> Chapter 3 includes a section on the history and current guidelines for using CPM.

### Weight-Bearing Considerations

The extent to which weight bearing is allowable after primary TKA depends on the type of prosthesis implanted; the type of fixation used; the patient's age, size, and bone quality; and whether a knee immobilizer is worn during ambulation or

transfers. With *cemented fixation*, weight bearing as tolerated using crutches or a walker is usually permitted immediately after surgery. The patient progresses to full weight bearing over a 6-week period.<sup>239</sup>

With *biological/cementless fixation*, recommendations for weight bearing vary from permitting only touch-down weight bearing for 4 to 8 weeks while using crutches or a walker<sup>215</sup> to weight bearing as tolerated within a few days after surgery while using crutches or a walker.<sup>39,258,260</sup>

A cane can be used during the progression from partial to full weight bearing. Ambulation without an assistive device, particularly during outdoor walking, is not advisable until the patient has attained full or nearly full, active knee extension ROM, and adequate strength of the quadriceps and hip musculature to control the operated lower extremity.<sup>39,167,215,260</sup>

### Exercise Progression

Goals and exercises for progressive phases of postoperative rehabilitation after current-day TKA, noted in Table 21.2, are discussed in the following sections.<sup>11,39,66,180,185,231,260,317</sup> Precautions for exercise during rehabilitation are summarized in Box 21.3.

Many of the exercises described for the early phase of rehabilitation were reported in a consensus document developed by physical therapists on the management of hospitalized patients after TKA.<sup>66</sup> Prior to discharge from inpatient rehabilitation, a home exercise program serves as the foundation for the remainder of the rehabilitation process, with some patients also undergoing home-based or outpatient rehabilitation for a limited number of visits.

#### BOX 21.3 Exercise Precautions Following TKA

- Monitor the integrity of the surgical incision during knee flexion exercises. Watch for signs of excessive tension on the wound, such as drainage or skin blanching.
- Postpone SLRs in side-lying positions for 2 weeks after cemented arthroplasty and for 4 to 6 weeks after cementless/hybrid arthroplasty to avoid varus and valgus stresses to the operated knee.
- Confer with the surgeon to determine when it is permissible to initiate exercises against low-level resistance. It may be as early as 2 weeks or as late as 3 months postoperatively.
- If a posterior cruciate-sacrificing (posterior-stabilized) prosthesis was implanted, avoid hamstring strengthening in a sitting position to reduce the risk of posterior dislocation of the knee.<sup>39</sup>
- Tibiofemoral joint mobilization techniques to increase knee flexion or extension may or may not be appropriate, depending on the design of the prosthetic components. It is advisable to discuss the use of these techniques with the surgeon before initiating them.
- Postpone unsupported or unassisted weight-bearing activities until strength in the quadriceps and hamstrings is sufficient to stabilize the knee.

### Exercise: Maximum Protection Phase

The focus of management during the first phase of rehabilitation and the acute/inflammatory and early subacute stage of tissue healing, which extends for about 4 weeks, is to control pain and swelling, achieve independent ambulation and transfers using an assistive device, prevent early postoperative medical complications such as pneumonia and DVT, and minimize the adverse effects of postoperative immobilization. The ROM goal is to attain 90° of knee flexion and full knee extension by the end of this first phase of rehabilitation. However, full knee extension may not be possible until joint swelling has subsided.

It is well established that pain and joint swelling limit the function of the quadriceps muscle. In addition, there is a high correlation between quadriceps muscle weakness and impaired functional abilities during the initial period of recovery after TKA.<sup>187</sup> Regaining quadriceps muscle strength, particularly in terminal extension, as early as possible after TKA is essential for functional control of the knee during ambulation and stair climbing. In addition to early postoperative exercise, neuromuscular electrical stimulation or biofeedback of the quadriceps may be beneficial as it has been shown to be safe when initiated as early as 2 days following surgery.<sup>8,185</sup>

### FOCUS ON EVIDENCE

Mizner and coinvestigators<sup>188</sup> compared the voluntary activation and force-producing capacity of the quadriceps femoris muscle group in 52 patients (mean age 64.9 years, range 49 to 78 years) 3 to 4 weeks after unilateral, cemented primary TKA for OA to 52 healthy individuals (mean age 72.2 years, range 64 to 85 years) without knee pathology. All patients in the TKA group had participated in a standard exercise program following surgery. Quadriceps force production and volitional activation of the operated limb were 64% and 26% less in the TKA group than in the healthy group, respectively, but there were no significant differences of the noninvolved knees in the TKA group compared with the healthy group. Based on the results of their study, the investigators recommended the use of neuromuscular electrical muscle stimulation or biofeedback as an adjunct to an individualized postoperative exercise program to augment quadriceps muscle force production after TKA.

Results of a prospective, randomized, controlled study conducted by Avramidis and colleagues<sup>9</sup> support the recommended use of neuromuscular electrical stimulation in addition to a postoperative exercise program after TKA. Thirty patients scheduled to undergo primary TKA were randomly assigned to either a treatment group or a control group (15 patients per group). Both groups underwent an individualized program of exercise and gait training following surgery, while the treatment group also received electrical stimulation to the vastus medialis muscle 4 hours a day for 6 weeks beginning on postoperative day 2. Patients in the treatment group demonstrated a significantly faster walking speed than those in the control group at 6 weeks and 12 weeks postoperatively.

**Goals and interventions.** The following goals and exercise interventions are included in the initial phase of rehabilitation after TKA.<sup>11,39,66,180,185,260,317</sup>

- **Prevent vascular and pulmonary complications.**
    - Ankle pumping exercises with the leg elevated immediately after surgery to prevent venous stasis and reduce the risk of a DVT or pulmonary embolism
    - Deep breathing exercises
  - **Control pain and swelling.**
    - Cold, compression, and elevation
  - **Minimize reflex inhibition or loss of knee and hip musculature strength.**
    - Muscle-setting exercises of the quadriceps (preferably coupled with neuromuscular electrical stimulation), hamstrings, and hip extensors and abductors
    - Active-assisted and active straight leg raise (SLR) exercises in supine and prone positions the first day or two after surgery, postponing SLRs in side-lying positions for as long as 2 weeks after cemented TKA and for as long as 4 to 6 weeks after cementless/hybrid replacement to avoid varus or valgus stresses to the operated knee
    - Active-assisted ROM progressing to active ROM of the knee while seated and standing for antigravity knee extension and flexion, respectively
    - As weight bearing on the operated lower extremity permits, terminal knee extension in standing, wall slides in a standing position, minisquats, and partial lunges to develop control of the knee extensors and reduce the risk of an extensor lag
  - **Maintain or improve strength of the contralateral lower extremity.**
    - PRE of nonoperated lower extremity, particularly the quadriceps and hip extensors and abductors<sup>317</sup>
  - **Regain knee ROM.**
    - Heel-slides in a supine position or while seated with the foot on the floor to increase knee flexion
    - Neuromuscular facilitation and inhibition techniques, such as the agonist-contraction technique (described in Chapter 4), to decrease muscle guarding and increase knee flexion
    - Gravity-assisted knee flexion by having the patient sit and dangle the lower leg over the side of a bed
    - Gravity-assisted or self-assisted knee extension in the supine or long-sitting position by periodically placing a rolled towel under the heel and leaving the knee unsupported, or by gently pressing downward on the distal femur with both hands
    - Gentle inferior and superior patellar gliding techniques
- PRECAUTION:** Avoid placing a pillow or rolled towel under the knee while lying supine or while seated with the operated leg elevated to reduce the risk of developing a knee flexion contracture.
- **Improve trunk stability and balance.**
    - Trunk stabilization exercises
    - Balance activities in sitting and weight shifting in bilateral stance while adhering to weight-bearing restrictions

- **Reestablish functional mobility.**

- Gait training with an appropriate assistive device to maintain weight-bearing restrictions
- Functional training (bed mobility, sit-to-stand transfers, basic ADLs)

**Criteria to progress.** The criteria to progress to the intermediate phase of rehabilitation include the following:

- Minimal swelling and pain
- Well-healed incision with no signs of infection
- Independent basic ADLs and ambulation with appropriate assistive device
- Full or nearly full active knee extension and 90° knee flexion

**Exercise: Moderate Protection/Controlled Motion Phase**

The emphasis of the intermediate phase of rehabilitation, which begins at about 4 weeks and extends to 8 to 12 weeks postoperatively, is to achieve approximately 110° knee flexion and active knee extension to 0° and to regain lower extremity strength and muscular endurance, balance, cardiopulmonary endurance, and additional functional mobility.

By 4 to 6 weeks postoperatively, if nearly full knee extension has been achieved and the strength of the quadriceps is sufficient, most patients transition to using a cane during ambulation. This makes it possible to focus on normalizing the patient's gait, sit-to-stand, and stair ascent and descent patterns and on improving the speed and duration of walking. In general, most improvements in a patient's functional abilities and quality of life tend to occur by 3 months postoperatively.<sup>132</sup>

**Goals and interventions.** The goals and exercise interventions for the intermediate phase of rehabilitation are the following:<sup>11,39,66,180,187,231,260,317</sup>

- **Increase strength and endurance of knee and hip musculature.**
  - Multiple-angle isometrics and low-intensity dynamic resistance exercises of the quadriceps, hamstrings, and hip musculature (extensors, abductors, external rotators) against a light grade of elastic resistance or a cuff weight around the ankle
  - Resisted SLRs in various positions to increase the strength of hip and knee musculature
  - As weight bearing allows, continue or begin closed-chain exercises including resisted terminal knee extension in standing, standing wall slides, minisquats, partial lunges, and the sit-to-stand task emphasizing proper lower extremity alignment. Include scooting forward and backward on a wheeled stool to improve functional control of the knee.
  - Add forward and backward step-ups/downs, progressing to lateral. Reinforce proper lower extremity alignment. To progress, increase the step height or perform against elastic resistance.
  - Stationary cycling with the seat positioned as high as possible to emphasize knee extension
  - Include strengthening exercises for the noninvolved lower extremity

- **Continue to increase knee ROM.**
  - Low-intensity self-stretching using a prolonged stretch or hold-relax technique to increase knee flexion and extension if limitation persists. Flexibility of the hip flexors, hamstrings, and calf muscles also may need to be improved for standing and ambulation activities.
  - Stationary cycling with seat lowered to increase knee flexion
  - Grade III inferior or superior patellar mobilization techniques to increase knee flexion or extension, respectively, if insufficient patellar mobility is restricting ROM
- **Improve standing balance and trunk stability.**
  - Trunk stabilization exercises
  - Proprioceptive and balance training progressing from bilateral to unilateral stance on stable surface, then to balance activities on an unstable surface
  - Functional reaching activities while standing or stooping
  - Tandem walking, grapevine walking initially in parallel bars for safety (see Chapter 23 for additional activities)

**PRECAUTION:** A progression of balance activities for patients with TKA is typically safe to begin about 8 weeks postoperatively but must be based on the ability to control the knee during stance, weight-bearing restrictions, and the absence of pain.<sup>231</sup>

- **Continue to improve functional mobility.**
  - Symmetrical heel-toe walking, ambulation on a variety of surfaces and inclines, kneeling and getting up to a standing position, and ascending and descending stairs
  - Functional exercises: backward walking, side-stepping, marching, stepping over small objects

### FOCUS ON EVIDENCE

Following TKA or UKA, patients often report difficulty kneeling or the inability to kneel even a year after surgery. Although many functional activities, such as housework and gardening, involve kneeling, patient education about this skill is not always included in postoperative rehabilitation. Jenkins and associates<sup>130</sup> conducted a single-blind, prospective, randomized, controlled study to investigate the impact of kneeling instruction following partial knee replacement. All patients participated in postoperative rehabilitation, but at 6 weeks after surgery, only half received a single physical therapy intervention of advice and instruction on kneeling. At 1 year following surgery, patient-reported kneeling ability was significantly better in the group who received kneeling advice and instruction than in the group that did not. As such, the investigators suggested that kneeling advice and instruction should be included in postoperative rehabilitation after partial knee replacement. Although the findings of this study may have implications for patients who have undergone TKA, the investigators pointed out that the results of the study can be applied to patients following only partial knee replacement.

- **Improve cardiopulmonary endurance.**
  - Aerobic conditioning on a stationary cycle or upper body ergometer, emphasizing increased duration

**Criteria to progress.** The following criteria typically must be met to progress to the final phase of rehabilitation following TKA:

- AROM: full knee extension (no extensor lag), 110° knee flexion
- Quadriceps/hamstring and hip muscle strength: at least 70% (or 4/5 muscle testing grade) compared to uninvolved leg
- Minimal to no pain during exercises and ambulation with or without a cane

### Exercise: Minimum Protection/Return to Function Phase

Beginning at approximately 8 to 12 weeks after surgery, the emphasis of the final phase of rehabilitation is on task-specific strengthening exercises, proprioceptive and balance training, advanced functional training (see Chapter 23), and continued cardiopulmonary conditioning so that the patient develops the strength, power, balance, and endurance needed to return to a full level of functional activities in the community. (Refer to Table 21.2 for a summary of goals and interventions during the final phase of rehabilitation.)

Despite persistent strength and power deficits, altered movement patterns, and insufficient speed and endurance during functional activities, patients often are discharged from supervised therapy 2 to 3 months postoperatively after attaining functional ROM of the knee and the ability to ambulate independently with an assistive device. However, deficits in physical function have been shown to persist for an average of 10 months<sup>297</sup> to a year or more after surgery.<sup>187</sup>

It is likely that some patients, especially those living in the community, could benefit from an intensive exercise program during the late phases of rehabilitation to perform demanding physical activities more efficiently, such as ascending and descending stairs and returning to selected recreational activities.

### FOCUS ON EVIDENCE

Moffet and associates<sup>189</sup> conducted a single-blind, randomized, controlled study to determine the effectiveness of an intensive, supervised functional training program initiated 2 months after primary TKA for OA. Patients in the experimental group (n = 38) participated in facility-based, twice-weekly, 60- to 90-minute exercise sessions consisting of hip and knee strengthening exercises, task-specific functional exercises, and aerobic conditioning. Patients also received a home program to be followed on the days they did not participate in the supervised program. Patients in the control group (n = 39) participated in a home exercise program for 6 weeks with periodic home visits by a therapist. No exercise-related adverse events occurred during the study.

Patients were evaluated by means of the 6-minute walk test and two functional outcome and quality-of-life (QOL) measures prior to beginning the exercise program (baseline

measurement at 2 months after surgery), at the conclusion of the 6-week exercise program, and at 6 and 12 months postoperatively. The two groups were comparable at baseline. At the conclusion of the intervention and at the 6- and 12-month follow-ups, patients in the intensive exercise group walked significantly longer distances (walked at a faster speed) during the 6-minute walk test than did those in the control group. Functional abilities and QOL were significantly better for the intensive exercise group than the control group immediately after the 6-week program and at 6 months postoperatively. At 1 year after surgery there were no significant differences in function or QOL measures between the two groups.

The investigators concluded that an intensive, functionally oriented exercise program initiated 2 months after primary TKA was safe and effective for improving physical function and QOL.

With the trend toward an increasing number of young (< 60 years of age) and active patients undergoing TKA,<sup>126</sup> patient education is essential to help patients understand the detrimental effects of repetitive, high-impact activities (work related, fitness related, and recreational) on the prosthetic implants and to learn how to select activities that promote fitness but are least likely to reduce the longevity of the prosthetic knee.<sup>110,147,174</sup> Accordingly, patients are advised to participate in low-impact physical activities after TKA to reduce the risk of component wear and mechanical loosening over time and the premature need for revision arthroplasty.

For the patient who wishes to participate in athletic activities after TKA, there are a number of considerations. Factors that influence participation include the level of demand (intensity and load) of an athletic activity, a patient's body weight, overall level of fitness, and preoperative experience with the activity and the technical quality of the knee replacement and related soft tissue balancing or reconstruction.<sup>110,147</sup>

Physical activities for fitness and recreation that are highly recommended, recommended with caution, or not recommended after TKA are noted in Box 21.4.<sup>110,147,174</sup>

## Outcomes

Although the ideal knee replacement that replicates the normal biomechanics of the native knee joint has yet to be developed, knee arthroplasty has been shown to be a successful procedure for patients with advanced joint disease. Extensive research has been published on patient-related outcomes and the survivorship associated with a wide variety of prosthetic designs, surgical techniques, methods of fixation, and types of materials.<sup>123,124,163,258,316</sup> Because of the variability of procedures and the fact that outcomes are often based on nonrandomized, retrospective studies, it has been difficult to draw general conclusions.<sup>259</sup> However, a recent large-scale (2,352 patients), multicenter, randomized study comparing patient-related outcomes following three variations of total knee component designs demonstrated no significant differences in clinical, functional, and QOL

### BOX 21.4 Recommendations for Participation in Physical Activities Following TKA

#### Highly Recommended\*

- Stationary cycling
- Swimming, water aerobics
- Walking
- Golf (preferably with golf cart)
- Ballroom or square dancing
- Table tennis

#### Recommended if Participated Prior to TKA\*\*

- Road cycling
- Speed/power walking
- Low-impact aerobics
- Cross-country skiing (machine or outdoor)
- Table tennis
- Doubles tennis
- Rowing, canoeing
- Bowling

#### Not Recommended\*\*\*

- Jogging, running
- Basketball
- Volleyball
- Singles tennis
- Baseball, softball
- High-impact aerobics
- Stair-climbing machine
- Handball, racquetball, squash
- Football, soccer
- Gymnastics, tumbling
- Water-skiing

\*Low impact, low load; appropriate at a moderate or high intensity on a regular basis for aerobic fitness.

\*\*Moderate impact; appropriate on a recreational basis if performed at low or moderate intensity.

\*\*\*High impact, high load; peak load occurs during knee flexion.

improvements between the randomized groups at 2 years following surgery.<sup>132</sup>

Patient-related outcomes after knee arthroplasty that have the most influence on patient satisfaction are relief of pain and an improved ability to perform necessary and desired functional activities for an extended number of years. Approximately 90% of patients who undergo primary TKA can expect 10 to 20 years of satisfactory function before revision arthroplasty may need to be considered.<sup>258</sup> For example, Dixon and colleagues<sup>60</sup> reported a 92.6% survival rate of modular, fixed-bearing TKA in patients followed for a minimum of 15 years.

Parameters typically measured by means of self-report and performance-based instruments to determine the success of knee replacement surgery are the level of pain, overall QOL, knee ROM, strength of the knee musculature, and a patient's ability to perform functional activities safely and with ease.

An understanding of evidence-based outcomes following TKA can assist a therapist in developing realistic goals with a patient and better determining a patient's prognosis.

**Pain relief.** Almost all patients who undergo knee arthroplasty report a significant reduction of pain during knee motion and weight bearing, with most patients reporting good to excellent pain relief.<sup>85,258,259,298</sup>

**ROM.** Improvements in knee ROM are not as predictable as relief of pain. Stiffness often persists after the initial recovery from surgery has occurred.<sup>85</sup> However, it also has been reported that ROM may continue to improve up to 12 to 24 months postoperatively.<sup>273</sup> Factors that influence postoperative ROM include preoperative ROM, the underlying disease, obesity, postoperative pain, and whether a primary or a revision arthroplasty was performed. Complications such as component malpositioning, inadequate soft tissue balancing or reconstruction, infection, and mechanical loosening of an implant can adversely affect postoperative ROM.<sup>220,269</sup>

Patients with restricted ROM preoperatively often continue to have limited postoperative knee flexion, extension, or both despite an aggressive exercise program.<sup>269,273</sup> In fact, the most important predictor of long-term postoperative knee ROM is preoperative ROM.<sup>155,257,269</sup> For example, in a study of 358 patients who underwent primary TKA for OA, total ROM of the knee was 110° preoperatively and 113° postoperatively due to a reduction in the average knee flexion contracture from 12° to 9°.<sup>257</sup> The results of several other studies found that despite patients' participation in an outpatient or home-based postoperative rehabilitation program, there was no significant change in preoperative versus postoperative knee ROM at 6 months<sup>11,187</sup> or at 12 months after surgery.<sup>238</sup>

Differences in prosthetic design, such as mobile-bearing versus fixed-bearing<sup>38,258</sup> or PCL-retaining versus PCL-substituting (posterior stabilized) designs,<sup>213,216,258</sup> and in the method of fixation<sup>215,258</sup> do not appear to affect ROM outcomes after primary TKA. A comparison of five designs of posterior cruciate-substituting implants, for example, showed no significant differences in the extent of improvement of knee ROM among designs.<sup>257</sup>

Limited knee ROM has a substantial impact on postoperative function, particularly if knee flexion is less than 90° and knee extension is limited by more than 10° to 15°.<sup>258</sup> With less than 90° to 100° of knee flexion, it is difficult to negotiate stairs, and having less than 105° makes it difficult to stand up from a standard height chair without using arm support.<sup>258</sup> In a retrospective study of more than 5,000 total knee arthroplasties, Ritter and associates<sup>246</sup> determined that greater than 105° of knee flexion was necessary for optimal postoperative function. Results of their study indicated that functional outcomes were highest when at least 128° of knee flexion was achieved following surgery but were substantially compromised if < 118° was achieved. In contrast, lack of full knee extension because of contracture or an extensor lag is thought to be a source of a patient's perception of knee pain or instability

during ambulation activities, particularly when ascending and descending stairs.<sup>144,258</sup>

**Strength and endurance.** It takes a minimum of 3 to 6 months after surgery for a patient to regain preoperative strength levels in the quadriceps and hamstrings of the operated knee.<sup>144,187,273</sup> Quadriceps weakness tends to persist longer after knee arthroplasty than does knee flexor weakness.<sup>273</sup> Furthermore, quadriceps weakness of the contralateral (nonoperated) side is a predictor of impaired functional outcomes at 1 and 2 years following unilateral TKA.<sup>317</sup>

Studies of patients after unilateral TKA with a conventional surgical approach have demonstrated that quadriceps strength in the operated leg correlates highly with performance on tests of functional abilities during the first 6 months after surgery.<sup>187</sup> For example, a study by Farquhar and associates<sup>70</sup> demonstrated that at 3 months post-TKA, patients had quadriceps weakness and an altered sit-to-stand movement pattern reflected by the use of increased hip flexion and greater reliance on hip extensor strength, thus reducing the demand on the knee extensors. Of additional interest was the finding that at 1 year after surgery, despite improved symmetry of quadriceps strength, the altered sit-to-stand pattern persisted, perhaps as the result of habit.<sup>70</sup>

Quadriceps strength is also significantly less than in similarly aged healthy individuals 6 months to a year after surgery<sup>67,85,187,298</sup> and the noninvolved leg 1 to 2 years postoperatively.<sup>251,270</sup> It has been suggested that eversion of the patella during a conventional surgical approach may contribute to impaired function of the quadriceps mechanism after surgery.<sup>163,270</sup>

A recent systematic review of lower limb isometric strength following TKA concluded that there were strength deficits in the quadriceps, hamstring, and calf of the involved leg at multiple time-points postoperatively when compared to unimpaired control groups. Quadriceps and calf strength deficits persisted for up to 3 years following surgery.<sup>254</sup>

Given the number of studies that have identified significant quadriceps weakness after TKA and the high correlation between quadriceps strength and functional performance, there is substantial evidence to support the importance of quadriceps-strengthening exercises in postoperative rehabilitation programs to optimize function after TKA.

**Physical function and activity level.** The greatest and most rapid improvements in physical performance following TKA occur during the first 12 weeks with an additional but small amount of improvement occurring beyond 12 weeks.<sup>137</sup> Relief of pain appears to significantly improve a patient's QOL and ability to perform functional activities. However, just 1 month after TKA, functional performance is dramatically worse than the preoperative level of function, despite a patient's participation in a rehabilitation program beginning the day after surgery.<sup>11</sup>

A systematic review of the literature by Ethgen and colleagues<sup>69</sup> revealed that a patient's postoperative level of function and QOL, as measured by self-report questionnaires,

typically begins to surpass the preoperative level at approximately 3 months, with most improvement in function occurring by 6 months. However, results of some studies have shown that additional improvements may occur for a year or more postoperatively.<sup>273,298</sup>

Overall, when comparing preoperative with postoperative function, patients with high preoperative scores on functional measures achieved a higher level of function postoperatively than patients with low preoperative functional scores.<sup>79</sup>

A survey of 176 patients (mean age, 70.5 years) by Weiss and colleagues<sup>301</sup> 1 year or more after TKA identified patients' level of participation in activities of graduated difficulty and determined which activities were most important to patients. The survey also identified activities that were difficult after TKA. The results of the survey indicated that in addition to basic ADLs—walking, stair-climbing, and personal care—patients performed a wide range of therapeutic and recreational activities after TKA. The activities in which the highest percentage of patients participated were stretching exercises (73%), leg-strengthening exercises (70%), gardening (57%), and stationary cycling (51%). These same activities were rated as important by patients. Functions that were the most difficult and most often caused knee pain were squatting (75%) and kneeling (70%).

Bradbury and colleagues<sup>30</sup> studied the pre- and postoperative sports participation of 160 patients who had undergone TKA 5 years earlier. Preoperatively, there were no significant differences in knee ROM, walking abilities, and radiographs in the patients who did and did not participate in sports activities. Postoperatively, the investigators found that 51 (65%) of the 79 patients (mean age 73 years at the 5-year follow-up) who had regularly (at least twice a week) participated in sports activities during the year prior to surgery were participating in some type of sport at the 5-year follow-up. Patients were more likely to return to low-impact rather than high-impact activities. Of the patients who did not regularly participate in a sport before surgery, none took up a sport postoperatively.

Despite an overall positive impact of TKA on physical function, long-term studies indicate that functional abilities typically remain below norms for age-matched, healthy populations.<sup>11,67,79</sup> A follow-up study of 276 community-dwelling patients 6 months after primary TKA revealed that overall physical function improved significantly for all patients, although 60% reported moderate to extreme difficulty descending stairs and 64% continued to have a similar degree of difficulty with heavy household tasks.<sup>133</sup>

Results of another study indicated that 1 year after TKA, despite a relative absence of pain and some improvement in functional abilities, significant deficits in strength and function were apparent when compared with the abilities of age-matched, healthy individuals.<sup>298</sup> The post-TKA patients had less strength of the knee musculature, slower walking and stair-climbing speeds, and a higher perceived level of exertion during activities than healthy individuals. The authors pointed out that the post-TKA patients as a group were heavier

than the control group and suggested that general physical deconditioning may have contributed to the postoperative group's functional limitations. This study emphasized the need for inclusion of a low-impact aerobic conditioning program during rehabilitation after TKA.

## Patellofemoral Dysfunction: Nonoperative Management

### Related Patellofemoral Pathologies and Etiology of Symptoms

Patellofemoral pain syndrome (PFPS) is a clinical diagnosis that encompasses multiple features, most commonly involving a general description of anterior knee pain, provoked by physical activities such as running and by increased PF joint compressive forces during activities such as squatting, sitting with flexed knees, and ascending and descending stairs.<sup>46,151,313</sup> The cause of anterior knee pain may be direct trauma; overuse; faulty patellar tracking; joint degeneration; soft tissue length and strength imbalances in the hip, knee, or ankle/foot; or a combination of factors.<sup>33,56,151,172,233,234,236,251,282,299,298</sup> For effective treatment, an attempt should be made to determine the causative factors based on the patient's history and a comprehensive examination. To encompass this variety of potential causes, several classification systems have been proposed and are summarized in this section.<sup>120,307</sup> In addition, consensus papers from several research retreats<sup>46,54,235</sup> have organized the condition into three primary categories—local, distal, and proximal—in order to identify etiologic factors. Because interventions should be directed to the underlying problem, it is helpful to look at the various diagnoses within the context of these three categories.

#### Local Factors

Local factors include structures around the knee joint itself, such as the infrapatellar fat pad, ligaments, quadriceps tendon, retinaculum, and subchondral bone. Symptoms may be provoked by faulty mechanics or activities that directly influence local factors such as those identified in the following diagnoses.

#### PF Instability

Instability includes subluxation or dislocation related to a single episode or recurrent episodes. Instability may be related to an abnormal Q-angle, dysplastic trochlea (shallow groove or flat lateral femoral condyle), patella alta, tight lateral retinaculum, or inadequate medial stabilizers (vastus medialis oblique muscle and medial patellofemoral ligament). Patellar instability is most often in a lateral direction. Dislocation may derive from direct trauma to the patella or from a forceful quadriceps contraction while the foot is planted and the femur is externally rotating while the knee is flexed. Recurrent dislocation is usually an indication for surgery to reorient the stabilizing forces across the PF joint.

### PF Pain With Malalignment or Biomechanical Dysfunction

Patella alta or baja and lateral patellar tilt are specific alignment alterations possible at the patellofemoral joint. Impairments that may contribute to biomechanical dysfunction include a tight lateral retinaculum, weak vastus medialis obliquus (VMO) muscle, neuromuscular deficits in the hip musculature, and generalized joint hypermobility. These impairments usually result in clinical evidence of abnormal patellar tracking, and there may be discordant firing of the quadriceps muscle.<sup>120</sup>

#### FOCUS ON EVIDENCE

Although it is widely reported that PF malalignment is seen in patients with PFPS and may be associated with symptoms, the evidence to support the existence of abnormal alignment in PFPS is lacking. Specifically, because there is little evidence to support the validity and reliability of various testing procedures currently used to measure patellar position and tracking, only assumptions can be made as to the relationship between malalignment and PFPS.<sup>311</sup>

### PF Pain Without Malalignment

Patellofemoral pain without malalignment includes many subcategories of lesions that cause anterior knee pain.

**Soft tissue lesions.** Soft tissue lesions include plica syndrome, fat pad syndrome, tendonitis, IT band friction syndrome, and bursitis.

- *Plica syndrome* describes a condition where embryological synovial tissue remnants or bands around the patella cause joint irritation during motion. With chronic irritation, the tissue remnant becomes an inelastic, fibrotic band that is tender during palpation. When symptoms are acute, the tissue is painful during palpation. Bands may be palpable medial to the patella, although there are variations in location.<sup>24,136</sup>
- *Fat pad syndrome* involves irritation of the infrapatellar fat pad from trauma or overuse.
- *Tendonitis* of the patellar or quadriceps tendons, sometimes called *jumper's knee*, typically occurs from overuse as the result of repetitive explosive jumping activities. Tenderness occurs at the attachment of the tendons on the patella. Symptoms may be related to or exacerbated by quadriceps tightness.<sup>299</sup>
- *IT band friction syndrome* is irritation of the IT band as it passes over the lateral femoral condyle during activities. Irritation may be the result of tight tensor fasciae latae or gluteus maximus muscles (see discussion in Chapter 20). Because the IT band attaches to the patella and lateral retinaculum, anterior knee pain may also be noted with IT band friction syndrome.
- *Prepatellar bursitis*, also known as housemaid's knee, can result from prolonged kneeling or recurrent minor trauma to the anterior knee. When inflamed, there may be restricted

motion due to swelling and direct pressure or pressure from the patellar tendon will be painful.

**Tight medial and lateral retinacula or patellar pressure syndrome.** There is increased contact force between the patella and distal femur in the trochlear groove.

**Osteochondritis dissecans of the patella or femoral trochlea.** Osteochondral lesions result in pain on the posterior patellar surface that increases during squatting, stooping, ambulating, and descending steps. There may be loose bodies within the joint that cause the knee to give way or lock.

**Traumatic patellar chondromalacia.** Chondromalacia is softening and fissuring of the cartilaginous posterior patellar surface, diagnosed with arthroscopy or arthrography.<sup>120</sup> It may eventually predispose the joint to degenerative arthritis or basal degeneration of the middle and deep zones of the cartilage.<sup>96</sup> Causes include trauma, surgery, prolonged or repeated stress, or lack of normal stress such as during periods of immobilization.<sup>214</sup>

**PF OA.** OA may be idiopathic or posttraumatic and is diagnosed by radiographic changes consistent with degeneration.

**Apophysitis.** Osgood-Schlatter disease (traction apophysitis of the tibial tuberosity) and Sinding-Larsen Johansson syndrome (traction apophysitis on the inferior pole of the patella) occur during adolescence as a result of overuse during rapid growth. They are self-limiting conditions.

**Symptomatic bipartite patella.** Most bipartite patellae (split due to patellar ossification variants) are asymptomatic, but trauma may disrupt the chondro-osseous junction, leading to symptoms.<sup>120</sup>

**Trauma.** Trauma includes tendon rupture, patella fracture, contusion, and articular cartilage damage that results in inflammation, swelling, limited motion, and pain when contracting the quadriceps, such as during stair climbing, squatting, and resisted knee extension.

### Proximal Factors

Factors arising from the hip and pelvis region include increased hip adduction and internal rotation during specific tasks such as running and single-limb activities of squatting, jumping, and drop landing. These hip kinematic alterations may be associated with hip abductor, extensor, and external rotator muscle weakness.

#### FOCUS ON EVIDENCE

The summary statement of the 3rd International Patellofemoral Pain Research Retreat<sup>313</sup> summarized studies that show evidence of greater hip adduction in women who develop PFP and conflicting results regarding contralateral pelvic drop. Studies also identified reduced hip extension moments during running, weaker isometric hip extension, and delayed activation in gluteus medius in those with PFP.

## Distal Factors

Factors arising from the foot include an externally rotated foot during relaxed stance, rearfoot eversion at heel strike, delayed or prolonged rearfoot eversion during walking and running, and increased midfoot mobility.<sup>54</sup> The extent to how these factors are related to the development of PF joint symptoms remains unclear.<sup>313</sup>

### FOCUS ON EVIDENCE

A systematic review of 7 prospective studies<sup>151</sup> identified the female gender and low peak torque in the quadriceps muscles as risk factors for developing PFPS. There was contradictory evidence for onset timing of VMO before VL and lack of evidence supporting the magnitude of the Q-angle as risk factors. Because of limitations in the studies reviewed, no additional risk factors were identified.

## Common Impairments

**Impairments of Structure and Function.** Impairments that may be associated with PF dysfunction include the following:<sup>33,56,136,151,172,230,233-236,251,296,299,313</sup>

- Pain in the retropatellar region
- Pain along the patellar tendon or at the subpatellar fat pads
- Patellar crepitus; swelling or locking of the knee
- Altered lower extremity alignment (Fig. 21.9), specifically increased hip adduction and internal rotation and dynamic knee valgus that occurs during weight-bearing activities, such as ascending and descending stairs, squatting, or landing after a jump<sup>125,177,233,234,236,247,278</sup>
- Weakness of the hip abductor, external rotator, and/or extensor muscles<sup>25,125,177,230,233,234,247,278</sup>
- Weakness, and atrophy in the quadriceps muscles<sup>93,94,151</sup>
- Decreased flexibility of the tensor fasciae latae, hamstrings, quadriceps, or gastrocnemius and soleus muscles<sup>230,233,237</sup>
- Overstretched medial retinaculum
- Restricted lateral retinaculum, IT band, or fascial structures around the patella
- Decreased medial gliding or medial tipping of the patella
- Pronated foot

### FOCUS ON EVIDENCE

There are a substantial number of studies that have reported altered lower extremity kinematics and/or hip musculature strength and activation deficits in individuals with PF pain versus those without.<sup>25,125,177,230,233-236,247,278</sup> Overall, the findings of most of these studies have revealed greater hip adduction and/or internal rotation during weight-bearing activities that involve knee flexion, such as squatting, ascending or descending stairs, or landing from a jump, in individuals with PF pain. Decreased strength of hip extensors, external rotators, and/or

**FIGURE 21.9** Excessive hip adduction and internal rotation with valgus collapse at the knee during descent from a step.

abductors, typically measured during a maximum voluntary isometric contraction, has also been identified in those with PF pain.

McKenzie and colleagues<sup>177</sup> reported diminished strength of hip extensors, abductors, and external rotators, as well as excessive hip adduction and internal rotation during stair descent and ascent in subjects with PFPS. Souza and colleagues<sup>278</sup> reported that females with PFPS had significantly decreased strength of the hip extensors and abductors with increased hip internal rotation during step-down movements, a drop-jump, and running, but no increase in hip adduction. In contrast, Bolgla and colleagues<sup>25</sup> identified weakness of the hip abductors and external rotators but no evidence of abnormal hip kinematics during stair descent in females with PFPS. The inconsistent findings may be attributed to a number of factors including differences in weight-bearing tasks and measurement techniques.

Although these studies suggest that an interdependence exists between the knee and more proximal regions of the body, specifically the hip, pelvis, and trunk, it is also important to recognize that the retrospective nature of these studies demonstrate

associations—not cause-and-effect relationships—among altered hip mechanics, deficits in hip muscle performance, and signs and symptoms of PF dysfunction.<sup>113,233,236</sup>

**Activity limitations and participation restrictions.** Limitations and restrictions associated with the impairments include the following:

- Limited performance of basic ADLs as the result of pain or poor knee control (valgus collapse)
- Pain-related limitations of functional activities that are necessary to carry out ADLs and IADLs; work; and community, recreational, or sport activities, such as getting in or out of a chair or car, ascending and descending stairs, walking, jumping, or running.
- Inability to maintain prolonged flexed knee postures, such as sitting or squatting, as the result of pain and stiffness in the knee

### Patellofemoral Symptoms: Management—Protection Phase

When symptoms are acute, treat them as any acute joint problem—with modalities, rest, gentle motion, and muscle-setting exercises in pain-free positions. Quadriceps inhibition is common with pain and joint effusion,<sup>286</sup> making it imperative to minimize these impairments in this management phase. Supporting the patella with a brace or tape may unload the joint and relieve the irritating stress. Foot orthoses may relieve pain and stress in patients with identified foot impairments.<sup>235</sup>

### Patellofemoral Symptoms: Management—Controlled Motion and Return to Function Phases

When signs of acute pain and inflammation are no longer present, management is directed toward correcting or modifying the biomechanical or alignment factors that may be contributing to the impairment. Because no one factor or combination of factors has been identified as the direct cause or effect of PF pain symptoms, it is imperative to develop interventions that address the scope of impairments identified during the examination.<sup>234</sup> It is also important to integrate the concept of regional interdependence in the application of exercise interventions by addressing the local, distal, and proximal factors that may place excessive stress through the PF joint.<sup>113,233</sup>

Management during the controlled motion and return to function phases of rehabilitation typically emphasizes increasing strength, dynamic control, and pain-free mobility of the knee and hip, and foot; modifying abnormal movement strategies that may contribute to impairments; improving stability of the lower extremity, pelvis and trunk; and on improving balance, and functional abilities.

### Patient Education

**Instructions.** Because end-range stress and prolonged postures tend to exacerbate symptoms, instruct the patient to avoid positions and activities that provoke the symptoms.

- Minimize or avoid stair climbing and descending until the hip and knee muscles are strengthened to a level at which they can control knee function without symptoms.
- Avoid sitting with the knees flexed for prolonged periods because increased knee flexion magnifies PF joint compressive forces. Periodically perform ROM of the knee while sitting to relieve stasis.

**Home exercise program.** Implement a home exercise program to reinforce the supervised training. Prior to discharge, provide instructions for a safe progression of exercises and functional activities.

### Increase Flexibility of Restricting Tissues

Identify all structures that may contribute to faulty mechanics and establish a stretching program to increase mobility. The gastrocnemius, soleus, quadriceps, hamstring, and tensor fasciae latae (TFL) muscles have been identified as specific muscles with reduced flexibility in some individuals with patellofemoral dysfunction.<sup>230,233,296</sup> Self-stretching techniques are described in the exercise section of this chapter. Techniques to stretch the two-joint muscles that cross the hip and knee are described in Chapter 20, and those that cross the knee and ankle are described in Chapter 22.

Because restrictions related to insertion of the IT band and the lateral retinaculum may contribute to decreased patellar mobility and faulty patellar tracking in some patients with PFPS, specific techniques to address these impairments are described in this section.

**Patellar mobilization: medial glide.** Position the patient side-lying. Stabilize the femoral condyles with one hand under the femur, and glide the patella medially with the base of the other hand (Fig. 21.10).<sup>99</sup> There is usually greater mobility with the knee near extension; progress by positioning the knee in greater flexion prior to performing the medial glide.

FIGURE 21.10 Medial glide of the patella.

**Medial tipping of the patella.** Position the patient supine. Place the thenar eminence at the base of the hand over the medial aspect of the patella. Apply a posterior force to tip the patella medially. While the patella is held in this position, apply friction massage with the other hand along the lateral border (Fig. 21.11). Teach the patient to self-stretch in this manner.

**FIGURE 21.11** Medial tipping of the patella with friction massage along the lateral border.

**Patellar taping.** Although taping to realign the patella and provide a prolonged stretch may have merit,<sup>99,172</sup> the primary benefit of taping appears to be reduced anterior knee pain during provoking activities after being taped.<sup>23,49</sup> The mechanism behind pain relief from tape is not known but may be due to patellar realignment or improved neuromuscular function.

### **FOCUS ON EVIDENCE**

A multicenter, single-blind study demonstrated little to no change in patellar alignment from the application of three different patellar taping techniques. Decreased symptoms occurred in 71 subjects with PFPS, regardless of the direction in which the tape was applied.<sup>310</sup> The investigators suggested that taping may alter proprioceptive input and increase tolerance to functional training and recommended its use while focusing treatment on proximal muscle weakness.

### **Improve Muscle Performance and Neuromuscular Control**

Because many possible diagnoses fall under the category of PFPS, various influences may precipitate or perpetuate the symptoms. Importantly, not all patients with PF symptoms benefit from the same exercises, making it imperative that the therapist design a progression of exercises that addresses each patient's specific impairments. In addition, it is now well accepted that exercise programs for patients with PFPS should target proximal regions, specifically the hip extensors and abductors in order to affect alignment and control of the knee.<sup>84,168,200,296</sup> Impaired strength, endurance, and neuromotor control of the knee and hip musculature, as well as impaired stability of the trunk and pelvis, must be addressed.<sup>233-236</sup>

In addition to the knee exercises described later in this chapter, exercises to improve muscle performance and functional

control in regions proximal and distal to the knee are described in Chapters 16, 20, and 22, respectively. Advanced functional exercises for the lower extremity are described in Chapter 23.

### **Nonweight-Bearing (Open-Chain) Exercises**

There is controversy regarding compressive forces and stress on the PF joint with open-chain exercises.<sup>67,98</sup> The type of resistance (constant, variable, or isokinetic) places different demands on the quadriceps muscle in terms of the required effort through the ROM. The resultant force from the quadriceps and patellar tendon vary through the ROM, as does the patellar contact area, which subsequently varies the pressure and stress on the PF articulating surfaces. With little or no contact of the patella with the trochlear groove from 0° to 15° of flexion,<sup>67</sup> pain felt in that range could derive from irritation of the patellar fat pads or synovial tissue. Greatest patellar stress is at 60° and compression loads at 75°, so when maximum torque from the resistance force is applied in these ranges, pain may be provoked.<sup>67</sup> The location of the joint pathology also affects where in the range the pain is noted.<sup>98</sup> It is recommended to identify where in the ROM pain is felt and avoid resistance loads in that range.

**Quadriceps setting (quad sets) in pain-free positions.** Have the patient set the quads with the knee in various positions. Because the location of irritation in the ROM varies among patients with PF dysfunction, identify pain-free positions to ensure nondestructive loading.<sup>67,98</sup>

**Quad sets with straight-leg raise.** Have the patient perform SLR exercises in supine or long-sitting positions to target quadriceps control.

**Progression of resisted isometrics.** Initiate multiple-angle isometrics against resistance to knee extension in pain-free positions as tolerated by the patient.

**Short-arc terminal extension.** Begin with the patient supine and knee flexed around 20° (see Fig. 21.23). If tolerated and the motion is not painful, apply light resistance at the ankle. Strengthening in terminal extension trains the muscle to function where it is least efficient because of its shortened position and where there is minimal joint compression because the patella is superior to the femoral groove. End-range knee extension is needed for activities such as lifting the leg into bed or a car.

**PRECAUTION:** If there is irritation of the suprapatellar pouch or bursa, terminal knee extension may be painful and should be avoided until the pain subsides.

### **Weight-Bearing (Closed-Chain) Exercises**

A progression of closed-chain/axial-loading exercises, typically performed in weight-bearing positions, should be a major component of an exercise program for PFPS to reduce PF symptoms; increase muscle performance and dynamic control of knee, hip, and trunk; and to improve neuromuscular control/response time and balance.<sup>12,26,115,168,200,296</sup> When excessive knee valgus occurs during weight-bearing

activities involving dynamic knee flexion (e.g., squats, lunges, stair ascent or descent, or landing from a jump), it may indicate hip abductor, extensor, and/or external rotator weakness. Strengthening these muscle groups in weight-bearing positions and practicing movement strategies in proper alignment should be a priority.<sup>115,168,233,234,296</sup>

**PRECAUTION:** Because there are higher patellar compressive loads when the knee is flexed beyond 60° during weight bearing, exercises and activities with the knee flexed beyond this angle may provoke symptoms. Use caution when the patient is ready to progress beyond 60°. Have the patient carefully monitor symptoms and stop the exercise if symptoms develop.

- If full weight bearing is painful, begin with partial weight-bearing exercises. Progress exercises in standing as tolerated.
- To improve strength and muscular endurance, have the patient perform multiple repetitions of appropriate exercises until PF symptoms or loss of control just begins to occur. Do not push beyond that point in order to avoid faulty mechanics or loss of control.
- Initiate terminal knee extension against light resistance in standing for end-range knee control (see Fig. 21.26).
- Introduce bilateral minisquats and progress to unilateral early in the exercise program when weight bearing and partial squatting are tolerated and do not provoke symptoms (see Fig. 21.27). Be sure that the knees remain aligned over the toes during squatting.
- Progress dynamic exercises by adding double-leg, then single-leg standing wall slides, short-step, then long-step lunges, and forward, backward, and lateral step-ups and step-downs to the exercise program. Add elastic resistance for further challenge.
- Select resistance equipment for progressive strengthening and muscular endurance training that incorporates weight bearing, such as the seated leg press, the Total Gym® unit, and the stepping machine.
- Combine balance and agility training with strengthening exercises in weight-bearing positions.
- Include plyometric training for individuals wishing to return to high-demand activities if symptoms do not recur (see Chapter 23).

### Functional Activities

Practice simulated functional activities and activity-specific drills without provoking symptoms to prepare the patient to return to the desired activities (see Chapter 23). If abnormal lower extremity alignment occurs during weight-bearing activities despite improvements in muscle strength and endurance, integrate movement reeducation into activity-specific drills to reinforce proper movement strategies.

### Modify Biomechanical Stresses

Assess lower extremity mechanics, and modify any faulty alignment. If the patient exhibits excessive foot pronation, a medial wedge foot orthosis may reduce the stresses at the knee and decrease PF pain.<sup>65,102</sup>

### Outcomes

Several systematic reviews of the literature focusing on quality randomized, controlled studies for PFPS have revealed that interventions most effective for reducing pain and improving function were quadriceps strengthening, acupuncture, and combinations of interventions that include quadriceps strengthening with patellar taping and use of biofeedback.<sup>14,23,49</sup> The effectiveness of a patellar brace was neither refuted nor supported, nor was the use of manual therapy techniques, such as stretching and manipulation. One systematic review looking specifically at the effect of exercise for PFPS concluded that exercise therapy is important to relieve pain and improve measures of patient reported activity limitations and participation restrictions.<sup>46</sup>

No particular exercise approach has been found to be superior to another for reducing symptoms and improving function. A recent systematic review of studies that utilized therapist-guided quadriceps muscle-strengthening exercises provided strong evidence that there was no difference in effectiveness based on the type of exercises used.<sup>145</sup>

There is a substantial body of evidence indicating that decreased strength and flexibility of regions proximal to the knee are associated with PFPS, and randomized controlled studies are now documenting the effectiveness of treatment programs that target the hip, pelvis, and trunk. A systematic review and meta-analysis of studies on the effectiveness of exercise programs that emphasize proximal musculature concluded that there is strong evidence supporting proximal rehabilitation, with or without quadriceps rehabilitation, utilizing both open- and closed-kinetic-chain exercises for pain reduction and improved function in subjects with PFPS.<sup>149</sup>

Fukuda<sup>84</sup> conducted a randomized, controlled study of 70 sedentary females with anterior knee pain: 22 received knee exercises that emphasized stretching and strengthening the knee musculature, 23 received the same program with the addition of hip strengthening and stretching, and 25 served as controls. After intervention (3 times a week for 4 weeks) both exercise groups showed significant improvement in function and reduced pain compared to the controls. The group that performed the combined hip and knee exercise program showed greater improvement than the knee exercise group in all measures, although only pain reduction during stair descent reached statistical significance. Using only hip-strengthening exercises for 8 weeks,<sup>139</sup> Khayambashi et al documented improved pain and health status in females compared to those not receiving exercises; the improvement was maintained at a 6-month follow-up for those in the exercise group.

Dolak et al<sup>61</sup> conducted a randomized controlled study of 33 females with PFPS who either received hip strengthening or quadriceps strengthening for 4 weeks; both groups then received the same functional weight-bearing exercises for an additional 4 weeks. After the initial 4 weeks, those in the hip strengthening group had significant decrease in pain compared with the quad strengthening group. By emphasizing hip strength and not stressing the patella with quadriceps exercises during the initial 4 weeks, the authors suggest the PF

pain was allowed time to heal while preparing the hip for the functional exercise phase of the program. Both groups improved function (measured by the lateral step-down test) and decreased pain by 8 weeks.<sup>61</sup>

Baldon et al<sup>12</sup> measured multiple parameters, including pain, function, kinematics, trunk endurance, and eccentric hip and knee muscle strength, in a randomized study of 31 recreational female athletes. The experimental group received exercises that emphasized hip muscle strengthening, limb and trunk movement control, and functional stabilization training; the control group received stretching and traditional exercises emphasizing quadriceps strengthening. Measurements were collected after 8 weeks of interventions with a follow up at 3 months. Both groups had decreased pain at 8 weeks; those in the experimental group demonstrated greater improvement and function, including improved trunk and extremity alignment during a single-leg squat at 8 weeks and less pain at 3 months.<sup>12</sup>

## Patellar Instability: Surgical and Postoperative Management

Following conservative management of a primary (first-time) patellar dislocation, the of dislocation recurrence rate is between 15% to 44% and as high as 50% after subsequent episodes.<sup>47</sup> When nonoperative interventions fail to control instability and related symptoms such as recurrent dislocation or chronic subluxation, pain, crepitus, or PF joint degeneration, surgery is usually indicated.

Surgical interventions can be used to alter patellar alignment, correct tension imbalances of the static stabilizers (see Fig. 21.4), modify the Q-angle (see Fig. 21.3 for depiction of Q-angle measurement), improve patellar tracking, and débride or repair PF joint articular surfaces. The correct surgical procedure is selected following a thorough physical examination coupled with radiographic and arthroscopic evaluations to determine the etiology of symptoms and identify the factors contributing to patellar instability.

### Overview of Surgical Options

Surgical options for lateral patellar instability are noted in Box 21.5.<sup>40,45,47,85,86,88,89,119,183,184,199,221,232,241</sup> Numerous variations of operative procedures fall under each of these options. Procedures may be arthroscopic, open, or a combination of these approaches.

When soft tissue factors contribute to lateral patellar instability, a proximal realignment procedure, such as MPFL repair or reconstruction or VMO imbrication, is often selected. When an osseous factor is the underlying cause, a distal realignment procedure that involves a tibial tubercle osteotomy with patellar tendon transfer is performed. Repair of chondral lesions associated with acute or recurrent patellar dislocation or trauma may also be necessary.<sup>184</sup> In contrast, TKA or patellectomy

### BOX 21.5 Surgical Options for Management of Lateral Patellar Instability and Associated Structural Impairments

#### Soft Tissue and Osseous Procedures for Patellar Instability

- Medial patellofemoral ligament repair or reconstruction with autograft or allograft
- Medial retinacular imbrication (advancement)
- Lateral retinacular release, including release of the lateral patellofemoral and patellotibial ligaments
- Imbrication and medialization of the VMO
- Distal realignment of the extensor mechanism (anteromedialization of the tibial tubercle and insertion of the patellar tendon)
- Trochleoplasty (to improve the size/shape of the trochlear groove) for trochlear dysplasia

#### Articular Cartilage Procedures

- Arthroscopic débridement
- Repair of patellofemoral articular cartilage lesions (microfracture, osteochondral autograft transfer/mosaicplasty, autologous chondrocyte implantation)
- Abrasion arthroplasty/chondroplasty of the posterior surface of the patella (used less frequently with the advent of surgeries to repair articular cartilage)

#### Procedures for End-Stage Patellofemoral Arthritis

- TKA or replacement arthroplasty of the posterior surface of the patella
- Patellectomy (salvage procedure)

(a salvage procedure) is performed only for end-stage PF arthritis and collapse of the joint space.<sup>86,184,221</sup>

The two broad categories of surgery for patellofemoral instability—proximal and distal realignment of the extensor mechanism—may be performed with or without a lateral retinacular release (LRR). As an independent procedure, LRR can alleviate or reduce patellofemoral pain if the cause of the pain is compression of lateral knee structures (lateral compression syndrome) related to excessive lateral tilt of the patella, but it is not recommended for management of lateral patellar instability.<sup>47,78,86,184,232</sup>

### FOCUS ON EVIDENCE

Several current literature reviews<sup>45,47,241</sup> report that the use of LRR *in isolation* for recurrent or acute lateral patellar instability yields poor long-term outcomes (high recurrence rates for dislocation). According to another review,<sup>86</sup> LRR failed to realign the patella more medially. All reviews concluded that LRR in isolation is not effective for treatment of lateral patellar instability.

Operative procedures other than proximal or distal realignment are also used for recurrent patellar instability. Trochleoplasty, which involves deepening of the trochlear sulcus, may be indicated if trochlear dysplasia is contributing to patellar instability.<sup>47</sup> When excessive rotational deformity of the lower extremity is the underlying cause of severe patellar malalignment and recurrent instability, a supratubercle, derotational, high tibial osteotomy may be indicated as an alternative to proximal or distal realignment procedures.<sup>224</sup>

Following proximal or distal extensor mechanism realignment, a number of factors influence the rate of progression of rehabilitation. Factors include the type of surgical procedure performed; the patient's age, general health, and severity of patellofemoral symptoms prior to surgery; the presence of other pathologies; the desired functional outcomes; and the patient's adherence to the prescribed home exercise program and motivation to return to functional activities.

## Proximal Extensor Mechanism Realignment: Medial Patellofemoral Ligament Repair or Reconstruction and Related Procedures

Repair, realignment, or reconstruction of the static and dynamic medial patellar support structures are surgical options for the patient with recurrent lateral patellar instability causing pain and compromised function.<sup>4,40,47,201</sup> MPFL repair or reconstruction, with or without LRR, is the primary surgical option when conservative management is unsuccessful. MPFL repair or reconstruction may also be indicated following an acute, first-time lateral patellar dislocation as the result of trauma. Other proximal realignment procedures include VMO imbrication (advancement) and medial retinacular reefing/tightening. These soft tissue procedures are appropriate for the skeletally immature patient with patellar instability and may be used in conjunction with a distal realignment involving an osteotomy in the skeletally mature patient.<sup>86,119</sup>

### Indications for Surgery

Although opinions vary among surgeons, the following are cited as indications for MPFL repair or reconstruction and other proximal realignment procedures with or without LRR.<sup>4,40,47,86,88,119,199,201,221,232</sup>

- Deficiency (acute tear, chronic laxity) of the medial patellar support structures, in particular the MPFL, leading to patellar malalignment and recurrent instability
- Excessive (or abnormal) lateral patellar tracking and VMO insufficiency
- Painful, lateral compressive forces at the PF joint and persistent lateral patellar tilt despite a previous LRR
- The skeletally immature patient with patellar instability for the purpose of realignment.<sup>119</sup>

**CONTRAINDICATIONS:** Proximal realignment procedures are not appropriate for patients with medial patella articular

degeneration, patella alta, or trochlear dysplasia because surgery may exacerbate or have no impact on symptoms.<sup>86,119</sup>

## Procedures

### Background and Operative Overview

Proximal realignment procedures combine an open surgical approach through a medial parapatellar incision with an arthroscopic examination of the knee; LRR; débridement of any loose osteochondral fragments or partial-thickness lesions; and, if necessary, microfracture for full-thickness chondral lesions.<sup>184</sup>

**MPFL repair or tightening.** An acute lateral patellar dislocation usually results in disruption of the MPFL and is managed with a direct repair.<sup>40,119</sup> Repair is also an option if the ligament is lax as the result of recurrent dislocations. To expose the MPFL, the medial retinaculum must be opened. Depending on the location of the tear(s), the ligament is reattached to the femoral condyle, the patella, or both bony surfaces using suture anchors. If the midsubstance of the ligament is disrupted, fragments are repaired with nonabsorbable locking sutures in a pants-over-vest fashion.

**MPFL reconstruction.** This procedure is used if the MPFL is incompetent as the result of recurrent lateral dislocation or subluxation or if a previous repair or reefing of the ligament has failed. Reconstruction involves reinforcement of the MPFL with an autogenous hamstring, TFL, or quadriceps tendon graft or allograft.<sup>4,62,201</sup> Depending on the type of reconstruction and graft selected, the patellar and femoral ends of the graft are secured in drill holes with sutures, suture anchors, or screw fixation. Some procedures do not use drill holes which eliminates the risk of patellar fracture.

**VMO imbrication (advancement).** This procedure improves the resting length-tension relationship of the VMO by moving the muscle to a more central and distal location.<sup>86,199,221,232</sup>

**Lateral retinacular release and other concomitant procedures.** If a lateral patellar tilt is identified, LRR is indicated to reduce the tilt and restore patellar alignment in the trochlea.<sup>45,86,232,241</sup> LRR is performed arthroscopically through several lateral parapatellar portals by “releasing” the lateral structures supporting the patellofemoral joint. Specifically, the superficial and deep portions of the lateral retinaculum and the lateral patellofemoral and patellotibial ligaments are released with an incision that extends from the superior lateral pole of the patella to just lateral and inferior to the patellar tendon.<sup>184</sup> The location of the incision is such that the superior lateral and inferior lateral geniculate arteries are cut and must be cauterized immediately and tied. The release leaves the tendinous portion of the VL muscle intact so as not to compromise quadriceps function. Electrocautery<sup>199</sup> and, most recently, radiofrequency ablation<sup>89</sup> are alternatives to surgically incising the retinaculum. The advantages of these methods for releasing the lateral structures are less bleeding and subsequent hemarthrosis.

In addition to repair or reconstruction of the MPFL, the medial patellotibial and medial patellomeniscal ligaments may be tightened or repaired.<sup>86,88</sup> A bony distal realignment procedure may also be combined with a medial soft tissue repair or reconstruction.<sup>86,88,199</sup>

### Complications

Postoperative complications that can occur with any of the patellofemoral surgeries include a superficial infection, an intra-articular infection, or a DVT. Patellar adhesions and arthrofibrosis can compromise postoperative ROM. In rare instances, complex regional pain syndrome can develop (see Chapter 13).<sup>48</sup>

**Complications following proximal realignment.** Several complications can increase medial articular surface loading and exacerbate pain, including “overtensioning” the native MPFL or graft tissue during repair or reconstruction, overtightening other medial soft tissues, inaccurate graft placement, and/or excessive imbrication of the VMO.<sup>4,40,47</sup> Significant scarring or overtightening of medial tissues may also cause increased patellar rotation and excessive medial tracking leading to retropatellar erosion and/or increased risk of *medial* instability of the patella.<sup>40,86</sup> In contrast, inadequate medial tightening or VMO realignment may result in no change in patellar position and

tracking, or in the patient’s symptoms. Although the risk of patellar fracture is low, it is a complication that can occur during MPFL reconstruction procedures that require patellar drill holes for graft placement and fixation.<sup>47</sup>

Entrapment, irritation, or a neuroma of the saphenous nerve as it passes the adductor tubercle and splits at the pes anserine tendon can also occur with any procedure involving structures on the medial side of the knee.<sup>86</sup>

**Complications following LRR.** Because of the location of the geniculate artery, hemarthrosis can occur if it is not adequately cauterized during surgery. Thermal injury to overlying skin can occur with radiofrequency ablation or electrocautery.<sup>89</sup> Another complication, postoperative medial patellar subluxation, can develop if the lateral release extends too far proximally and causes weakness of the VL muscle. In rare instances, rupture of the quadriceps tendon occurs following VMO advancement.

### Postoperative Management

Postoperative rehabilitation after MPFL repair or reconstruction or other proximal realignment procedures follows a course summarized in Table 21.3.<sup>4,40,88,164,201</sup> The patient is progressed through each phase of rehabilitation based on signs and symptoms and the attainment of phase-specific goals.<sup>209</sup>

**TABLE 21.3** MPFL Repair or Reconstruction: Intervention for Each Phase of Postoperative Rehabilitation

Phase and General Time Frame	Maximum Protection Phase: Weeks 1–4	Moderate Protection Phase: Weeks 4–8	Minimum Protection Phase: Weeks 8–12 and Beyond
<b>Patient presentation</b>	<ul style="list-style-type: none"> <li>■ Rehab begins within 1–2 days after surgery</li> <li>■ Postoperative pain</li> <li>■ ROM limited</li> <li>■ Weight bearing as tolerated in locked extension orthosis</li> </ul>	<ul style="list-style-type: none"> <li>■ Minimum pain</li> <li>■ Joint effusion controlled</li> <li>■ Full weight bearing with orthosis locked until full, active knee extension achieved</li> <li>■ Functional ROM of knee</li> <li>■ Able to perform SLR (no extensor lag) by 6 weeks</li> </ul>	<ul style="list-style-type: none"> <li>■ No pain, swelling, or tenderness</li> <li>■ No signs or symptoms of patellar subluxation, during the previous phase</li> <li>■ Muscle function: at least 75% (4/5 MMT) of noninvolved extremity</li> <li>■ Unrestricted ADL and IADL</li> </ul>

### Immobilization and Weight-Bearing Considerations

A compression dressing is applied following surgery, and the knee is immobilized in a range-limiting, hinged orthosis locked in extension or in a posterior orthosis to prevent excessive knee flexion and protect the soft tissues. Some surgeons allow early ROM in a protected range within a few days after surgery,<sup>4,40,164,201</sup> whereas others advocate continuous immobilization for a week postoperatively.<sup>119,232</sup> Depending on the surgeon's preference, protected ROM is performed

with the patient wearing the range-limiting orthosis or with it removed for therapy.

During ambulation with crutches in the early postoperative period, the knee orthosis is locked in extension. Weight-bearing status on the operated extremity ranges from 25% of body weight to weight bearing as tolerated. Full weight bearing with the immobilizer locked is permitted by about 4 weeks after surgery.<sup>201</sup> Full weight bearing with the orthosis unlocked and without an assistive device is permitted only when

the patient can control the knee and has achieved full, pain-free passive and active knee extension (no evidence of an extensor lag/quadriceps lag).<sup>164,232</sup>

### Exercise Progression

Exercise goals following proximal realignment are directed toward restoring and improving the function of the entire lower extremity and trunk, not just the knee.<sup>78,164,168,234</sup> As with non-operative management of patellofemoral dysfunction, many of the rehabilitation exercises focus on regaining pain-free knee ROM, maintaining patellar mobility, and recruiting the quadriceps mechanism as a unit and the VMO in particular. These interventions are designed to prevent or remediate patellar motion restrictions and an extensor lag.<sup>56,135,164,281,289</sup> A more recent but equally important postoperative focus is mediating strength deficits in the trunk; pelvis; and hip abductor, external rotator, and extensor muscles and improving flexibility of the hip and ankle musculature.<sup>125,168,230,233,234</sup>

Exercise goals, a progression of exercise interventions, and criteria to progress from one phase of rehabilitation to the next after proximal realignment procedures are summarized in the following sections.<sup>88,164,201</sup> Exercise precautions after proximal and distal extensor realignment procedures are noted in Box 21.6.<sup>119,164,201</sup>

### Exercise: Maximum Protection Phase

**Goals and interventions.** During the first 4 weeks after surgery, the repaired or reconstructed medial patellar tissues are in the acute and subacute stages of healing and vulnerable to excessive stresses. The goals and interventions during this period are directed toward achieving independent ambulation with crutches; controlling pain and swelling; preventing complications, such as a DVT or adhesions; regaining quadriceps control; and restoring ROM of the knee while protecting the reconstructed soft tissues (see Table 21.4).

- **Achieve independent ambulation.** Gait training with crutches for protected weight bearing and knee orthosis locked in extension
- **Control pain and swelling.** Apply cold and compression regularly throughout the day.
- **Patient education.** Review weight-bearing and exercise precautions with the patient to protect the repaired ligament or graft tissue while it is most vulnerable to excessive stresses (see Box 21.6). Establish and teach a home exercise program.
- **Restore ROM.** Perform knee flexion/extension exercises (PROM, A-AROM, and AROM) within a day or two after surgery. Follow the surgeon's preference regarding removing the orthosis for ROM. Depending on the type of repair or reconstruction performed, the goal is to attain full passive and active knee extension and *at least* 90° flexion by the end of week 4.<sup>88,164,201</sup> Stretch hip and ankle musculature, if restricted.
- **Maintain patellar mobility.** Apply gentle (grades I and II) patellar mobilization (superior and inferior) to reduce pain and prevent tissue adhesions.
- **Reestablish neuromuscular control and improve muscle performance.** Begin gentle quadriceps setting for knee

### BOX 21.6 Exercise Precautions After Proximal or Distal Realignment of the Extensor Mechanism

- Initiate PROM or A-AROM, AROM exercises in a hinged, range-limiting orthosis to prevent excessive knee flexion or a valgus stress to the knee.
- Progress knee flexion gradually so as not to disrupt sutures after MPFL repair or reconstruction, advancement of the VMO, or tibial tubercle osteotomy with medial transfer of the patellar tendon.
- When assisting with supine-lying hip and knee flexion/extension ROM, stand on the contralateral side of the operated extremity to avoid placing a valgus stress on the knee and stretching repaired medial structures.
- Perform SLR on the operated side with the orthosis locked in extension.
- Begin weight-bearing exercises, such as weight shifting, in bilateral stance with the knee orthosis locked in extension.
- Begin bilateral closed-chain exercises, such as minisquats, in the unlocked, range-limiting knee orthosis when 50% weight bearing on the operated side is permissible.
- Continue to keep the orthosis locked in extension during closed-chain exercises or ambulation in full weight bearing until quadriceps control has been established (full, active knee extension/no extensor lag).
- Postpone unilateral weight-bearing exercises that involve full weight on the operated side and without the orthosis:
  - For at least 4 to 6 weeks after soft tissue reconstruction
  - For at least 8 weeks or until radiographic healing has occurred after a distal realignment involving a tibial tubercle osteotomy
- Do not perform a maximum voluntary contraction of the quadriceps for at least 12 weeks after VMO advancement or tibial tubercle osteotomy.

control augmented with pain-free neuromuscular electrical muscle stimulation or biofeedback. While wearing the orthosis locked in extension, initiate SLRs in supine, prone, and side-lying positions for hip control. With the orthosis unlocked, begin partial-range heel-slides in the supine position and bilateral minisquats and heel raises when 50% pain-free weight bearing on the operated side is allowed.

**Criteria to progress.** Criteria to progress to the intermediate phase of rehabilitation include:<sup>164,201</sup>

- Minimal pain and swelling
- Incision healing well; no signs of infection
- Full, active knee extension (no evidence of extensor lag) and at least 90° of knee flexion

### Exercise: Moderate Protection/Controlled Motion Phase

**Goals and interventions.** During the intermediate phase of rehabilitation, from approximately 4 to 8 weeks postoperatively,

soft tissues are in the repair and remodeling stage of healing. Full weight bearing without an assistive device but with the orthosis locked is usually permitted by 4 to 6 weeks after surgery. The patient should be able to achieve functional knee ROM by the end of this phase of rehabilitation.

As symptoms subside and quadriceps activation improves, the focus of this phase is to establish a normal gait pattern with the orthosis unlocked, increase knee ROM, and restore hip and ankle flexibility and function. It is also important to develop strength and endurance of the hip and trunk muscles, improve neuromuscular control/response times, ensure sufficient balance and proprioception, regain cardiopulmonary endurance, and progress and reinforce the home exercise program.

- **Normalize the gait pattern.** If full weight bearing is pain free and quadriceps control is sufficient, practice walking with crutches or a cane with the orthosis unlocked.
- **Restore ROM and joint mobility.** Begin low-intensity, prolonged stretching and grade III joint mobilization to increase ROM of restricted areas. Achieve 0° to 120° knee ROM by the end of week 6 and 0° to 135° by the end of week 8.<sup>4,88,164</sup> Stretch all tight lower extremity musculature, specifically the gastrocnemius, soleus, hamstring muscles, and IT band, because they have been shown to be tight in patients with PF dysfunction.<sup>230</sup>
- **Improve muscle performance.** Progress pain-free, closed-chain, and open-chain resistance training to increase strength and muscular endurance of the entire lower extremity. Emphasize knee extensor and hip extensor, abductor, and external rotator strengthening exercises. (Suggestions for a progression of nonweight-bearing and weight-bearing exercises are noted in the previous section on nonoperative management and described in the final section of this chapter and Chapter 20.)

**PRECAUTION:** The patient must only perform resisted exercises in pain-free ranges and in positions consistent with weight-bearing precautions. During weight-bearing exercises, reinforce proper lower extremity alignment to avoid knee valgus during flexion.

- **Improve neuromuscular control and response time, proprioception, and balance.** While wearing the orthosis locked in extension, begin neuromuscular/proprioceptive training and stabilization and balance activities on a stable surface and progress to unstable surfaces. Emphasize maintaining proper lower extremity alignment. Progress from bilateral to unilateral stance and by adding first uniplanar and then multiplanar movements of the nonaffected extremities or trunk. As knee control improves, unlock the orthosis during training.
- **Improve cardiopulmonary endurance.** Begin a stationary cycling program while wearing the range-limiting orthosis. Begin with a high seat and low resistance. If wound healing is adequate, pool exercise such as walking, marching, or jogging can begin.

**Criteria to progress.** The following criteria should be achieved to advance to the final phase of rehabilitation.<sup>164</sup>

- No swelling or extensor lag
- Knee ROM: 0° to 135°
- Sufficient strength of knee and hip musculature (at least 75% compared to nonoperated side) to initiate lower extremity functional activities

### Exercise: Minimum Protection/Return To Function Phase

**Goals and interventions.** During the final phase of rehabilitation, which extends from 8 to 12 weeks and beyond, the patient gradually participates in more demanding functional activities. By 12 weeks postoperatively, the patient should be able to begin land-based jogging, and by 16 to 20 weeks, they should be able to return to a full level of activity without symptoms. It may be necessary to modify or limit some activities to minimize the risk of provoking symptoms or the recurrence of instability.<sup>4</sup>

Emphasize activity-specific training, always maintaining proper lower extremity alignment. The patient's lifestyle may need to be modified temporarily to avoid symptom-provoking activities. Develop and implement a self-managed program to continue to improve and maintain strength, flexibility, and balance and devise a plan for adherence to this program.

**NOTE:** Continued use of patellar taping or a patellar tracking orthosis during exercise may be useful during the progression of exercises and transition to high-demand functional activities.

Refer to the exercise progression previously discussed for advanced nonoperative management and selected exercises described in the final sections of this chapter and Chapter 20. More advanced exercises, including plyometric training and agility drills, are described in Chapter 23.

### Outcomes

Outcomes reported after MPFL repair or reconstruction vary considerably among studies because the procedures used differ widely, with some performed in isolation and others combined with lateral release or distal realignment. For the patient with a first-time lateral dislocation, rates of subsequent patellar dislocation were similar for nonoperative management and surgical repair, suggesting there is no advantage of undergoing surgery prior to a course of nonoperative exercises.<sup>219</sup>

Camp and colleagues<sup>40</sup> carried out a retrospective review of 27 patients (29 knees) who underwent MPFL repair at an average of 19 years of age for recurrent patellar instability. The success rate for the prevention of recurrence of patellar dislocation for an average of 4 years following MPFL repair was 72% (21 of 29 knees), which the investigators considered a relatively high rate of recurrence. The patients who reported a postoperative dislocation subsequently underwent additional procedures, including MPFL reconstruction and/or distal realignment (tibial tubercle osteotomy). Recurrent instability following MPFL

reconstruction has been associated with malpositioning of the MPFL graft during surgery.<sup>27</sup>

In contrast, MPFL reconstruction procedures have resulted in high patient satisfaction and low redislocation rates. For example, in a retrospective case series, Drez and coinvestigators<sup>62</sup> reported the use of MPFL reconstruction with a soft tissue graft (and no distal realignment) in 15 patients with recurrent lateral instability after first-time patellar dislocation. At a mean follow-up of 31.5 months (minimum of 2 years), 93% of patients had excellent results (10 patients) or good results (3 patients) on an objective functional outcome and patient satisfaction scale. Only 1 of the 15 patients reported one episode of subluxation during the follow-up period.

There is general agreement that LRR performed in isolation is not an effective procedure for management of acute or chronic patellar instability.<sup>45,47,232,241</sup> The poor results can be attributed to the inability of LRR to align the patella in a more medial position.<sup>86</sup>

Poor outcomes, overall, following the many proximal realignment procedures described in the literature appear to be due more to retropatellar pain than to recurrent instability.<sup>119</sup> Patients with generalized joint hypermobility or uncorrected trochlear dysplasia tend to have a high rate of redislocation and typically require a distal realignment procedure.<sup>88</sup>

## Distal Realignment Procedures: Patellar Tendon With Tibial Tubercle Transfer and Related Procedures

For a patient with recurrent subluxation/dislocation of the patella, a distal realignment of the extensor mechanism may be the surgical intervention of choice. A medial transfer of the tibial tubercle is performed to decrease laterally directed forces on the patella by improving patellar tracking and shifting contact stresses away from chondral lesions of the distal and lateral articular surface of the patella.<sup>47,85</sup> Anterior tubercle transfers are done to increase the patellar lever arm, which decreases quadriceps forces and in turn, patellofemoral contact forces.<sup>105</sup> Combined medial and anterior transfers are used when realignment and reduced forces are both deemed necessary.<sup>105</sup> Distal realignment procedures may be used in isolation or coupled with LRR or a proximal soft tissue procedure, such as MPFL repair or reconstruction or medial capsular reefing.<sup>47,88,199</sup>

### Indications for Surgery

The following are indications for distal realignment procedures:<sup>47,85,86,184,199,221,232</sup>

- Recurrent episodes of lateral patellar instability and a sense of the knee “giving way” because of patellar malalignment due to lateralization of the tibial tubercle and patellar tendon insertion

- Painful lateral tracking of the patella with no instability
- Anterior knee pain associated with patellar maltracking and patellofemoral arthrosis (chondral or osteochondral defects) of the lateral and distal retropatellar surfaces
- Abnormally increased Q-angle
- Excessive tibial tubercle-trochlear groove distance (> 15 mm)

**CONTRAINDICATION:** Bony procedures are not recommended for the skeletally immature patient whose tibial tubercle growth plate is open. Recurvatum of the knee can develop with premature closure of this epiphyseal plate.<sup>85,119</sup>

## Procedures

### Background and Operative Overview

The purpose of distal realignment procedures is to reduce patellar instability and anterior knee pain by reducing laterally directed forces on the patella, reducing the magnitude of patellofemoral contact forces and improving patellar tracking.<sup>47,85,86,221,232</sup> Distal realignment procedures are performed using an open surgical approach. However, arthroscopic examination of the knee joint, débridement of the articular surface of the patella, and sometimes an LRR may precede the distal realignment procedure.

A number of surgical techniques for distal realignment have been reported.

**Tibial tubercle transfer (Elmslie-Trillat procedure).** An osteotomy of the tibial tubercle is performed; the bony prominence is then transferred medially and secured with screw fixation.<sup>47,85,88</sup>

**Anteriorization (elevation) of the tibial tubercle.** Often combined with a medial tibial tubercle transfer, this procedure involves displacing the tubercle anteriorly by means of a bone graft.<sup>232</sup> This serves to reduce contact forces on the patella and offloads the distal patellar articular surfaces.<sup>47,85,232</sup>

**Distal medialization of the patellar tendon.** This procedure involves only a soft tissues transfer for the skeletally immature patient.

### Complications

Uncommon but serious complications associated with distal realignment procedures include tibial fracture during placement of fixation screws, neurovascular injury during surgery, inadequate skin closure or sloughing over the osteotomy site, soft tissue infection or osteomyelitis, and nonunion of the transposed bone.<sup>85,232</sup> Redislocation can occur laterally because of undercorrection or medially with overcorrection, particularly in patients who return to high-demand activities.<sup>85,199</sup>

Pain at the anterior tibial tubercle from the fixation screws is not unusual. Therefore, screws are routinely removed 6 to 12 months after surgery.<sup>85</sup> As with all patellofemoral surgeries, patellar adhesions can occur, restricting knee motion. Because distal realignment shifts retropatellar loads medially and

proximally, excessive medialization of the tibial tubercle and patellar tendon can cause excessive contact pressure on the medial patellar facet and medial compartment, contributing to arthrosis of these areas over time.<sup>47</sup>

## Postoperative Management

### Immobilization and Weight-Bearing Considerations

Depending on the type of fixation used, rehabilitation after distal realignment involving bony procedures must progress more gradually than rehabilitation following proximal realignment of soft tissues. Ambulation with crutches while wearing a knee orthosis locked in extension is permissible the day after surgery. Weight bearing is limited to touch-down/toe-touch for the first 4 weeks or until radiographic verification of bone callus formation has occurred at the osteotomy site.<sup>85,164</sup> Weight bearing is progressed gradually, with full weight bearing permissible without the immobilizer at 8 weeks if quadriceps control is sufficient.<sup>164</sup>

### Exercise Progression

ROM also is progressed more gradually than after soft tissue procedures (refer to exercise precautions noted in Box 21.6). A range-limiting orthosis is worn that allows motion from only 0° to 30°<sup>164</sup> or 0° to 60°<sup>88</sup> of flexion during the first week; to 90° of flexion by the end of week 4; and to 135° by the end of week 8.<sup>164</sup> Closed-chain exercises are initiated in the range-limiting knee orthosis as increased weight bearing is permitted. Otherwise, exercises are similar to those for nonoperative management, LRR, and proximal realignment procedures. The return to full activity generally takes about 5 to 6 months and is based on bone healing and lower extremity strength.

### Outcomes

Patients without degeneration of the retropatellar surface or those with lateral and distal lesions tend to have better results than those with medial articular lesions or advanced PF arthritis.<sup>47,184</sup> Outcomes following medial tibial tubercle transfer were shown to be better for patients with painful lateral patellar tracking without instability than for patients with at least a 1-year history of recurrent instability.<sup>142</sup> However, because improvement occurred in both groups of patients tibial tubercle transfer appears beneficial for painful maltracking and recurrent instability.

Distal realignment procedures are often coupled with a proximal repair and/or lateral release to correct malalignment and relieve symptoms. Results of studies of combined procedures reflect good to excellent outcomes for most patients. Garth and colleagues<sup>88</sup> studied a group of young adults (mean age, 18 years) with recurrent patellar instability after an acute, traumatic, lateral dislocation of the patella. After undergoing distal realignment coupled with MPFL repair and advancement of the patellomeniscal ligament, 90% (18 of 20) of the patients reported good to excellent results in knee function and patient satisfaction and no recurrence

of instability at a minimum follow-up of 24 months. In another study<sup>199</sup> evaluating the combination of three procedures (lateral release, repair of medial supporting structures, and distal realignment), 32 of 42 knees (76%) in 37 patients had good or excellent outcomes at follow-up (mean, 44 months; range, 25 to 85 months), with only four knees experiencing redislocations.

## Ligament Injuries: Nonoperative Management

### Mechanisms of Injury

Ligament injuries occur most frequently in individuals between 20 and 40 years of age during sport participation (e.g., skiing, soccer, football) but can occur in individuals of all ages. The ACL is the most commonly injured knee ligament. Often, more than one knee ligament is damaged during a single injury episode.

### FOCUS ON EVIDENCE

Sprain and strain injuries are classified as knee instability and movement coordination impairments in the **Clinical Practice Guidelines** linked to the International Classification of Functioning, Disability, and Health.<sup>159</sup>

### Anterior Cruciate Ligament

ACL injuries can occur from both contact and noncontact mechanisms (Fig. 21.12). The most common contact mechanism is a force applied to the lateral side of the knee that results in a large valgus moment. This mechanism can injure not only the ACL, but also the MCL and the medial meniscus. Such an injury is termed the “unholy triad” or “terrible triad” injury because of the frequency with which these three structures are injured in a single trauma (Fig. 21.13).

The most common noncontact injury occurs through a rotational mechanism in which the tibia is externally rotated on the planted foot. Literature supports that this mechanism accounts for as many as 78% of all ACL injuries.<sup>208</sup> The second most common noncontact mechanism is forceful hyperextension of the knee.

With prolonged ambulation on a knee that has a deficient ACL, the secondary restraints (LCL and posterolateral joint capsule) are stressed and become lax, and a “quadriceps avoidance gait” may develop.<sup>116</sup> The quadriceps avoidance gait in ACL-deficient knees was originally documented and described by Berchuck and colleagues<sup>15</sup> as a reduction in the magnitude of the flexion moment about the knee during the limb loading phase of gait due to the patient’s effort to reduce contraction of the quadriceps.

**FIGURE 21.12** Sagittal MRI demonstrating a complete midstructure tear of the anterior cruciate ligament (outlined). (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging, ed. 4. Philadelphia: F.A. Davis, 2014, p 396, Fig. 13.48 B, with permission.*)

**FIGURE 21.14** Sagittal MRI demonstrating a rupture of the posterior cruciate ligament seen as an interruption in the cordlike structure (outlined). (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging, ed. 4. Philadelphia: F.A. Davis, 2014, p 396, Fig. 13.47 B, with permission.*)

**FIGURE 21.13** The “terrible triad,” a combination of injuries to the medial meniscus (MM), medial collateral ligament (MCL), and anterior cruciate ligament (ACL). (A) Intact ligaments stretched by valgus force. (B) Rupture of the MCL, ACL, and MM. (From McKinnis, LN: *Fundamentals of Musculoskeletal Imaging, ed. 4. Philadelphia: F.A. Davis, 2014, p 395, Fig. 13.45 A and B, with permission.*)

### Posterior Cruciate Ligament

PCL (Fig. 21.14) injuries occur most commonly from a forceful trauma to the anterior tibia while the knee is flexed, such as contact with the car dashboard in a motor vehicle accident or falling onto a flexed knee. A study by Schulz<sup>256</sup> evaluating

587 acute and chronic PCL-deficient knees reported that the three most common mechanisms of injury were a “dash-board”/anterior injury mechanism (38.5%); followed by a fall on the flexed knee with the foot in plantarflexion (24.6%); and lastly, a sudden, violent hyperflexion of the knee joint (11.9%).

### Medial Collateral Ligament

Isolated injuries to the MCL can occur from valgus moments that create high tensile loads across the medial joint line of the knee. Injuries to the MCL can be partial or incomplete and are graded utilizing a I, II, III grading classification of ligament injuries described in Chapter 10 (see Fig. 21.13).

### Lateral Collateral Ligament

Injuries to the LCL are infrequent and are usually the result of a traumatic varus moment at the knee that loads the ligament. With this mechanism, it is not uncommon for additional ligaments, the joint capsule, and sometimes the menisci to also be damaged and result in posterolateral knee instability.

## Ligament Injuries in the Female Athlete

The increased number of females participating in organized sports since the passage of Title IX in 1972 has also resulted in a concurrent increase in the number of injuries to female athletes. A significant percentage of these injuries are ACL tears, specifically from noncontact mechanisms. In fact, when injury to the ACL is sustained in a noncontact manner, a woman is three times more likely to tear the ACL than is a man.<sup>8</sup> This phenomenon has led the American Academy of Orthopaedic Surgeons to publish a consensus paper examining

the risk factors and prevention strategies of noncontact ACL injuries.<sup>100</sup> In addition, clinicians and scientists interested in ACL injury gender bias have met regularly to present research, develop consensus, and suggest future investigations on gender bias in ACL injuries.<sup>53</sup>

Risk factors identified in the consensus papers generated by these groups fall into four major categories: biomechanical, neuromuscular, structural, and hormonal, and they are summarized here.<sup>53,100</sup>

- **Biomechanical risk factors** include the effect of the total chain (trunk, hip, knee, and ankle) on ACL injuries, including awkward or improper dynamic body movements during activities such as deceleration and changes of direction. For example, increased hip adduction is related to increased knee valgus, which is associated with ACL injury risk in the female. Also, decreased hip and knee flexion angles have been demonstrated during cutting activities in the female athlete.
- **Neuromuscular risk factors** have an influence on biomechanical factors in that neuromuscular control influences joint position and movement. Valgus collapse at the knee and decreased use of the hip extensors have been reported to be more common in women who have sustained an ACL injury than in men with an ACL injury. It is suggested that this is related to increased anterior shear of the tibia and strain of the ACL during deceleration such as landing with hip-knee flexion following a jump.<sup>233</sup> Not only are females weaker in hip and knee strength compared to males (normalized to body weight), but muscle timing and activation patterns of the quadriceps, hamstrings, and gastrocnemius muscles also differ between males and females.
- **Structural risk factors** include femoral notch size, ACL size, and lower extremity alignment. The femoral notch height is smaller and notch angle larger in the male compared to the female, which may affect ACL size. The female ACL is smaller than the male ACL even when adjusted for body size. The ACL in the female has a lower modulus of elasticity (i.e., less stiff) and lower failure strength (i.e., fails at a lower load), leading to greater joint mobility than in the male.
- **Hormonal differences** between males and females may also be a factor related to the increased incidence of female ACL injuries. There are hormone receptor sites for estrogen, progesterone, and testosterone in the ACL of humans. The sex hormones have a time-dependency effect that influences ACL tissue characteristics, such as increasing risk of injury during the pre-ovulatory phase of the menstrual cycle in females.<sup>159</sup>

## Common Impairments, Activity Limitations, and Participation Restrictions

- Following trauma, the joint usually does not swell for several hours. If blood vessels are torn, swelling is usually immediate.
- If tested when the joint is not swollen, the patient feels pain when the injured ligament is stressed.

- If there is a complete tear, instability is detected when the torn ligament is tested.
- When effused, motion is restricted, the joint assumes a position of minimum stress (usually flexed 25°), and the quadriceps muscles are inhibited.<sup>279</sup>
- When acute, the knee cannot bear weight, and the person cannot ambulate without an assistive device.
- With a complete tear, there is instability, and the knee may give way during weight bearing, preventing the return to specific work, sport, and recreational activities requiring dynamic knee stability.

## Conservative Management of Ligament Injuries

Acute sprains, partial ligament tears, and sometimes complete rupture of a single knee ligament can be treated conservatively with rest, joint protection, and exercise. After the acute stage of healing, exercises should focus on ROM, balance, normalizing the gait pattern, and developing strength and endurance of muscles that support and dynamically stabilize the joint during functional activities.<sup>59,76,121</sup> The degree of instability following a ligament tear affects the demands the patient can place on the knee when returning to full activity.

A patient's preinjury activity level and the postinjury level of activity to which he or she expects to return both influence the success of a nonoperative treatment program. Relatively sedentary individuals can usually function with some loss of knee stability and can expect to return to preinjury activities following a course of nonoperative management. For select athletes who wish to return to high-demand activities following ACL injury, an intensive rehabilitation program, including balance/perturbation training to stimulate neuromuscular control and develop dynamic knee stability, can be effective.<sup>75,76</sup> In contrast, for patients with extensive ligament damage or concomitant injuries (such as meniscus damage) and poor dynamic knee stability after a period of nonoperative treatment, surgical reconstruction is typically recommended for return to high-level work or sports and preinjury level of function.

### FOCUS ON EVIDENCE

The descriptive terms “potential copers” and “potential non-coper” have been used in the literature<sup>64,76,121,190</sup> to identify and classify those individuals early after ACL injury who are good versus poor candidates for nonoperative rehabilitation. Potential copers are described as having sufficient dynamic knee stability; the ability to compensate following injury; and good potential to return to preinjury, high-level activities following a course of nonoperative treatment. In contrast, potential noncopers are thought to have poor potential to return to preinjury activities following nonoperative treatment; these individuals typically have poor dynamic knee stability and are advised to consider surgical management. A study by Moksnes and associates<sup>190</sup> evaluated both copers and noncopers after 1 year of intensive rehabilitation. For those not

undergoing surgery, 19 of the 27 noncopers (70%) showed excellent knee function and were reclassified as true copers. In the coper group, 15 of 25 (60%) were true copers. (The term “true coper” applies to individuals able to return to preinjury activity level 1 year after ACL injury with no episodes of the knee giving way during activities.)

The results suggest limited prognostic accuracy of the screening examination and therefore support the importance of including all patients with ACL injury in intensive rehabilitation, not just those who initially meet the definition of coper.

If the collateral or coronary ligaments are involved, because of their superficial location, they may benefit from cross-fiber massage to align the healing fibers and maintain their mobility. Because of the structural characteristics of the MCL (a broad, flat ligament with deep and superficial portions, parallel alignment of collagen fibers, and fan-shaped attachments proximally and distally), injuries to this ligament are typically

managed with a conservative (nonsurgical) approach.<sup>306</sup> Conservative management of knee ligament injuries is described in Table 21.4; progression is based on presenting signs and symptoms.<sup>209</sup>

### Nonoperative Management: Maximum Protection Phase

Follow the principles described for an acute joint lesion earlier in this chapter.

- If possible, examine before effusion sets in.
- Utilize cold and compression with rest and elevation.
- Teach protected weight bearing with use of crutches and partial weight bearing as tolerated.
- Teach safe transfer activities to avoid pivoting on the involved extremity.
- Initiate quadriceps-setting exercises. The knee may not fully extend for end-range muscle-setting exercises, so begin the exercises in the range most comfortable for the patient. As the swelling decreases, initiate ROM within tolerance.

**TABLE 21.4** Nonoperative Management of Knee Ligament Injuries: Intervention for Each Phase of Rehabilitation\*

### Nonoperative Management: Moderate Protection (Controlled Motion) Through Return to Activity Phases

As swelling decreases, examine the patient for impairments and functional losses. Initiate joint movement and exercises to improve muscle performance, functional status, and cardiopulmonary conditioning.<sup>64,159</sup>

#### Improve Joint Mobility and Protection

**Joint mobility.** Use supine wall slides (see Fig. 21.19), patellar mobilizations, and stationary cycling; encourage as much movement as possible. Unless there has been an extended period of immobilization, there should be minimal need to stretch contractures.

**Protective bracing.** Bracing may be necessary for weight-bearing activities to decrease stress to the healing ligament or to provide stability when ligament integrity has been compromised. Bracing can be one of two types: (1) range-limiting post-operative type braces that are used to protect healing tissues and discontinued during later phases of rehabilitation or (2) functional braces that are used during advanced rehabilitation and upon return to functional activities. The patient must be advised to modify activities until appropriate stability is obtained.

#### Improve Muscle Performance

**Strength and endurance.** Initiate isometric quadriceps and hamstring exercises, and progress to dynamic strength and

muscular endurance training. Quadriceps strength is important for knee stability.<sup>159</sup>

- Utilize both open-chain and closed-chain resistance.
  - Open-chain resistance has been shown to be more effective for increasing quadriceps strength than closed-chain single-leg squat in patients with an ACL injury.<sup>288</sup>
  - Progress closed-chain exercises using partial squats, step-ups, leg press, and heel raises.
- Reinforce quadriceps contractions with high-intensity electrical stimulation if there is an extensor lag.<sup>275</sup>

### FOCUS ON EVIDENCE

Eitzen and associates<sup>64</sup> reported results of a progressive 5-week exercise program with patients (n =100) who had a recent ACL injury (within 3 months) prior to deciding on whether or not to have reconstructive surgery. Pre- and post-tests included isokinetic quadriceps and hamstring strength, four single-leg hop tests, two self-assessment questionnaires, and a global rating of knee function. Both potential copers and noncopers without additional symptomatic injuries were included in the study. The program utilized progressive strength training (heavy resistance open and closed chain); plyometric, balance, and stability exercises; and perturbation training. A standardized response mean for each variable was calculated and demonstrated clinically relevant improvements in both

groups. Adverse events (swelling, pain, or knee giving way) occurred in only 5 subjects.

**Neuromuscular control.** Neuromuscular control is compromised when stabilizing muscles fatigue.<sup>118</sup> Emphasize neuromuscular reeducation (proprioceptive training) with stabilization, acceleration, deceleration, and perturbation training in weight-bearing positions.<sup>159</sup> Begin with low-intensity, single-plane movements and progress to high-intensity, multiplane movements. These exercises are described in Chapter 8 and summarized in the last section of this chapter.

### FOCUS ON EVIDENCE

In a randomized, controlled study, 26 athletes with an acute ACL injury or rupture of ACL grafts participated in a standard rehabilitation program or a standard rehabilitation program with perturbation training.<sup>75</sup> Of those in the perturbation group (n = 12), only one had unsuccessful rehabilitation, with the knee giving way while playing football prior to completing the program. In the control group (no perturbation training; n = 14), one-half of the subjects had unsuccessful outcomes and were considered at high risk for re-injury at the 6-month follow-up examination. The authors stated that although both groups returned to high-level physical activities, those in the perturbation-training group demonstrated greater long-term success.

### Improve Cardiopulmonary Conditioning

Utilize a program that is consistent with the patient's goals, such as biking (begin with a stationary bike), jogging (begin with walking on a treadmill), using a ski machine, or swimming.

### Progress to Functional Training

Develop activity-specific exercises and drills that replicate the demands of the individual's outcome goals.<sup>294</sup> Suggestions for functional training are described in the exercise section of this chapter and Chapter 23.

## Ligament Injuries: Surgical and Postoperative Management

### Background

Knee ligaments are the key static stabilizing structures for accessory and rotational motions of the tibiofemoral joint (see Fig. 21.2). The main accessory motions of the joint are anterior and posterior translation and medial and lateral translation, while the primary rotational motions are varus and valgus moments and long-axis rotation. Strong ligamentous support is necessary because the shallow concave tibial articulating surface

allows significant translatory motions if unrestrained. Acute traumatic disruption or chronic laxity of the ligaments results in increased accessory and/or rotational joint motions, which can impair functional abilities and accelerate joint degeneration. Although injuries to each of the four primary knee ligaments (ACL, PCL, MCL, and LCL) are discussed extensively in the literature, the ACL is, by far, the most frequently injured and surgically repaired.<sup>19,208</sup>

**General considerations and indications for ligament surgery.** Factors influencing the decision for surgical reconstruction include the specific ligament injured, the location and extent of the lesion, the degree of instability experienced by the patient, the presence of concomitant pathology such as a meniscal or articular cartilage damage, and the potential for achieving the patient's desired level of function.<sup>1,2,72,138,186,271</sup> The risk of re-injury and prevention of future impairment are also considerations because if not managed adequately, acute ligament injury can lead to chronic joint instability.<sup>19</sup> In turn, chronic instability is thought to contribute to degeneration of articular cartilage and early-onset OA.<sup>160</sup>

Surgical intervention for ligament injury is indicated when the patient has failed to achieve functional goals established in a conservative rehabilitation program or has early joint degeneration. Many authors<sup>19,33,82,186,267,271</sup> recommend surgical intervention for acute, isolated ACL and LCL injuries after a brief period of acute symptom management in recreationally active individuals. Surgical management of chronic ligament deficiency is recommended when a patient's function has become compromised or when secondary joint pathology has developed. However, there is no evidence to suggest that ACL reconstruction prevents or reduces the rate of progression of early-onset joint degeneration.<sup>160</sup>

**Types of ligament surgery.** Ligament surgeries are classified as *intra-articular*, *extra-articular*, or combined procedures and can be performed using an open, arthroscopically assisted, or all-arthroscopic approach.<sup>33,150,186</sup> Initially, intra-articular procedures were performed through an open approach and involved a direct repair of the ligament. The repair was accomplished by re-opposing and suturing the torn ligament. Postoperatively, a long period (usually 6 weeks) of immobilization and restricted weight bearing were required because of extensive tissue disruption associated with the open approach and the poor healing qualities of ligamentous tissue.<sup>150</sup> Surgical outcomes were unacceptable due to postimmobilization contractures, patellofemoral dysfunction, muscle weakness, and an unacceptably high incidence of rerupture. Consequently, direct ligament repairs were abandoned and reconstruction procedures were developed.

Intra-articular reconstruction of ligament injuries is the primary means by which ACL and PCL injuries are managed surgically. In general terms, reconstruction involves using a tissue graft to replicate the function of the damaged ligament and act as an inert restraint of the knee.<sup>20,33,150,165,186,205,271</sup> Initially, intra-articular reconstructions were performed through an open approach, and the need for lengthy postoperative immobilization

continued.<sup>150</sup> Today, intra-articular ligament reconstructions are performed through an arthroscopically assisted or all-arthroscopic approach, causing far less tissue damage and resulting in a more rapid postoperative recovery.

**NOTE:** Overviews of intra-articular ACL and PCL reconstruction procedures are described later in this chapter.

Extra-articular reconstructions involve transposing either dynamic musculotendinous or static tissue restraints to locations that provide external stability to the knee joint. Extra-articular procedures are used rarely today as primary procedures because they do not restore normal kinematics to the knee as effectively as intra-articular procedures. Extra-articular procedures used to augment intra-articular reconstructions have shown little additional benefit.<sup>150</sup>

**Grafts:** Types, healing characteristics, and fixation. The tissue used for intra-articular reconstructions is most often an *autograft* (the patient's own tissue), but is occasionally an *allograft* (donor tissue) or a *synthetic graft* (Fig. 21.15).<sup>140,182,205,267</sup> An allograft or synthetic graft is used only when a suitable autograft is not available—for example, when a patient's own tissue is not suitable for graft harvesting.<sup>150,205</sup> Autografts are preferred for intra-articular reconstruction because remodeling and incorporating both allografts and synthetic grafts after implantation may be slower than with the patient's native tissue.<sup>182</sup> (Refer to Chapter 12 and Box 12.9 for additional information about tissue grafts.)

**FIGURE 21.15** Lateral view of the knee depicting graft placement for ACL reconstruction.

Although several types of tissues are harvested for knee ligament reconstruction,<sup>140,152,165, 182,191,205</sup> the bone-patellar tendon-bone autograft has the longest history of successful and

continued use as a replacement ligament, has been the gold standard for ACL reconstruction for several decades,<sup>33,71,150,152,194</sup> and remains the most frequently selected graft for the procedure.<sup>20,72,81,140,152,165,186</sup> An alternative graft that has also become widely used for ACL reconstruction is a semitendinosus-gracilis tendon graft.<sup>71,150,152,191,263,287</sup> Research has shown that the material strength and stiffness of both of these grafts are greater than that of the native ACL.<sup>263</sup>

An extensive body of knowledge exists on graft healing, placement, and fixation, as well as the strength and stiffness of the tissues used as grafts and their responses to imposed loads. Most of this research has focused on grafts for ACL reconstruction because of the much higher incidence rates and subsequent reconstructions for this injury.<sup>20,31,81,138,152,271</sup>

### CLINICAL TIP

Because graft type and graft fixation characteristics affect rehabilitation and surgical outcomes, it is important to understand that an implanted graft undergoes a series of changes as it heals. Initially, there is a period of avascular necrosis during which the graft loses substantial strength. This period is followed by a period of revascularization, then remodeling, and finally maturation, which typically takes at least 1 year. During the first 6 to 8 weeks postoperatively, graft integrity is most vulnerable to excessive loads because the strength of the graft is derived solely from the fixation, not the graft itself.<sup>20,31,138,140</sup>

With advances in graft selection, preparation, placement, and fixation and with the evolution of arthroscopic techniques, the need for a long postoperative period of immobilization and protected weight bearing following primary ACL reconstruction has been eliminated.<sup>20,31,271</sup> Nevertheless, there is still a need to carefully limit and progress the stresses imposed on the healing graft during early rehabilitation.

**General considerations for rehabilitation.** The expected outcomes following ligament reconstruction and postoperative rehabilitation are (1) restoration of joint stability and motion, (2) pain-free and stable weight bearing, (3) sufficient postoperative strength and endurance to meet functional demands, and (4) the ability to return to preinjury activities.

Whenever possible, successful postoperative outcomes start with a *preoperative* program that includes edema control, exercise to minimize atrophy and maintain ROM, protected ambulation, and patient education.<sup>59,190,225,265</sup> Preoperative intervention is often possible because ligament reconstruction is usually delayed until acute symptoms subside. Exercises used for preoperative therapy are similar to those used for the early phase of nonoperative management of ligament injuries discussed in the previous section of this chapter. Depending on the location and extent of injury, a preoperative exercise program may be carried out for several weeks or months before a surgical decision is made.<sup>190</sup> Regardless of the duration

of the preoperative exercise program, exercises should not cause additional swelling or pain.

The progression and duration of postoperative rehabilitation programs published in the literature vary and no single program has been shown to be optimal. Throughout rehabilitation, open communication with the surgeon enables the therapist to discuss any precautions or concerns specific to the individual patient and their procedure.

Regardless of the ligament injured or specific surgical procedure, the emphasis of rehabilitation is on restoring the patient's functional abilities while protecting the healing graft and preventing postoperative complications and re-injury. Early controlled motion and weight bearing decrease the incidence of postoperative complications such as contracture, patellofemoral pain, and muscle atrophy<sup>225,265,250,308</sup> and allow patients to return to activity as quickly as possible without compromising the integrity of the reconstructed ligament.<sup>198,250</sup>

To progress patients through rehabilitation after ligament reconstruction, contemporary practice follows guidelines that are based on the attainment of specific criteria and measurable goals or performance on functional tests rather than time-based protocols.<sup>112,155,157,198,209,308</sup> For example, exercises and activities are advanced only after the patient achieves full, active knee extension or a specific benchmark on a single-leg balance test. This transition to criterion-based progression is advocated to ensure a safe return to high-level sporting activities and to prevent re-injury.<sup>198,308</sup>

### FOCUS ON EVIDENCE

*Clinical practice guidelines (CPGs)* have been published that summarize available evidence and provide recommendations to support evidence-based decision-making during rehabilitation following ligament injury and surgery.<sup>159</sup> One published CPG reports that there is moderate evidence to support immediate postoperative bracing, immediate mobilization (motion), and neuromuscular electrical stimulation for patients following ACL reconstruction and for in-clinic and home exercises for patients with knee stability impairments. The same CPG notes strong evidence for both nonweight-bearing and weight-bearing exercises for those with stability and movement coordination impairments.<sup>159</sup>

Another CPG reports moderate evidence supporting early, accelerated, and nonaccelerated postoperative rehabilitation protocols following ACL reconstruction, as all three have similar outcomes.<sup>3</sup>

## Anterior Cruciate Ligament Reconstruction

Because the healing capacity of a torn ACL is poor, surgical reconstruction is frequently recommended to restore knee stability, particularly in the young, active individual.<sup>19,138</sup> Although the incidence of re-injury of the knee is lower after

ACL reconstruction than with nonoperative management, particularly in patients younger than 25 years of age,<sup>63</sup> many individuals who have sustained an acute, primary ACL injury participate in a conservative course of treatment before choosing between surgical reconstruction or further nonoperative treatment.<sup>64,190</sup>

### Indications for Surgery

Although there are no rigid criteria for patient selection, the most frequently cited indications for ACL reconstruction include the following.<sup>19,33,165,186,190,191</sup>

- Disabling instability of the knee due caused by a complete or partial acute ACL tear or chronic ACL laxity
- Frequent episodes of the knee giving way during routine ADLs as the result of significantly impaired dynamic knee stability despite a course of nonoperative management
- A positive pivot-shift test indicating rotational instability associated with concomitant injury to other knee structures such as the MCL
- Injury of the MCL at the time of ACL injury to prevent lax healing of the MCL
- Increased risk of re-injury because of participation in high-demand work, sports, or recreational activities

**NOTE:** Increased anterior translation of the tibia on the femur compared with the contralateral, noninvolved knee, as measured by an arthrometer, is not considered a reliable indication for ACL reconstruction because a strong correlation among these measurements of stability and a patient's symptoms of instability has not been established.<sup>19</sup>

**CONTRAINDICATIONS:** Relative, not absolute, contraindications for ACL reconstruction are noted in Box 21.7.<sup>19,33,165,191</sup>

### BOX 21.7 Relative Contraindications to ACL Reconstruction

- Relatively inactive individual with little to no exposure to work, sport, and recreational activities that place high demands on the knee
- Inability to make lifestyle modifications that eliminate high-risk activities
- Inability to cope with episodes of instability
- Advanced arthritis of the knee
- Poor likelihood of complying with postoperative restrictions and adhering to a rehabilitation program

## Procedures

### Operative Overview

**Surgical approach, graft selection, and harvesting.** To reduce tissue damage and reduce recovery time, the current standard practice for most reconstruction procedures is the use of arthroscopically assisted or endoscopic techniques.<sup>19,20,71,150</sup> In

an arthroscopically assisted approach, only the intra-articular portions of the procedure, such as meniscus débridement or repair, enlargement of the intercondylar notch of the femur, or drilling the femoral and tibial bone tunnels, are performed arthroscopically.<sup>150</sup>

The most common ACL reconstruction procedure today is an arthroscopically assisted or endoscopic procedure using an autograft. If a bone-patellar tendon-bone graft is selected, it is harvested through a small, longitudinal incision over the patellar tendon from the patient's involved knee<sup>20,33,72,165,186</sup> or occasionally from the contralateral knee.<sup>267</sup> The central one-third of the patellar tendon with small bone fragments from the patella and tibial tubercle attached is harvested. These fragments serve as bone plugs for graft fixation. When a semitendinosus-gracilis tendon autograft (hamstring tendon graft) is used, it is harvested through an incision over the tibial insertion of the semitendinosus and gracilis tendons.<sup>71,191,263,268,271,280,287</sup> Hamstring tendon grafts harvested with bony attachment to allow faster ligament incorporation are becoming more common.<sup>169</sup>

Although systematic reviews indicate no significant difference in outcomes based on the use of bone-patellar tendon-bone versus hamstring tendon grafts,<sup>159</sup> there are advantages, disadvantages, and potential complications associated with each type of autograft. For example, the transition from mechanical fixation to biological fixation is thought to occur more rapidly with a patellar tendon graft, which involves bone-to-bone healing, than with a hamstring tendon graft, which requires tendon-to-bone healing (6 to 8 weeks versus 12 weeks, respectively).<sup>271</sup> Other reported advantages and disadvantages of these two types of autografts are summarized in Boxes 21.8 and 21.9.<sup>1,71,150,152,169,250,263,268,280,287</sup> Recently, the use of a bone-hamstring tendon-bone autograft for ACL reconstruction was reported, allowing bone-to-bone healing and affording some of the same advantages associated with a bone-patellar tendon-bone autograft.<sup>169</sup>

**Graft placement and fixation.** After the graft is harvested and prepared for implantation, the arthroscopic instrumentation is reinserted and femoral and tibial bone tunnels are drilled.<sup>20,82,150,165</sup> Graft placement (see Fig. 21.15) is achieved by passing the graft through the tunnels to its final position in the tibia and femur. Precise anatomical graft placement is crucial for restoration of joint stability and mobility; improper placement can lead to loss of postoperative ROM.<sup>1</sup> A graft placed too far posteriorly may result in failure to regain full flexion, and a graft placed too far anteriorly may limit extension.<sup>31</sup>

**NOTE:** Limited ROM into extension also may be caused by graft impingement due to an inadequate femoral notch size or buildup of scar tissue in the notch.<sup>1</sup> A *femoral notchplasty* (enlargement of the intercondylar notch) is often performed during the reconstruction to ensure adequate graft clearance during knee extension.

Graft fixation is vital to the success of ACL reconstruction. With a bone-patellar tendon-bone graft, both bone plugs are

### BOX 21.8 Advantages and Disadvantages/Complications of the Bone-Patellar Tendon-Bone Autograft

#### Advantages

- High tensile strength/stiffness, similar or greater than the ACL
- Secure and reliable bone-to-bone graft fixation with interference screws
- Rapid revascularization/biological fixation (6 weeks) at the bone-to-bone interface permitting safe, accelerated rehabilitation
- Ability to return to preinjury, high-demand activities safely

#### Disadvantages/Potential Complications

- Anterior knee pain in area of graft harvest site
- Pain during kneeling
- Extensor mechanism/patellofemoral dysfunction
- Long-term quadriceps muscle weakness
- Patellar fracture during graft harvest (rare, but significant adverse effects)
- Patellar tendon rupture (rare)

### BOX 21.9 Advantages and Disadvantages/Complications of the Semitendinosus-Gracilis Autograft

#### Advantages

- High tensile strength/stiffness greater than ACL with quadrupled graft
- No disturbance of epiphyseal plate in skeletally immature patient
- Evidence of hamstring tendon regeneration at donor site
- Loss of knee flexor muscle strength remediated by 2 years postoperatively

#### Disadvantages/Potential Complications

- Tendon-to-bone fixation devices (particularly tibial fixation) not as reliable as bone-to-bone fixation
- Longer healing time (12 weeks) at tendon-bone interface
- Hamstring muscle strain during early rehabilitation
- Short- and long-term knee flexor muscle weakness (not associated with functional limitation)
- Possible increased anterior knee translation (not associated with functional limitations)

secured in the prepared tunnels (bone-to-bone fixation) by means of screw fixation (metal or bioabsorbable interference screws).<sup>31,33,82,152,165,271</sup> Several types of soft tissue fixation devices are used to secure a hamstring tendon graft, including endobuttons, washers, and staples, while interference and transfixation screws may also be used.<sup>31,71,138,191,263</sup> Despite fixation advances, strong tendon-bone integration remains a challenge, particularly at the tibial site.

An advantage of current-day fixation devices is that they can withstand early but controlled tensile forces on the graft so that with proper placement and fit of these fixation devices there is a low risk of compromising the security of the graft itself.<sup>20,31,71</sup> This, in turn, permits early weight bearing and ROM of the knee, both of which are typical elements of contemporary, accelerated rehabilitation programs.<sup>21,90,112,157,198,263,250,308</sup>

After graft fixation and prior to closure, the knee is moved through the ROM to check the graft's integrity and the tension on the graft during movement. As with graft placement, proper graft tension at the time of fixation has a direct effect on postoperative joint mobility and stability. Too little tension can result in excessive knee laxity and potential instability, and too much tension can limit knee ROM.<sup>20</sup> After the incision is closed, a small compression dressing is immediately placed on the knee, and the knee may be immobilized for protection.

### Complications

There are a number of intraoperative and postoperative complications that can compromise outcomes after ACL reconstruction (see Boxes 21.8 and 21.9). Even minor technical errors during reconstruction can adversely affect function. As discussed in the previous section, inappropriate placement of the graft or bone tunnels, problems with graft harvesting such as inadequate graft length, and improper graft tension can adversely affect joint stability and mobility.<sup>1,261</sup> Insufficient graft length occurs more frequently during hamstring than patellar tendon graft harvesting. If graft fixation is insufficient, graft slippage and early failure can occur.<sup>261,263</sup> With a bone-patellar tendon-bone graft, a bone plug can fracture during harvesting or implantation, necessitating an alternative autograft or an allograft.<sup>261</sup>

Potential postoperative complications are knee pain, loss of motion, persistent strength deficits, and inadequate joint stability.<sup>1,191,261</sup> Anterior knee pain at the patellar tendon graft donor site or at the patellofemoral joint is common and may affect functional activities. A neuroma of the infrapatellar branch of the saphenous nerve can cause significant knee pain during kneeling.

Loss of full knee extension and persistent quadriceps weakness are recognized as significant complications after ACL reconstruction, particularly if full extension is not achieved preoperatively.<sup>170</sup> Permanent damage to the extensor mechanism is possible after patellar tendon graft harvesting, leading to quadriceps weakness or even patellar tendon rupture in rare instances. Limited ROM of the knee may have been present prior to surgery or may develop after surgery possibly from scar tissue in the intercondylar notch that will then require arthroscopic notchplasty. Loss of patellar mobility may also be a source of limited knee ROM.

postoperative knee extension motion loss and quadriceps weakness. They found that patients with loss of knee extension preoperatively were more likely to have limited knee extension postoperatively. However, a preoperative quadriceps muscle strength deficit did not predict postoperative quadriceps weakness 6 months after surgery.

Lastly, graft failure and the need for revision reconstruction may occur even in the absence of risk factors related to surgical technique. Graft failure is most likely to occur during the early months after surgery,<sup>83</sup> and the most common cause of graft failure is poor adherence to postoperative rehabilitation, in particular prematurely returning to high-risk, high joint-load activities.<sup>1,83,261</sup>

### Postoperative Management

Advances in surgical techniques and a better understanding of graft healing and the impact of stress on the healing graft, early postoperative motion and weight bearing—often referred to as “accelerated rehabilitation”—has become the standard of care after primary ACL reconstruction with an autogenous graft for the active, typically young patient.<sup>21,36,90,112,157,198,222,225,265,266,308</sup> Accelerated rehabilitation is based on the premise that a precisely placed and appropriately tensioned graft not only is strong enough to withstand the stresses of early motion and weight bearing, but is subjected to favorable healing conditions in response to these stresses.<sup>20,36,265,266,250,308</sup>

Table 21.5 outlines a contemporary, accelerated program following primary ACL reconstruction. The sequence of goals and interventions identified in Table 21.5 and described in the phases of rehabilitation that follow reflects guidelines common to a number of published programs.<sup>21,36,90,112,159,181,198,222,225,243,245,250,265,288,308</sup>

**NOTE:** It is important to recognize that although the descriptor “accelerated” is used frequently in the literature to characterize current-day rehabilitation after primary ACL reconstruction, there is no consensus on the initiation, progression, or duration of postoperative exercise, weight bearing, and other interventions.

### Immobilization and Bracing

The rationale for a brief period of immobilization and using a brace in the early phase of rehabilitation after ACL reconstruction is to protect the graft from excessive strain and prevent the loss of full knee extension.<sup>20,244,314</sup> However, with advances in graft fixation, the use of immobilization and protective bracing are no longer universally recommended.<sup>20,21,222,265,308</sup>

Decisions about immobilization and postoperative bracing are based on many factors. These include the surgeon's philosophy, the type of graft used, intraoperative observations about the quality of fixation, comorbidities and concomitant surgical procedures, and an assessment of the patient's expected level of adherence to a postoperative rehabilitation program.<sup>112,225</sup>

**Types of postoperative bracing.** Bracing the knee after ACL reconstruction falls into two broad categories: *rehabilitative*

### FOCUS ON EVIDENCE

McHugh and associates<sup>175</sup> evaluated 102 patients (age 31 ± 1 year) within 2 weeks and 6 months after primary ACL reconstruction to determine preoperative indicators of

*bracing* and *functional bracing*.<sup>20,244,314</sup> Rehabilitative bracing uses a hinged orthosis with a locking mechanism that can restrict the allowable ROM. It is typically only worn for the first 6 weeks following surgery. In contrast, a functional brace is worn when returning to high-demand sports or work-related activities to potentially reduce the risk of re-injury.

#### **Brace use and initiation and progression of knee ROM.**

If a rehabilitative brace is prescribed after surgery, it may be locked initially to maintain the knee in full extension. If locked in full extension for a short period of time, the brace is unlocked for exercise as soon as ROM is permitted. It is worn throughout the day for a few weeks to 6 weeks<sup>20</sup> and is sometimes worn during sleep for protection during the first postoperative week.<sup>225</sup> The brace is also locked in full extension during ambulation with crutches to prevent graft injury in the event of a fall.<sup>112,157,225,265,308</sup> When ROM is initiated, the rehabilitative brace can be set to incrementally progress the range of knee flexion that is allowed during exercise and functional activities.

#### **CLINICAL TIP**

Guidelines for the duration of immobilization in extension and the initiation and progression of knee ROM vary somewhat.<sup>7,20,21,112,191,198,222,225,265,308</sup> The literature supports the initiation of immediate or at least early knee motion (within the first week after primary, isolated ACL reconstruction) to reduce pain and adverse effects on articular cartilage and soft tissues surrounding the joint and improve ROM outcomes.<sup>20,36,159</sup>

Full, active knee extension and 90° to 110° of flexion ROM is expected by 4 to 6 weeks postoperatively. The patient is

weaned from brace use at about 6 weeks postoperatively if full extension has been achieved. Depending on the stability of the knee, the protective brace may need to be worn longer in some cases. These timelines are progressed more slowly when ACL reconstruction is combined with another procedure, such as a collateral ligament, meniscus, or articular cartilage repair.<sup>222</sup>

Some patients are advised to wear a functional brace during the advanced phases of rehabilitation and when participating in high-demand sports or heavy manual labor after rehabilitation is completed. However, the effectiveness of functional bracing after ACL reconstruction is unclear because the literature contains conflicting evidence.<sup>159</sup>

Despite the widespread use of protective bracing following ACL reconstruction, the literature provides a critical analysis of its efficacy during early rehabilitation and when returning to high-risk activities.

#### **FOCUS ON EVIDENCE**

The literature reflects a common belief that protective bracing during early recovery and when returning to activities following ACL reconstruction leads to improved outcomes by decreasing pain, joint swelling, and wound drainage by improving knee extension and by protecting the graft from excessive strain and the risk of re-injury. However, a recent systematic review by Wright and Fetzer<sup>314</sup> of 12 level I randomized, controlled trials determined that there is insufficient evidence to support the effectiveness of bracing. All but one of these studies evaluated bracing during early rehabilitation. The review indicated no significant differences between groups who did and did not use protective bracing during early recovery in outcomes such as postoperative pain, anterior-posterior knee stability, ROM, and functional testing. No conclusions could be drawn about the

effectiveness of functional bracing to prevent re-injury during high-demand activities because of low re-injury rates in the study that evaluated this outcome. The overall conclusion of the review was that the available evidence does not support the routine use of protective bracing after ACL reconstruction.

### Weight-Bearing Considerations

Early weight bearing is possible after primary ACL reconstruction with a bone-patellar tendon-bone or hamstring tendon autograft because of advances in graft fixation. Recommendations for the period of protected weight bearing immediately after surgery range from some degree of restricted weight bearing the first 2 weeks to weight bearing as tolerated with use of two crutches immediately after surgery.<sup>21,71,157,198,222,250,265,294,308</sup> Weight bearing is increased during the next 2 to 3 weeks based on the patient's symptoms. A longer duration of protected weight bearing will be required when other structures in the knee have been injured and/or repaired.<sup>308</sup>

Full weight bearing and ambulation without crutches, with or without an unlocked protective brace, is usually permitted by 4 weeks if weight bearing is pain free and the patient has achieved full, *active* knee extension and sufficient strength of the quadriceps to control the knee.<sup>21,112,191,198,225</sup>

Weight-bearing recommendations do not appear to be based on the type of graft or graft fixation used or whether protective bracing is worn but rather are determined on an empirical basis. The few randomized studies that have evaluated the effects of immediate and delayed weight bearing during the first few weeks after surgery indicate that both produce similar outcomes.<sup>20</sup>

### FOCUS ON EVIDENCE

Tyler and colleagues<sup>295</sup> compared the effects of immediate versus delayed weight bearing during the first 2 weeks after ACL reconstruction with a bone-patellar tendon-bone graft in 49 patients. An immediate weight-bearing group was advised to bear weight as tolerated and discontinue crutch use as soon as they felt comfortable doing so while the delayed weight-bearing group was advised not to wear a shoe on the operated side and remain nonweight bearing during ambulation with crutches for the first 2 weeks. After that, there were no restrictions placed on the progression of weight bearing. Neither group wore protective bracing. With the exception of weight-bearing status, the rehabilitation program for all patients was the same.

At a mean of 7.3 months postsurgery, there were no significant differences between groups with respect to knee ROM, knee stability, VMO activation, or overall function. However, patients in the immediate weight-bearing group had a lower incidence of anterior knee pain than the patients in the delayed weight-bearing group (8% and 35%, respectively). The investigators concluded that immediate weight bearing did not compromise knee joint stability or function

and was beneficial in that it resulted in a lower incidence of postoperative anterior knee pain.

### Exercise Progression

A progression of carefully selected exercises and functional activities coupled with patient education is a foundation of rehabilitation following ACL injury and reconstruction.

**Preoperative exercise.** Because surgery is typically delayed until acute symptoms have subsided, there is ample time to implement a *preoperative* exercise program to restore full knee ROM, particularly extension; prevent atrophy and weakness of leg musculature; and address the strength and flexibility of hip and ankle muscles.<sup>59,107,190,225,265,308</sup>

**Postoperative exercise progression.** After ACL reconstruction, exercise begins immediately on the first postoperative day. Use of strong grafts, such as bone-patellar tendon-bone and quadrupled hamstring autografts, and reliable graft fixation make early motion possible.<sup>21,112,198,222,225,265,308</sup>

Sometimes CPM is used while a patient is hospitalized or when at home after discharge. Although a valid mechanism for controlling postoperative pain and initiating early motion,<sup>171,265</sup> it is being used infrequently for postoperative care.<sup>112</sup> Two recent systematic reviews indicate no additional long-term benefit of CPM after ACL reconstruction.<sup>274,315</sup>

### CLINICAL TIP

Be mindful that a tendon graft goes through a necrotizing process the first 2 to 3 weeks postoperatively before revascularization commences and maturation gradually occurs.<sup>20,81,138,140</sup> Exercises must be progressed cautiously during each phase of rehabilitation, even during accelerated programs. If protective bracing has been prescribed, exercises are carried out while wearing the brace.

The rate of progression of exercise and functional training after ACL reconstruction depends on many factors. Patient-related factors such as age and preinjury health status affect the healing process, enabling younger, healthier patients to progress more rapidly. The type of graft and graft fixation also may influence the exercise progression. Some resources advocate more rapid progression of exercise for bone-to-bone fixation with a patellar tendon graft than for tendon-to-bone fixation with a quadrupled hamstring graft, suggesting that bone-to-bone healing may be faster than soft tissue-to-bone healing.<sup>112,225,308</sup> In contrast, others advocate the same accelerated program for both procedures.<sup>71,250,263</sup> If concomitant injuries are present or were managed surgically, the progression of exercises is more gradual than after isolated ACL injury and reconstruction.<sup>222</sup>

Exercises for progressive phases of rehabilitation after ACL reconstruction, summarized in Table 21.5, are described in the following sections. Exercise precautions are noted in Box 21.10.<sup>21,90,112,175,198,222,245,265,275,304,308</sup>

### BOX 21.10 Exercise Precautions After ACL Reconstruction

#### Resistance Training—General Precautions

- Progress exercises more gradually for reconstruction with hamstring tendon graft than bone-patellar tendon-bone graft.
- Progress knee flexor strengthening exercises cautiously if a hamstring tendon graft was harvested and knee extensor strengthening if a patellar tendon graft was harvested.

#### Closed-Chain Training

- When squatting in an upright position, be sure that the knees do not move anterior to the toes as the hips descend because this increases shear forces on the tibia and could potentially place excess stress on the autograft.
- Avoid closed-chain strengthening of the quadriceps between 60° to 90° of knee flexion.\*

#### Open-Chain Training

- During PRE to strengthen hip musculature, initially place the resistance above the knee until knee stability and control is established.
- Avoid resisted, open-chain knee extension (short-arc quadriceps training) between 45° or 30° to full extension for at least 6 weeks or as long as 12 weeks.\*
- Avoid applying resistance to the distal tibia during quadriceps strengthening.\*

\*Contraction of the quadriceps in these positions and ranges causes the greatest anterior tibial translation and can create potentially excessive stress to the graft during the early stage of healing.<sup>67,101,304,308</sup>

### Exercise: Maximum Protection Phase

During the early postoperative period, a delicate balance exists between adequate protection of the healing graft and the donor site with the prevention of adhesions, contractures, articular degeneration, muscle weakness, and atrophy associated with immobilization. Early motion generates stresses that benefit the graft but must be carefully controlled to avoid excessive tension on the graft during the first 6 to 8 weeks after implantation.

The following goals and exercise interventions are emphasized during the first 4 weeks after surgery when considerable protection of knee structures is warranted.<sup>21,112,157,159,175,198,222,225,265,308</sup>

**Goals.** Immediately after surgery through the first few postoperative weeks, in addition to controlling pain and swelling and initiating ambulation with crutches, exercise goals are to prevent reflex inhibition of knee musculature, prevent adhesions, restore knee mobility, regain kinesthetic awareness and neuromuscular control of the lower extremity, and improve strength and flexibility of hip and ankle musculature.

The goal for knee ROM is to achieve 90° of flexion and full passive extension by the end of the first 1 to 2 weeks as joint swelling subsides and to reach 110° to 125° of flexion by 3 to 4 weeks.

**Interventions.** Pain, joint swelling, and peripheral edema are controlled in a standard manner. Exercises begin the day of or the day after surgery with an emphasis on (1) preventing vascular complications (DVTs), (2) activating knee musculature, and (3) reestablishing knee mobility. Patient education during the first phase of rehabilitation supports these interventions through the home exercise program.

### CLINICAL TIP

It is important to activate and strengthen the quadriceps early in the rehabilitation process to reestablish dynamic knee extension control, particularly for safe weight-bearing activities. However, it is equally important to activate and strengthen the hamstrings as they provide a dynamic restraint to limit anterior translation of the tibia on the femur.

When a protective brace has been prescribed, weight-bearing exercises are performed while in the brace. Low-intensity closed-chain exercises and proprioceptive/neuromuscular control training are initiated as soon as weight bearing is permissible. The value of early closed-chain/weight-bearing exercises and proprioceptive/neuromuscular control training for quadriceps control after ACL reconstruction is supported by many studies and is discussed in the exercise section of this chapter.<sup>11,36,59,112,121,157,181,198,243,245,265,250,308</sup>

The following exercises are advocated for the maximum protection phase:<sup>21,90,112,157,157,175,181,198,222,225,243,245,265,304,308</sup>

- **Ankle pumping exercises.** Perform ankle pumping frequently throughout the day to reduce DVT risk.
- **Voluntary isometric and dynamic activation of knee musculature.**
  - Begin muscle setting of quadriceps, hamstrings, and hip abductors, adductors, and extensors within the patient's comfort level. An isometric quadriceps contraction with the knee in full extension generates little to no anterior translation of the tibia on the femur because the knee is in a closed-pack position.
  - Use electrical stimulation or biofeedback to augment quadriceps activation. A recent literature review concluded that neuromuscular electric stimulation may be more effective in improving quadriceps strength than exercise alone. However, there were no differences found in long-term functional performance.<sup>141</sup>
  - Perform four-position SLRs, first with assistance, then progress to active hip motions with the knee maintained in extension. Add external resistance when the patient is able to maintain knee extension control during hip movements.
  - When knee movement is permissible, initiate low-intensity, multiple-angle isometrics of the knee musculature with emphasis on quadriceps control and co-contraction of the quadriceps and hamstrings.

- Consider *low-intensity*, eccentric quadriceps training between 20° and 60° on a motorized, eccentric ergometer, if available. Negative work training, if progressed gradually, has been shown to be safe when initiated as early as 3 weeks after ACL reconstruction.<sup>90</sup>
- To activate the hamstrings dynamically, include supine heel-slides to a comfortable level of hip and knee flexion, standing knee flexion (hamstring curls without resistance added), and scooting *forward* while seated on a rolling stool.

**PRECAUTION:** Postpone dynamic activation of the knee flexors if a hamstring graft was used for reconstruction (see Box 21.10).

#### ■ **ROM and patellar mobility.**

- Begin ROM in a protected range. Include therapist-controlled PROM or A-AROM within the patient's comfort level.
- Include patellar mobilization to prevent adhesions.
- To increase passive knee extension, have the patient assume a supine or long-sitting position and prop the heel on a rolled towel or bolster with the knee unsupported (see Fig. 21.18).
- To increase knee flexion, include supine, gravity-assisted wall slides (see Fig. 21.19) or dangle the leg while sitting on the side of a bed.
- Stretch hip and ankle musculature if flexibility is limited.

#### ■ **Neuromuscular control/responses, proprioception, stability, and balance.**

- Begin neuromuscular training with trunk and lower extremity stabilization exercises in bilateral stance. Have the patient wear a protective brace locked in extension, if prescribed. Distribute weight equally on both lower extremities, and support some weight through the upper extremities. Have the patient maintain a stable, well-aligned position and apply alternating resistance with varying directions and speeds to the pelvis.
- Progress training with weight-shifting activities and bilateral minisquats in the 0° to 30° range and with stepping and marching movements. Gradually decrease upper extremity support. When the knee is pain free and full weight bearing is possible, progress to unilateral stabilization activities.
- Perform *nonresisted*, multijoint movements, such as stationary cycling and exercise on a seated leg press machine or in a semireclining position on a Total Gym® unit, at 3 to 4 weeks. If incision healing allows, begin exercises in a pool.

**Criteria to progress to next phase.** Criteria include:

- Minimal pain and swelling
- Full, *active* knee extension (no extensor lag)
- At least 110° knee flexion
- Quadriceps strength at least 50% to 60% of contralateral side (measured isometrically at 60°)
- No evidence of excessive joint laxity (determined by arthrometric measurements)

### Exercise: Moderate Protection/Controlled Motion Phase

The moderate protection phase begins about 4 to 5 weeks postoperatively or when identified criteria have been met and extends to about 10 to 12 weeks postoperatively. The emphasis of this phase is to achieve full knee ROM; increase strength, dynamic stability, and endurance; and to normalize gait and neuromuscular control/response time and balance in preparation for a transition to functional activities. A protective brace may be worn for gait and most exercises until about 6 weeks when brace use is gradually discontinued.

#### ▶ **CLINICAL TIP**

By 8 to 10 weeks graft revascularization is becoming well established and exercises can be performed more vigorously while continuing to closely monitor the patient's response.<sup>81,138,140</sup>

**Goals.** Rehabilitation goals during the intermediate phase are to attain full ROM (full knee extension and 125° to 135° flexion); improve lower extremity strength and muscular endurance; ambulate without assistive device or protective brace using a normal gait pattern; continue to improve neuromuscular control/response time, proprioception, and balance; and regain cardiopulmonary fitness.

**Interventions.** Include and progress the following interventions during the moderate protection phase:<sup>21,90,112,157,157,175,181,198,225,243,245,265,308</sup>

#### ■ **ROM and joint mobility.**

- Continue low-intensity, end-range self-stretching to gain full knee ROM.
- Use grade III joint mobilization techniques to restore full knee flexion.
- Continue flexibility exercises for hip and ankle musculature, especially the hamstrings, IT band, and plantarflexors.

#### ■ **Strength and muscle endurance.**

- Continue closed-chain exercises against body weight resistance (bridging, wall slides, partial squats, straight-line lunges, step-ups/step-downs, heel raises).
- Progress from double-leg to single-leg exercises.
- Initiate open-chain hip extension and abduction and knee extension/flexion against light-grade elastic resistance in appropriate portions of knee ROM (see Box 21.10). The literature supports both closed-chain and open-chain training for ACL deficiency<sup>64,288</sup> or following ACL reconstruction.<sup>159</sup>

### FOCUS ON EVIDENCE

Although an emphasis has been placed on closed-chain strengthening during the past few decades,<sup>36</sup> recent studies also demonstrate the value in including both open- and

closed-chain exercises in an ACL rehabilitation program.<sup>181</sup> Bynum and colleagues<sup>36</sup> compared open- and closed-chain rehabilitation after primary ACL reconstruction with a bone-patellar tendon-bone autograft. When strengthening exercises were initiated, one group followed an open-chain regimen and the other a closed-chain regimen. One year after surgery, patients in the closed-chain exercise group had significantly less anterior knee pain, closer to normal knee stability as measured by an arthrometer, earlier return to functional activities, and greater overall satisfaction with the outcome of the surgery compared with the open-chain group.

A subsequent study by Mikkelsen and associates<sup>181</sup> demonstrated that the addition of open-chain quadriceps strengthening at 6 weeks postoperatively resulted in no significant differences in anterior knee laxity between a group that performed closed- and open-chain strengthening and a group that performed only closed-chain strengthening. A significantly higher proportion of participants who performed the additional open-chain training returned to sports at their pre-injury level, and did so on average 2 months sooner, than those who trained with closed-chain exercises only.

#### ■ **Neuromuscular control/responses, proprioception, and balance.**

- Progress neuromuscular training with stabilization and static and dynamic balance activities in bilateral stance, progressing to unilateral stance on stable and then unstable surfaces. Focus on developing quick responses to alternating resistance and unexpected perturbations in varying directions.
- Emphasis on hip and lumbopelvic stability as well as awareness of proper lower extremity alignment and knee control is crucial to correct pathomechanical alignment or movements.<sup>233</sup>
- **Gait training.** Practice ambulation in a controlled environment without bracing or with the protective brace unlocked and without crutches. Emphasize symmetrical alignment, step length, and timing to reestablish a normal gait pattern.
- **Aerobic conditioning.** Continue stationary cycling, increasing the duration and speed, or initiate a swimming or pool walking/running program, treadmill walking, or use of an elliptical trainer or stepping machine.
- **Activity-specific training.** Integrate simulated functional activities or components of activities into the exercise program.

**Criteria to progress to next phase.** Criteria to progress to the advanced phases of rehabilitation include:

- Absence of pain and joint effusion
- Full, active knee ROM
- At least 75% strength of knee musculature compared to the contralateral side
- Hamstrings/quadriceps ratio > 65%

- Functional hop test > 70% of contralateral side
- No evidence of knee instability on arthrometer readings or clinical examination

#### **Exercise: Minimum Protection/Return to Function Phase**

The advanced phase of rehabilitation and preparation for a return to a preinjury level of activity begins at about 10 to 12 weeks postoperatively or when the patient has met specified criteria. Most post-ACL reconstruction rehabilitation programs described in the literature continue until about 6 months postoperatively.<sup>20,21,112,198,222,225,308</sup> The intensity and duration of training are typically based on the patient's goals and the level of activity to which the patient wishes to return. Individuals involved in high joint-loading, work-related activities, or competitive sports are advised to participate in a maintenance exercise program.

**Goals.** From 12 to 24 weeks postoperatively, the aims are to further increase strength, endurance, and power; further enhance neuromuscular control and agility; and participate in progressively demanding functional activities.

**Interventions.** Exercise interventions during the final phase of rehabilitation include PRE with an emphasis on eccentric training, advanced closed-chain strengthening (lunges, step-ups, step-downs against elastic resistance); advanced neuromuscular, balance, and agility training with directional changes, acceleration, and deceleration; plyometrics; and activity-specific drills coupled with a gradual return to progressively demanding activities. Patient education emphasizing prevention of re-injury continues throughout the advanced phases of rehabilitation and as the patient returns to full activity. (Refer to the exercise section of this chapter and to Chapter 23 for examples of exercises and activities.)

A functional knee brace may be worn to reduce the risk of re-injury during high-demand activities, particularly those that involve turning, twisting, cutting, or jumping motions. As noted previously in this section, conflicting evidence exists for the use of functional bracing following ACL reconstruction.<sup>159</sup> For additional information on efficacy of functional bracing, refer to the section on Outcomes.

**Return to activity.** Recommended timelines for returning to vigorous activities, including competitive sports, range from 6 months to a year after surgery.<sup>21,250,263</sup> Criteria to return to a preinjury level of activity must be individualized for each patient and are contingent on clinical examination findings, particularly quadriceps strength, knee stability, and the expected work, recreational, or sports-related demands. Box 21.11 identifies criteria, suggested by several sources,<sup>107,148,157,198,250,304,308</sup> that should be met prior to a return to high-risk, high joint-loading activities.

#### **Outcomes**

ACL reconstruction followed by a carefully progressed postoperative rehabilitation program is a reliable means of reestablishing knee stability. Long-term success rates following ACL

### BOX 21.11 Criteria Used to Inform Decisions About Return to High-Demand Activities After ACL Reconstruction

- No knee pain or joint effusion during final phase of rehabilitation
- Full, active knee ROM
- Quadriceps strength > 85% to 90% of contralateral side or peak torque/body mass 40% and 60% for men and 30% and 50% for women (tested at 300°/sec and 180°/sec, respectively).
- Hamstring strength 100% of contralateral side
- Hamstring/quadriceps ratio > 70%
- No postoperative history of knee instability/giving way
- Negative pivot shift test
- Knee stability measured by arthrometer: < 3 mm difference between reconstructed and uninjured side
- Proprioceptive testing: 100%
- Functional testing (a series of hop, jump, and/or squat tests): > 85% or > 90% of contralateral side or normative values
- Acceptable patient-reported score on comprehensive, quantitative knee function measurement tool, such as the International Knee Documentation Committee Subjective Knee Form
- Acceptable confidence and motivation based on standardized outcome measures for psychological variables such as kinesiophobia or emotional preparedness for return to activities

reconstruction range from 82% to 95%, and graft failure leading to recurrent instability occurs in approximately 8% of patients.<sup>2</sup> However, outcomes are predicated on numerous factors, including the patient's age, sex, overall health status, and preinjury activity level; the presence or absence of injuries associated with the ACL injury; the surgical procedure; postoperative complications; and the patient's adherence to the rehabilitation program. The effects of several of these variables are addressed in this section.

**Graft selection and outcomes.** Numerous prospective and retrospective studies have been conducted comparing the effects of graft selection on outcomes. Bone-patellar tendon-bone and hamstring tendon autografts are studied most often. An extensive review and analysis of the literature revealed that although both types of grafts have their merits and limitations (summarized in Boxes 21.9 and 21.10), long-term (2 years or more) functional outcomes are essentially the same.<sup>268</sup>

**Approaches to rehabilitation.** There are few studies that have evaluated the effects of postoperative exercise program variables such as the components and rate of progression of rehabilitation and the degree of supervision. Neuromuscular training is one ACL postoperative rehabilitation component that has been studied. Risberg and colleagues<sup>243</sup> compared a program of neuromuscular training to a traditional strength-training program over a 6-month period after ACL reconstruction and showed

that the neuromuscular training group had significantly better scores on selected functional tests than the traditional strength-training group. There were no significant between group differences in knee pain, joint laxity, proprioception, or knee muscle strength. Although the study did not include a long-term follow-up, the investigators concluded that neuromuscular training is an important component of rehabilitation following ACL reconstruction.

Beynon and coinvestigators<sup>21</sup> compared outcomes between accelerated (19 weeks) and nonaccelerated (32 weeks) rehabilitation programs following ACL reconstruction with bone-patellar tendon-bone autografts. The two programs contained the same rehabilitation components but were implemented over two different timelines. At 24 months postoperatively, there were no significant between group differences in knee laxity, functional testing, patient satisfaction, or activity level.

The effect of supervision during rehabilitation has also been studied. Specifically, home-based rehabilitation with limited therapist supervision has been compared with clinic-based rehabilitation with therapist supervision throughout the program. Two literature reviews report that, for the most part, these two approaches produced similar outcomes.<sup>20,315</sup> Importantly, all participants in these studies had some direct instruction and supervision from a therapist. The reviewers emphasized the importance of therapist-directed assessments and initial instruction in an exercise program and recommended periodic, rather than continuous, supervision over the course of rehabilitation.

**Functional bracing.** The effect of functional bracing during the intermediate and advanced phases of rehabilitation and its use during high-risk sports after completion of rehabilitation is unclear. Risberg and colleagues<sup>244</sup> prospectively investigated 60 patients randomly assigned to a braced or a nonbraced group. After ACL reconstruction with a patellar tendon autograft, patients in the braced group wore a protective brace for 2 weeks and then wore a functional brace for an additional 10 weeks. At the conclusion of rehabilitation, the braced group was advised to wear the functional brace for all high joint-loading activities. The nonbraced group had no brace at any time during or after rehabilitation. Both groups underwent the same rehabilitation program and patient education. At a 2-year follow-up, there were no significant differences between groups for knee ROM, knee joint laxity, muscle strength, functional testing, or ACL re-injury rates. These results are similar to those of a more recent study by McDevitt and associates,<sup>173</sup> who found that wearing an “off-the-shelf” functional brace for 1 year after ACL reconstruction during all high-demand activities (jumping, pivoting, and cutting) had no significant impact on knee function or re-injury.

Sterret and colleagues<sup>284</sup> also investigated the role of functional bracing in preventing re-injury in patients returning to downhill skiing after ACL reconstruction. Investigators prospectively evaluated 820 skiers who had undergone ACL reconstruction with a patellar tendon autograft at least 2 years

previously. Of the 820 post-ACL reconstruction skier/employees, 257 were considered at significant risk for re-injury of the ACL based on the results of preseason screening. These individuals were given and advised to wear a functional knee brace during skiing. The remaining 563 skier/employees were not determined to be at significant risk for re-injury and were not issued a functional brace. There were a total of 61 ACL re-injuries: 51 in the nonbraced skiers and 10 in the braced skiers. The nonbraced group was 2.74 times more likely to sustain re-injury to the ACL than the braced group. The authors recommend functional knee bracing after recovery from ACL reconstruction for patients returning to the high-risk sport of skiing regardless of their assessed risk of re-injury.

## Posterior Cruciate Ligament Reconstruction

In contrast to ACL injury, injury of the PCL is relatively infrequent.<sup>312</sup> When a PCL injury does occur, it usually is accompanied by damage to other structures of the knee. There is general agreement that a PCL injury combined with an injury to another ligament or knee structure usually warrants early surgical intervention.<sup>73,210,211</sup>

When an isolated PCL injury occurs, most patients respond well to nonoperative management and are able to return to a preinjury level of activity. However, an increased incidence of OA in the medial compartment of the knee over time has been observed following a PCL injury.<sup>312</sup> Motion analysis of the PCL-deficient knee has detected altered kinematics of the medial compartment of the knee, specifically anterior subluxation of the medial femoral condyle.<sup>156</sup> These kinematic changes may explain the degenerative changes observed in the PCL-deficient knee and lend support for managing the injury with surgical intervention.

### Indications for Surgery

Although there is limited consensus, the most frequently cited indications for surgical reconstruction of the PCL include the following.<sup>5,43,73,211,271,312</sup>

- Complete tear or avulsion of the PCL with posterolateral, posteromedial, or rotary instability of the knee combined with damage to another ligament and often the menisci or articular cartilage
- Isolated, symptomatic, grade 3 PCL tear with greater than 8- to 10-mm posterior tibial displacement compared with the contralateral knee, resulting in instability during functional activities
- Persistent pain and instability after an unsuccessful course of nonoperative treatment following an isolated PCL injury
- Chronic PCL insufficiency associated with posterolateral instability, pain, limitations in functional activities, and articular surface degeneration

## Procedures

### Operative Overview

There are a number of arthroscopic, arthroscopically assisted, or open procedures used for management of a torn or ruptured PCL. Although a tear mechanism that includes a bony avulsion is occasionally managed with primary repair, reconstruction is the much more frequent procedure.<sup>73</sup> As with ACL reconstruction, PCL reconstruction involves implantation of a graft to replace the damaged ligament. Graft options using single-bundle or double-bundle reconstruction include a bone-patellar tendon-bone autograft, a hamstring or quadriceps tendon autograft, an Achilles tendon or anterior tibialis tendon allograft, or occasionally a synthetic graft.<sup>5,43,73,211,271,312</sup>

The operative procedure begins with diagnostic arthroscopy followed by graft harvest. There are two methods of graft placement—transtibial tunnel and tibial inlay.<sup>43</sup> With the arthroscopic transtibial technique, femoral and tibial tunnels are drilled and prepared, and the graft is drawn through and secured in the tunnels with bony or soft tissue fixation devices. The tibial inlay technique can be performed as an open procedure through a posteromedial incision or less frequently as an arthroscopic procedure. No significant differences in outcomes have been identified following the transtibial versus the open tibial inlay procedures.<sup>43</sup>

Graft placement must be precise to mimic the function of the native PCL regardless of the method used. Prior to closure, the knee is flexed and extended to ensure that graft placement and tension allow full ROM. After wound closure, a sterile compression dressing is applied, and the knee is immobilized in full extension.

### Complications

Because PCL reconstruction involves the posterior aspect of the knee, there is risk of damage to the popliteal neurovascular bundle, particularly while drilling the tibial bone tunnel. Postoperative bleeding can lead to compartment syndrome. If a patellar tendon autograft was used, the patient may experience anterior knee pain and pain during kneeling. Knee flexion motion can become limited postoperatively. As with any ligament reconstruction, graft failure can occur, leading to joint instability and the need for revision reconstruction.<sup>43,73</sup>

## Postoperative Management

### Immobilization, Protective Bracing, and Weight Bearing

The knee is immobilized in a hinged, range-limiting protective brace locked in full extension following surgery. The immobilizer is worn during the day and even during sleep for the first 4 to 8 weeks to prevent posterior displacement of the tibia as the result of gravity or sudden contraction of the knee flexors. It may be unlocked or removed for therapy 1 day to a week after surgery and removed after the first postoperative week for bathing.<sup>5,43,73,210,211,312</sup> The protective brace remains locked in extension during weight bearing and ambulation for an extended period of time.

## FOCUS ON EVIDENCE

In theory, protective bracing is prescribed following PCL reconstruction to prevent posterior tibial translation that could disrupt the graft in the early stage of healing. However, a recent literature review indicates that there is no evidence to support this assumption.<sup>159</sup>

In contrast to weight bearing after ACL reconstruction, weight bearing is progressed more gradually after PCL surgery.<sup>43,73,210,211,312</sup> The time frames for initiating and progressing weight bearing range from partial weight bearing (about 30%<sup>43</sup>) immediately after surgery using two crutches and wearing the protective brace locked in extension<sup>51,210,211</sup> to nonweight bearing for a week to 5 weeks postoperatively.<sup>73,312</sup> Weight bearing is increased over several weeks while keeping the brace locked in extension. As quadriceps control of full knee extension improves and pain and joint effusion are well controlled, the brace is unlocked, allowing movement in a protected range during ambulation with crutches and weight-bearing exercises.

Crutches are discontinued and full weight bearing with the brace unlocked is permitted when the patient has met specified criteria (Box 21.12), typically by 8 to 10 weeks postoperatively.<sup>43,51,210,211</sup> Brace use is discontinued gradually after meeting these criteria.

### Exercise Progression

Postoperative exercises during rehabilitation following PCL reconstruction are similar to those performed after ACL reconstruction (see Table 21.5).<sup>43,51,73,210,211</sup> The key differences are that exercises are progressed more gradually, and those that place posterior shear forces on the tibia are postponed during the initial and intermediate phases of rehabilitation when the graft is most vulnerable.

Strengthening the quadriceps is emphasized for knee control after PCL reconstruction because it acts as a dynamic restraint to posterior tibial translation. When resistance exercises for hamstring strengthening are initiated during advanced rehabilitation, they are adjusted based on the stability of the

### BOX 21.12 Suggested Criteria for Ambulation Without Crutches After PCL Reconstruction

- Minimal to no pain or joint effusion
- Full, active knee extension (no extensor lag) with a straight-leg raise in the supine position
- Passive and active knee flexion from 0° to at least 90°
- Quadriceps strength: approximately 70% compared with the contralateral side or at least 4/5 manual muscle test grade
- No gait deviations

knee. Box 21.13 summarizes precautions for exercise and functional activities after PCL reconstruction.<sup>43,51,210,211</sup>

### Exercise: Maximum Protection Phase

The emphasis during the first, maximum protection phase of rehabilitation, which extends for 4 to 6 weeks, is to protect the integrity of the graft while simultaneously beginning to regain function, mobility, and quadriceps control.<sup>43,51,73,210,211</sup>

**Goals.** The goals during this phase of rehabilitation are to control or reduce acute symptoms, prevent vascular complications, reestablish quadriceps control, maintain patellar mobility, regain approximately 90° of knee flexion by 2 to 4 weeks after initiating knee motion, begin to reestablish neuromuscular control and balance, improve strength and flexibility of the hip and ankle musculature if limited, and improve cardiopulmonary fitness.<sup>43,51,210,211</sup>

**Interventions.** Control pain and swelling using effective methods such as cold, compression, and elevation. Immediately

### BOX 21.13 Exercise Precautions After PCL Reconstruction

#### General Precautions

- Avoid exercises and activities that place excessive posterior shear forces and cause posterior displacement of the tibia on the femur, thus disrupting the healing graft.
- Throughout the rehabilitation process, limit the numbers of repetitions of knee flexion to minimize potential abrasion to the PCL graft.

#### Early and Intermediate Rehabilitation

- Begin exercise to restore knee flexion while in a seated position, allowing gravity to passively flex the knee and the hamstrings to remain essentially inactive.
- During squatting exercises to increase quadriceps strength:
  - Avoid excessive trunk flexion, because it causes increased activity in the hamstrings.
  - Avoid knee flexion past 60° to 70°, because it tends to cause posterior translation of the tibia.
- When performing open-chain exercises to strengthen hip musculature, such as resisted SLRs in standing, place resistance above the knee.
- Postpone open-chain, active knee flexion against the resistance of gravity (prone or standing) for 6 to 12 weeks.

#### Advanced Rehabilitation

- Postpone resistance training for the knee flexors, such as use of a hamstring curl machine, for 5 to 6 months.
- When performing resisted hamstring curls, use low-loads.
- Avoid downhill inclines during walking, jogging, or hiking.
- Avoid activities that involve knee flexion combined with rapid deceleration when one or both feet are planted.
- Postpone returning to vigorous functional activities for at least 9 to 12 months.
- Consider wearing a functional knee brace during high-demand activities.

after surgery, begin ankle-pumping exercises, patellar-gliding techniques, quadriceps-setting exercises augmented by neuromuscular electrical stimulation, and four-position SLRs while wearing the protective brace locked in full extension. Use an upper extremity ergometer for aerobic conditioning. Establish a home exercise program.

When knee motion is permitted, follow the exercise precautions for early rehabilitation previously noted (see Box 21.13). Begin multiple-angle isometrics of the quadriceps from full extension to 25° to 30° of flexion. Perform assisted knee extension, progressing to active knee extension while seated. To regain knee flexion, begin with *gravity-assisted* flexion in a seated position. Hold the patient's leg in full knee extension and have the patient control leg lowering as gravity induces knee flexion.

Begin trunk and lower extremity stabilization exercises and heel raises in a supported standing position while following weight-bearing restrictions and wearing the locked brace. When it is permissible to unlock the protective brace, begin closed-chain quadriceps strengthening in bilateral stance while holding on to a stable surface for support. As with ACL reconstruction, hip and lumbopelvic stabilization is critical to controlling knee movements.<sup>233</sup> Stretch the hip and ankle musculature, in particular the hamstrings, IT band, and plantarflexors.

**Criteria to progress to next phase.** Criteria to advance to the intermediate phase of treatment include:<sup>43,51,210,211</sup>

- Minimal joint swelling
- Full, active knee extension (no extensor lag)
- At least 100° of knee flexion
- A grade of 3/5 quadriceps strength on manual muscle test
- Knowledge of home program and exercise and activity precautions

### Exercise: Moderate and Minimum Protection Phases

**Goals and interventions.** As with early rehabilitation, the goals and interventions during the intermediate and advanced phases of rehabilitation following PCL reconstruction are similar to those following ACL reconstruction (see Table 21.5). However, the suggested timelines continue to be more extended, particularly for hamstring strengthening.

The exercises and activities during the intermediate phase of rehabilitation are essentially an extension of those initiated during the first phase. By 9 to 12 weeks postoperatively, the patient should have achieved full knee ROM (0° to 135°), making it possible to discontinue use of the protective brace if quadriceps control is sufficient.<sup>43,51,210,211</sup>

During the intermediate and advanced phases of rehabilitation, precautions to prevent excessive posterior translational forces on the tibia during exercises and functional activities continue (see Box 21.13). Strengthening continues to focus on the quadriceps to reestablish full, active knee extension, while also emphasizing the quadriceps, hip, and ankle musculature for the return to functional weight-bearing activities.

Initiating resistance training to improve strength and muscular endurance of the hamstrings depends on the posterior

stability of the knee. Strengthening of the knee flexors is typically delayed until 2 to 3 months postoperatively and then progressed cautiously. Begin hamstring strengthening with closed-chain exercises, such as bilateral bridging that progresses to unilateral. A recent literature review supports an eccentric squat program following PCL reconstruction.<sup>159</sup> Add open-chain hamstring strengthening (hamstring curls) when posterior knee stability allows.

Advanced neuromuscular training with plyometrics, balance activities, and agility drills, plus progressive aerobic conditioning and activity-specific training, are critical for a safe transition to a full level of functional activities. A full return to vigorous activities after PCL reconstruction may take 9 months to a year.<sup>43,51,73,210,211</sup>

## Meniscus Tears: Nonoperative Management

### Mechanisms of Injury

The medial meniscus is injured more frequently than the lateral meniscus. Meniscal injuries may occur during femur on tibia rotation during weight bearing when the foot is firmly fixed on the ground, as when pivoting, getting out of a car, or in many sport- or work-related activities. Medial meniscus injuries often accompany ACL tears. Simple squatting or high-force trauma may also cause a meniscus tear.

### Common Impairments and Activity Limitations

A meniscus tear can cause acute locking of the knee or chronic symptoms with intermittent catching/locking. There is joint swelling and some degree of quadriceps atrophy, with pain along the joint line during forced hyperextension or maximum flexion due to stress to the coronary ligament.<sup>142</sup> When there is joint catching/locking, the knee does not fully extend and there is a springy end feel with passive extension. When the joint is swollen, there is usually end-range flexion or extension motion limitation. The McMurray test or Apley's compression/distraction test may be positive.<sup>162</sup>

With an acute meniscus tear the patient may be unable to bear weight on the involved side. Unexpected locking or giving way during ambulation often occurs, causing safety problems.

### Management

- Often the patient can actively move the leg to “unlock” the knee, or the unlocking happens spontaneously.
- Passive manipulative reduction of the medial meniscus may unlock the knee (Fig. 21.16).
  - *Patient position and procedure:* Supine. Passively flex the involved knee and hip, and simultaneously rotate the

**FIGURE 21.16** Manipulative reduction of a medial meniscus. Internally and externally rotate the tibia during hip and knee flexion (not shown); then laterally rotate the tibia and apply a valgus stress to the knee during knee extension. The meniscus may click into place.

tibia internally and externally. When the knee is fully flexed, externally rotate the tibia and apply a valgus stress at the knee. Hold the tibia in this position and extend the knee. The meniscus may click into place.

- Once reduced, the knee may react as an acute joint lesion. If this occurs, treat as described earlier in the chapter in the section on nonoperative management of joint hypomobility.
- After acute symptoms have subsided, exercises should be performed in open- and closed-chain positions to improve strength, endurance, and functional stability and to prepare the patient for functional activities.

## Meniscus Tears: Surgical and Postoperative Management

With a significant meniscus tear or rupture or if nonoperative management of a partial tear is unsuccessful, surgical intervention may be necessary. Surgical procedures aim to retain as much of the meniscus as possible to preserve the load transmission and shock-absorbing functions of the tissue and reduce tibiofemoral articular surface stresses.

Primary surgical options are *partial meniscectomy* and *meniscal repair*, both of which are preferable to total meniscectomy.<sup>285,292</sup> The surgical approach used is influenced by the location and nature of the tear, as well as the patient's age and level of activity. Tears located toward the vascularized perimeter heal well, while tears extending into the less vascularized central portion have marginal healing properties (Fig. 21.17).<sup>293</sup> Age and the patient's activity level factor into the decision-making process because it has been shown that removing even a portion of a meniscus increases the long-term risk of articular degeneration.<sup>293</sup>

Partial meniscectomy is often used to manage complex, fragmented tears and tears involving the central (middle third), relatively avascular zone of a meniscus.<sup>292</sup> In contrast,

**FIGURE 21.17** Vascularity of the medial and lateral menisci. The peripheral zone (outer one-third) is highly vascular; the central one-third is relatively avascular; and the inner one-third is avascular.

peripheral tears are usually repaired rather than excised.<sup>293</sup> However, the young or physically active older patient with a central zone tear may also be good candidates for a repair.<sup>111,203,204</sup> If there is extensive damage to a major portion of the meniscus and it is determined to be unsalvageable, total meniscectomy remains the only surgical option.<sup>292</sup>

For the relatively young and/or active patient who previously underwent total meniscectomy and now is symptomatic as the result of early osteoarthritic changes in the tibiofemoral joint, a recently developed option—*meniscal transplantation*—using human allograft tissue has become available.<sup>111,206,227</sup> Although this procedure is expected to fail in the long term with only a 40% survival rate reported after 15 years, the short-term benefits of symptom resolution and improved function is justified for this population.<sup>202</sup>

The progression of postoperative rehabilitation and the time required to return to full activity after each of these procedures depends on the extent and location of the tear and the type of surgical approach and procedure performed. Rehabilitation proceeds more conservatively after meniscus repair or transplantation and after total meniscectomy than after a partial meniscectomy. Any damage and repair or reconstruction of other soft tissues of the knee will also affect the course and progression of rehabilitation after surgery.

## Meniscus Repair

### Indications for Surgery

Repair of a torn meniscus is indicated in the following situations:<sup>111,203,292</sup>

- A lesion in the vascular outer third of the medial or lateral meniscus
- A tear extending into the central, relatively avascular third of the meniscus of a young (younger than age 40) or physically active older (older than age 50) individual

**CONTRAINDICATIONS:** Contraindications include the presence of a tear localized to the innermost, avascular third of the meniscus, a tear with considerable tissue fragmentation, or a tear that cannot be completely re-opposed during surgery.<sup>111</sup>

## Procedure

### Operative Overview

Prior to the operative procedure, a comprehensive arthroscopic examination of the joint is performed to determine if a meniscus tear is suitable for repair and to identify any concomitant injuries. The meniscus repair itself is performed using an arthroscopically assisted open approach or a fully arthroscopic approach.<sup>111,192,193,203</sup> The determination of which approach is used is primarily based on the location and nature of the tear.<sup>292</sup>

There are several surgical procedures—referred to as inside-out, outside-in, or all-inside techniques—for meniscus repair. The inside-out and outside-in techniques are arthroscopically assisted, with a portion of the procedure being performed through an incision at the posteromedial or posterolateral aspect of the knee.<sup>192,203</sup> The all-inside technique is fully arthroscopic.<sup>193,293</sup>

Variations in fixation include suturing with nonabsorbable or bioabsorbable sutures or the use of other devices such as darts or staples. Of the many repair variations, the arthroscopically assisted, inside-out suture repair is most common and considered by some in the orthopedic community to be the “gold standard.”<sup>111,192,203,293</sup>

At the beginning of the procedure, small incision portals are made and saline is arthroscopically introduced into the joint to distend the capsule. After the joint is examined, arthroscopic débridement is performed to remove all unstable tissue fragments and prepare the torn meniscus for repair. The repair procedure is performed endoscopically or through a posteromedial or posterolateral incision. During the repair the edges of the tear are closely approximated and sutured every 3 to 4 mm to ensure complete closure with no gapping. All sutures are tied with the knee fully extended or in 10° of flexion to allow full extension postoperatively without causing undue stress on the repaired meniscus.

Several methods to improve healing by introducing growth factors or endogenous blood to the tear site are also used with meniscal repairs. Trephination (creating several burr holes) or rasping of the tear surface to cause local bleeding are two such methods. Similarly, a fibrin clot from the patients' venous blood may be created and used to augment healing.<sup>128</sup> These clots are applied to the tibial joint surface at the tear site prior to tightening the sutures and reduced failure rates from 64% to 8% in one early study.<sup>114</sup>

After closure, a compression dressing is applied to control postoperative joint effusion and the knee is immobilized.

**NOTE:** Detailed descriptions of medial and lateral meniscal allograft transplantation techniques are published in several resources.<sup>91,111,206,207,227</sup>

### Complications

Complications specific to meniscus surgery include intraoperative damage to the neurovascular bundle at the posterior aspect of the knee during the suturing process. With a medial meniscus repair, there is a risk of damage to the saphenous nerve; with a lateral meniscus repair, there is risk of damage

to the peroneal nerve. Postoperatively, these same nerves can become entrapped by adherent scar tissue.<sup>192,292,293</sup>

A postoperative flexion contracture or extensor lag compromises knee alignment and stability during gait and functional activities. The risk of failure of the repair is greatest during activities that involve joint loading and knee flexion beyond 45° and highest during the first few postoperative months.<sup>179,285</sup>

## Postoperative Management

Factors that influence the components and progression of postoperative rehabilitation after meniscus repair are noted in Box 21.14.<sup>51,111,179,203</sup> Some variables permit relatively rapid rehabilitation, whereas others necessitate a more cautious progression. For example, exercise and weight bearing are progressed more rapidly after repair of a peripheral zone tear than after a central tear and after a single tear than after a complex pattern tear.

Malalignment of the knee affects compressive forces on a repaired meniscus and thus influences the progression of weight bearing during ambulation and exercise. With varus alignment, a repaired medial meniscus is subjected to increased stress and increased risk of displacement during healing. In such a case, weight bearing must be progressed more slowly than when there is normal knee alignment.<sup>51</sup>

**NOTE:** Although timelines vary somewhat in published postoperative guidelines, the progression of exercises presented in the following rehabilitation program is appropriate after *isolated* meniscus repair in a stable knee. These same guidelines are appropriate after meniscal transplantation, although the duration of rehabilitation and protection of the transplanted meniscus is extended.<sup>111,227</sup> If a concomitant procedure such as ligament reconstruction is performed, adjustments to protect the affected structure will be necessary.

### Immobilization, Protective Bracing, and Weight Bearing

**Immobilization and protective bracing.** The knee is maintained in full extension in the postoperative immobilizer and then in a long-leg brace after the compression dressing is

#### BOX 21.14 Factors Influencing the Progression of Rehabilitation After Meniscus Repair

- Location and size of the tear (i.e., the zone[s] affected and their vascularity)
- Type of tear (tear pattern and complexity)
- Type of surgical fixation device used
- Alignment of the knee joint (normal, varus, valgus)
- Concomitant injuries (ligament, chondral defect) with or without reconstruction or repair

removed a few days after surgery.<sup>51,111,292</sup> Occasionally, for carefully selected patients with a peripheral zone repair, no protective bracing is used after the postoperative dressing is removed.<sup>192</sup> Thigh-high compression stockings to control swelling may be worn.

To protect the repaired meniscus during the first few postoperative weeks, the range-limiting long-leg brace is worn continuously (day and night) and locked in full extension. The brace can be unlocked periodically during the day to initiate early ROM exercises and for bathing. Depending on the site of the lesion and repair, flexion motion is kept between 0° to no more than 90° for 2 weeks or longer. Thereafter, weekly 10° increases in flexion ROM are allowed until full flexion has been achieved.<sup>111</sup> The brace is unlocked throughout the day as early as 2 weeks postoperatively if the patient has achieved full knee extension.

After a central zone repair, the patient typically wears the brace for about 6 weeks or until adequate quadriceps control has been reestablished. After a meniscal transplant, the brace may be worn even a few weeks longer.

**Weight bearing.** Following a peripheral zone repair, partial weight bearing (ranging from 25% to 50%) during ambulation with crutches and with the brace locked in full extension is allowed during the immediate postoperative period (first 2 weeks).<sup>111</sup> The percent of body weight permitted during weight bearing is lower and progressed more cautiously after a central zone repair or meniscus transplantation. If quadriceps control is sufficient, full weight bearing may be permitted by 4 weeks after a peripheral repair<sup>111</sup> and by 6 to 8 weeks after a central repair or transplantation.<sup>51,111,179,206,227</sup>

### FOCUS ON EVIDENCE

A recent literature review compared outcomes of “standard” with “accelerated” rehabilitation programs following meniscus repairs.<sup>142</sup> In the standard programs, knee ROM and weight bearing were delayed for a period of time after surgery, whereas in the accelerated programs, ROM and weight bearing as tolerated were permitted immediately after surgery. The review found no deleterious effects from accelerated rehabilitation and no significant differences in patient outcomes between the standard versus accelerated groups. Importantly, there were conflicting timeframes for the rate of progression of knee motion and weight bearing across studies. Therefore, ROM and weight bearing must be progressed gradually, regardless of the procedure, and must be based on the patient’s signs and symptoms.

### Exercise: Maximum Protection Phase

Exercises and gait training with crutches begin the first postoperative day. A standard approach to control pain, joint effusion, and vascular complications is used. Patient education focuses on establishing a home exercise program and reinforcing weight-bearing precautions. Exercise precautions are noted in Box 21.15.<sup>51,111,179,292,293</sup>

## BOX 21.15 Exercise Precautions After Meniscus Repair\*

### General Precautions

- Progress exercises and weight bearing more gradually after central zone meniscus repairs or meniscus transplantations than after peripheral zone repairs.
- If the patient experiences a clicking sensation in the knee during exercise or weight-bearing activities, report it immediately to the surgeon.

### Early and Intermediate Rehabilitation

- Increase knee flexion gradually, especially after a central zone repair.
- If a stationary bicycle is used for cardiopulmonary conditioning, set the seat height as high as possible to limit the range of knee flexion.
- During weight-bearing exercises, such as lunges and squats, do not perform knee flexion beyond 45° for 4 weeks or beyond 60° to 70° for 8 weeks. Flexion beyond 60° to 70° places posterior translation forces on a repaired meniscus, increasing the risk of displacement during early healing.
- Postpone use of a leg press machine until about 8 weeks. Limit motion from 0° to 60°.
- Avoid twisting motions during weight-bearing activities.
- Postpone hamstring curls until about 8 weeks.

### Advanced Rehabilitation

- Do not perform exercises that involve deep squatting, deep lunges, twisting, or pivoting for at least 4 to 6 months. (The greater the flexion angle, the greater the stress on the meniscus.)
- Do not begin jogging or running program until 5 to 6 months.

### Return to Activity

- Refrain from recreational and sports activities that involve repetitive, high joint compressions and shear forces.
- Avoid prolonged squatting in full flexion.

\*These precautions also are applicable after meniscus transplantation, but time frames for the precautions are extended.

**Goals.** During the first 4 weeks after surgery, exercise goals are to regain functional ROM, prevent patellar restrictions, reestablish control of knee musculature, restore postural stability, improve strength and flexibility of the hip and ankle, and maintain cardiopulmonary fitness. By 4 weeks, the patient should achieve full, active knee extension. Recommendations for maximum flexion during the first 2 weeks vary from 60° to 90°.<sup>29,51,111,179,292</sup> After 4 weeks, the patient should attain 120° of knee flexion.<sup>111</sup>

**Interventions.** During the first 4 weeks after meniscus repair, the following interventions are included:<sup>29,51,111,179</sup>

- **Knee ROM.** CPM may be prescribed at the surgeon’s discretion. The day after surgery, begin A-AROM and AROM exercises of the knee within a protected range. Knee flexion may be restricted by a hinged, range-limiting brace. Include

exercises such as gravity-assisted knee flexion in a sitting position and with assistance, then progress to active heel slides in a supine position.

- **Patellar mobility.** Teach the patient grade I and II patellar gliding exercises.
- **Activation of knee musculature.**
  - Emphasize quadriceps control in full extension with quadriceps-setting exercises, assisted SLRs in the supine position, and assisted progression to active open-chain knee extension/flexion in a sitting position for concentric/eccentric quadriceps control. Augment quadriceps activation with neuromuscular electrical stimulation or biofeedback.
  - Perform hamstring-setting exercises and multiple-angle isometrics.
- **Neuromuscular control/responses, proprioception, and balance.**
  - Begin balance training in a standing position within the limits of weight-bearing restrictions and with the brace locked in extension.
  - Emphasize trunk and lower extremity stabilization exercises.
  - When it is permissible to unlock the brace during carefully controlled weight bearing, initiate bilateral closed-chain exercises, such as minisquats and standing wall slides, initially limiting flexion to no more than 45°.
- **Flexibility and strength of the hip and ankle musculature.**
  - Stretch the hamstrings and plantarflexors, if restricted.
  - Begin gluteal and adductor setting exercises the first postoperative day. Perform four-position SLRs with the brace locked or with the brace unlocked when the patient can perform an SLR in supine position without an extensor lag.
  - Perform bilateral heel raises when 50% weight bearing on the operated extremity is permitted.
- **Cardiopulmonary function.** Use an upper body ergometer for aerobic conditioning exercises.

**Criteria to progress to next phase.** The following criteria should be met:

- Minimal joint effusion and pain
- Evidence of superior gliding of the patella with quadriceps setting
- Full, active knee extension (no extensor lag)
- Approximately 120° of knee flexion

### FOCUS ON EVIDENCE

A CPG for meniscal and articular cartilage lesions reports moderate evidence supporting the use of therapeutic exercise for strengthening, endurance, and functional performance for patients who have undergone a surgical meniscectomy and for the application of neuromuscular electrical stimulation to increase muscle strength in patients with meniscal or chondral injuries. All other recommendations regarding

interventions for patients with meniscus or cartilage lesions were weak or conflicting.<sup>158</sup>

### Exercise: Moderate Protection/Controlled Motion Phase

The moderate protection phase extends from 4 to 6 weeks to about 12 weeks postoperatively. The knee brace is discontinued at about 6 to 8 weeks if there is adequate control of the knee and no extensor lag. Use of a cane or single crutch is advisable to provide some degree of protection during ambulation.

**Goals.** Restoring full knee ROM; improving lower extremity flexibility, strength, and muscular endurance; continuing to reestablish neuromuscular control and balance; and improving overall aerobic fitness are emphasized during the moderate protection phase of rehabilitation.

**Interventions.** Include and progress the following exercises and activities during the intermediate phase of rehabilitation:<sup>29,51,111,179</sup>

- **ROM.** Progress low-load, long-duration stretching exercises if the patient is having difficulty achieving full knee ROM.
- **Muscle performance (strength and muscular endurance).**
  - Initiate stationary cycling against light resistance.
  - Use elastic resistance for low-intensity, open-chain, and closed-chain exercises.
  - Progress hip- and ankle-strengthening exercises. Emphasize strengthening of the hip abductors and extensors.
- **Neuromuscular control/responses, proprioception, and balance.** With each of these activities, emphasize maintaining proper lower extremity alignment.
  - Continue or—if not initiated previously—begin closed-chain exercises. Add disturbed balance activities (perturbation training) standing on an unstable surface, such as a minitrampoline or BOSU.
  - When full weight bearing is permissible, begin unilateral balance activities, partial lunges, step-ups, and step-downs. Practice walking on an unstable surface, such as high-density foam rubber.
  - Initiate low-intensity agility drills.
- **Flexibility of the hip and ankle.** Stretch the IT band and rectus femoris after the patient has achieved full knee flexion with hip flexion.
- **Cardiopulmonary fitness.** Begin stationary cycling or a pool-walking program at the beginning of this phase. Initiate treadmill training, land walking, a cross-country ski machine or elliptical trainer at around 9 to 12 weeks.
- **Functional activities.** Gradually resume light functional activities during this phase.

**Criteria to progress to next phase.** By 12 to 16 weeks postoperatively, the following criteria should be met:

- No pain or joint effusion
- Full, active knee ROM
- Lower extremity strength (maximum isometric contraction): 60% to 80% compared to the contralateral side

### Exercise: Minimum Protection/Return to Function Phase

Some degree of protection is still warranted at the beginning of the final phase of rehabilitation, which typically begins at around 12 to 16 weeks and may continue until 6 to 9 months. The return to a high level of physical activity depends on achieving adequate strength, full, nonpainful ROM, and an acceptable clinical examination.<sup>51,111,179</sup>

**Goals.** The primary goal of this phase is to prepare the patient to resume a full level of functional activities using normal movement patterns while continuing patient education to reinforce the importance of selecting activities that do not overstress the repaired meniscus (see Box 21.15).

**Interventions.** During advanced resistance training, focus on movement patterns that simulate functional activities. Begin and gradually progress drills, such as plyometric training and agility drills, to improve power, coordination, and rapid response times. Continue to stress the importance of proper trunk and lower extremity alignment. Increase the duration or intensity of the aerobic conditioning program. Transition from a walking program to a jogging/running program, if desired, at about 4 to 6 months. A detailed progression of aerobic conditioning activities after meniscus repair is available in published resources.<sup>111,179</sup>

### Outcomes

Medial or lateral meniscus repair is a well-tested procedure that results in predictably successful outcomes, particularly for suture repair of a peripheral zone tear.<sup>111,192,293</sup> Although repairing tears that extend into the central zone has less predictable results, there is increasing evidence that these repairs heal well and provide long-term relief of symptoms.<sup>203,204</sup>

Although the various surgical techniques used and the frequency of concomitant pathologies and surgeries make it difficult to compare across studies, several generalizations can be made. One of the most important factors influencing outcomes of meniscus repair is the status of the ACL. When an ACL injury occurs in combination with a meniscus tear, patients who undergo ACL reconstruction have better outcomes than patients with ACL deficiency. Recurrent tears of a repaired meniscus occur more frequently in an ACL-deficient knee than in an ACL-stable knee.<sup>204,293</sup>

Although the patient's age is cited as a factor influencing surgical decisions regarding meniscal repairs, a study by Noyes and colleagues<sup>203</sup> demonstrated high success rates following repair of central zone tears in a group of patients 40 years of age or older. With regard to postoperative rehabilitation, no single protocol has been shown to result in superior outcomes.<sup>293</sup>

Lastly, short-term results of meniscus transplantation with an allograft appear to be promising but are challenging to summarize because of evolving surgical techniques. Long-term effectiveness of current-day procedures has yet to be determined.<sup>91,206,227</sup>

## Partial Meniscectomy

### Indications for Surgery

The following are indications for partial meniscectomy as a surgical option for a meniscus tear:<sup>292</sup>

- A displaced tear of the meniscus that is associated with pain and locking of the knee sustained by an older, inactive individual
- A tear extending into the central, less vascular third of the meniscus that is not determined repairable when arthroscopically visualized and probed
- A tear localized to the avascular inner third of the meniscus

### Procedure

Arthroscopic meniscectomy is usually performed under local anesthesia on an outpatient basis. Small portal incisions are made and saline is injected through one of the portals to distend the knee. The torn portion of the meniscus is identified, grasped, and divided endoscopically by knife or scissors and removed by vacuum. Intra-articular debris or loose bodies are also removed. After the knee is irrigated and drained, skin incisions at the portal sites are closed, and a compression dressing is applied.<sup>285,292</sup>

### Postoperative Management

The overall goal of rehabilitation after partial meniscectomy is to restore ROM of the knee and develop strength in the lower extremity to reduce stresses on the knee and protect its articular surfaces. The progression of exercises and functional activities depends on the patient's presenting signs and symptoms.

### Immobilization and Weight Bearing

A compression dressing is placed on the knee, but it is not necessary to immobilize the knee postoperatively. For the first few postoperative days, cryotherapy, compression, and elevation of the operated leg are used to control edema and pain. Weight bearing is progressed as tolerated.<sup>51,292</sup>

### Exercise: Maximum and Moderate Protection Phases

Although the ideal situation is to begin exercise instruction on the day of or after surgery, most patients do not see a therapist for supervised exercise immediately after an outpatient procedure. When a patient is referred for supervised therapy, the emphasis is often placed on establishing a home exercise program. Under these circumstances, it is preferable to teach the patient initial exercises to reduce atrophy and prevent contracture *preoperatively*, so he or she can initiate the exercises at home immediately after surgery.

There is no need for an extended period of maximum protection following arthroscopic partial meniscectomy because there is little soft tissue trauma during surgery. Moderate protection is warranted for approximately 3 to 4 weeks. All exercises and weight-bearing activities should be pain free and progressed gradually during the first few postoperative weeks.<sup>29</sup>

**Goals.** During the early phase of rehabilitation, the emphasis of treatment is to control inflammation and pain, reestablish independent ambulation, and restore knee control and ROM.

**Interventions.** Immediately after surgery, begin muscle-setting exercises, SLRs, active knee ROM, and weight bearing as tolerated. Full weight bearing is usually achieved by 4 to 7 days, and at least 90° of knee flexion and full extension are attained by 10 days. Initiate closed-chain exercises and stationary cycling a few days after surgery, or as pain and weight bearing status allow, with the goal of regaining dynamic strength and endurance.

**PRECAUTION:** Patients who have undergone partial meniscectomy must be cautioned not to progress themselves too quickly. An accelerated progression of exercise can cause recurrent joint effusion and may damage articular cartilage.

### Exercise: Minimum Protection/Return to Function Phase

By 3 or 4 weeks postoperatively, minimum protection of the knee is necessary, but full, pain-free, active knee ROM and a normal gait pattern should be achieved before progressing to high-demand exercises. Resistance training, endurance activities, bilateral and unilateral closed-chain exercises, and proprioceptive/balance training to develop neuromuscular control can all be progressed rapidly. Advanced activities such as plyometrics, maximum effort isokinetic training, and simulated high-demand functional activities can be initiated as early as 4 to 6 weeks or 6 to 8 weeks postoperatively with emphasis on reestablishing normal mechanics in movement.

**PRECAUTION:** High-impact weight-bearing activities such as jogging or jumping, if included in the program, should be added and progressed cautiously to prevent articular damage. Improper lower extremity alignment during weight bearing, such as valgus collapse and/or pelvic drop should be corrected prior to advancing with plyometric and high-impact activities.

## Exercise Interventions for the Knee

Strength and flexibility imbalances between muscle groups can be caused by several factors such as disuse, faulty joint mechanics, joint swelling, immobilization (due to fracture, surgery, or trauma), and nerve injury. In addition to the hamstrings and rectus femoris, most of the two-joint muscles that cross the knee function primarily at the hip or the ankle, yet have an effect on the knee. If there is an imbalance in length or strength in the hip or ankle muscles, altered mechanics may manifest throughout the lower extremity.<sup>113,253</sup> Refer to the chapters on the hip and the ankle and foot for a complete picture of these interrelationships.

## Exercise Techniques to Increase Flexibility and Range of Motion

When attempting to increase ROM, the mechanics of the tibiofemoral and patellofemoral joints and their importance in lower extremity function must be respected. Because the knee is a weight-bearing joint, mobility coupled with adequate strength and stability is necessary for normal function.

Principles of passive stretching and PNF stretching are presented in Chapter 4, joint mobilization/manipulation of the extremities is described in Chapter 5, and techniques directed toward specific tibiofemoral joint and patella restrictions are presented earlier in this chapter. Additional manual and self-stretching techniques to increase knee ROM are described in this section.

### To Increase Knee Extension

Decreased extensibility of the hamstring musculature and periarticular tissue posterior to the knee can restrict full knee extension. Increasing knee extension is a two-step process. First, full extension of the knee is obtained without placing tension on the hamstrings at the hip by maintaining the hip at or near 0° extension. After full knee extension has been attained, a stretch is applied to the two-joint hamstring muscle group by progressively flexing the hip while maintaining the knee in extension (SLR position). Techniques to stretch the hamstrings using SLRs are described in Chapter 4 and the exercise section of Chapter 20.

### PNF Stretching Techniques

- **Patient position and procedure:** Supine, with the hip and knee extended as much as possible. Have the patient perform an isometric contraction of the knee flexors as you resist with your hand placed proximal to the heel. Then ask the patient to relax as you passively extend the knee into the newly gained range, or have the patient actively extend the knee as far as possible (hold-relax and hold-relax/agonist-contraction techniques, respectively).
- **Patient position and procedure:** Prone, with the hip and knee extended as much as possible. Place a small pad or folded hand towel under the femur proximal to the patella to protect the patellofemoral joint from compressive forces. Stabilize the pelvis to prevent hip flexion, and then apply the hold-relax technique to increase knee extension.

### Gravity-Assisted Passive Stretching Techniques

Use a low-intensity, long-duration stretch to ensure that the patient stays as relaxed as possible.

#### Prone Hang

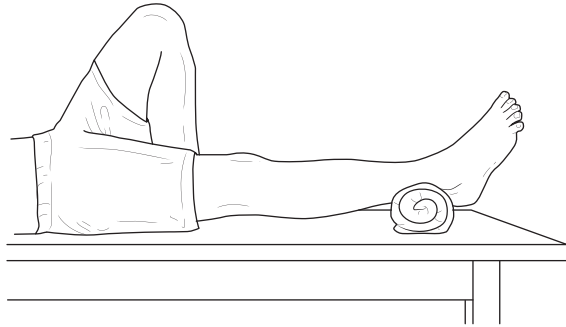

**Patient position and procedure:** Prone, hips extended with the patient's foot off the edge of the treatment table. Place a

rolled towel under the patient's femur just proximal to the patella and a cuff weight around the ankle. As the muscle relaxes, the weight places a sustained passive stretch on the hamstrings, which increases knee extension.

### Supine Heel Prop

**Patient position and procedure:** Supine, with the knee extended as far as possible. Place a rolled towel or padding under the distal leg and heel to elevate the calf and knee off the table (Fig. 21.18). For a sustained stretch, secure a cuff weight across the distal femur but proximal to the patella to avoid patellar compression.

**FIGURE 21.18** Heel prop in supine to increase knee extension. A cuff weight or sandbag placed across the distal femur increases the stretch force.

**NOTE:** This position is not effective for severe knee flexion contractures. Use it only for restrictions that are near the end of the range of knee extension.

### Self-Stretching Technique

**Patient position and procedure:** Long-sitting, with the distal leg supported on a rolled towel. Have the patient press down with the hands against the femur just above (not on) the patella to cause a sustained force to increase knee extension.

## To Increase Knee Flexion

Before stretching to increase knee flexion, be sure the patella is mobile and is able to glide distally in the trochlear groove as the knee flexes; otherwise, it restricts knee flexion. Patellar mobilization techniques to increase patellar gliding are described in Chapter 5 (see Figs. 5.53 and 5.54). Techniques to increase mobility of the IT band at the knee to improve patellar tracking are described later in this section. Once full range of knee flexion is restored, the two-joint rectus femoris and TFL muscles should be stretched across the hip joint while maintaining the knee in flexion. These techniques are described in Chapter 20.

### PNF Stretching Techniques

**Patient position and procedure:** Sitting, with the knee at the edge of the treatment table and flexed as far as possible. Place your hand just proximal to the ankle and manually resist an isometric contraction of the knee extensors. Have the patient relax as you passively flex the knee to the end of the range, or have the patient actively flex as far as possible.

### Gravity-Assisted Passive Stretching Technique

**Patient position and procedure:** Sitting with the lower legs dangling and knee flexed to the end of the available range. Instruct the patient to relax the thigh muscles and let the weight of the leg create a low-intensity, long-duration stretch. Place a light cuff weight around the distal leg to increase the stretch force.

### Self-Stretching Techniques

#### Gravity-Assisted Supine Wall Slides

**Patient position and procedure:** Supine, with buttocks close to the wall and lower extremities resting vertically against the wall (hips flexed, knees extended). Have the patient slowly flex the involved knee by sliding the foot down the wall until a gentle stretch sensation is felt. Hold the position for a period of time, then slide the foot back up the wall (Fig. 21.19).

**FIGURE 21.19** Gravity-assisted supine wall slide. The patient flexes the knee to the limit of its range and holds it there for a sustained stretch.

#### Self-Stretch With Uninvolved Leg

**Patient position and procedure:** Sitting with legs dangling over the edge of a bed and ankles crossed. Using the uninvolved leg, have the patient apply sustained pressure to the involved leg just above the ankle to increase knee flexion.

#### Rocking Forward on a Step

**Patient position and procedure:** Standing, with the foot of the involved knee on a step. Have the patient rock forward over the stabilized foot, flexing the knee to the limit of its range, then rock back and forth in a slow, rhythmic manner, or sustain the stretched position (Fig. 21.20). Begin with a low step or stool; increase the height as more range is obtained.

**FIGURE 21.20** Self-stretching on a step to increase knee flexion. The patient places the foot of the involved side on a step, then rocks forward over the stabilized foot to the limit of knee flexion to stretch the quadriceps femoris muscle. A higher step is used for greater flexion.

**PRECAUTION:** Do not allow the patient to move into a position that causes pinching at the anterior aspect of the ankle.

### Sitting

**Patient position and procedure:** Sitting in a chair, with the involved knee flexed to the end of its available range and the foot firmly planted on the floor. Have the patient move forward in the chair, not allowing the foot to slide. Hold the position for a comfortable, sustained stretch of the knee extensors (Fig. 21.21).

**FIGURE 21.21** Self-stretching in a chair to increase knee flexion. The patient fixates the foot of the involved leg on the floor and then moves forward in the chair over the stabilized foot to place a sustained stretch on the quadriceps femoris muscle and increase knee flexion.

## To Increase Mobility of the IT Band at the Knee

The IT band is a strong fibrous band of connective tissue that is not easily stretched. Mobility of the IT band distal attachment at the knee is necessary for proper patellar tracking and knee flexion and, if restricted, may contribute to patellofemoral pain or patellar maltracking. The distal attachment of the TFL and approximately one-third of the gluteus maximus insert into the proximal IT band and also affect its mobility. Stretching of these muscles is described in Chapter 20. The “foam roller fascial release” that follows is used to increase the mobility of the IT band and its effect at the knee.

### Foam Roller Fascial Release

**Patient position and procedure:** Side-lying with the involved thigh on a foam roller (dense foam cylinder) positioned perpendicular to the femur. Maintain the hip of the involved side in extension, flex the top hip and knee, and plant the foot on the floor (Fig. 21.22). Have the patient prop on the forearm or hands to lift the trunk and adduct the hip of the involved leg. Then roll the lateral thigh proximally and distally on the roll along the IT band or maintain a sustained pressure against the IT band.

**FIGURE 21.22** Foam roller fascial release for a tight IT band.

**NOTE:** The planted foot, along with the hands, serve to guide the rolling motion and can partially reduce the pressure on the lateral thigh, making the release technique more tolerable.

## Exercises to Develop and Improve Muscle Performance and Functional Control

The primary emphasis of strengthening exercises for the knee muscles are to develop stability and sound patellofemoral and extensor mechanism biomechanics. After stability and patellar mechanics are well established, the emphasis shifts to the coordination and timing of muscle contractions, as well as the endurance needed to perform functional activities. To accomplish this, closed-chain exercises using low-intensity

(low resistance) and a high number of repetitions are more effective than open-chain exercises for improving dynamic functional stability and muscular endurance of the knee.

Although closed-chain control of the knee is essential, remember that the knee functions in both an open- and closed-chain fashion during most daily activities. Not only do the quadriceps and hamstrings function using co-contractions during closed-chain activities, but they also contract independently using concentric and eccentric contractions during functional activities. To be most effective, exercises under all these conditions should be incorporated into a comprehensive knee rehabilitation program. It is also important to change the position of the hip during quadriceps- and hamstring-strengthening exercises to affect the length-tension relationship of the rectus femoris and hamstrings.<sup>74</sup>

- In the exercises that follow, open-chain exercises are described before closed-chain exercises simply because weight bearing after knee injury or surgery is often restricted for a period of time.
- Isolated activation of knee musculature also is necessary for functional activities that involve open-chain movements, such as lifting the leg to get in and out of bed or a car or flexing and extending the knee during dressing.
- The quadriceps has been shown to develop greater strength using resisted open-chain than closed-chain exercises.<sup>288</sup>
- Closed-chain strengthening should be initiated first in partial weight bearing and later in full weight bearing as healing allows and then integrated with balance and proprioceptive training and functional weight-bearing activities.

Considerable research has been done comparing joint reaction forces and muscle function during open- and closed-chain exercises. Comparisons of outcomes are difficult because of differing research designs and exercise variables.<sup>67</sup> Table 21.6 summarizes results from a study comparing two dynamic exercises, with recommendations for exercise modification with specific knee impairments. Special adaptations also have been highlighted in the conservative management and surgical management sections of this chapter.

## Open-Chain (Nonweight-Bearing) Exercises

### To Develop Control and Strength of Knee Extension (Quadriceps Femoris)

A wide variety of static and dynamic exercises can be used to improve the function of the quadriceps femoris muscles in open-chain positions. Because of variations in muscle fiber orientation and attachments of the knee extensor muscles, individual components of the quadriceps femoris muscle group place different biomechanical stresses on the patella.

Although it is not possible to isolate contraction of the different parts of the quadriceps femoris muscle because of the common innervation, emphasis is often placed on activation of the VMO and vastus medialis muscles to prevent potentially harmful lateral patellar tracking. Tactile cues, biofeedback, and electrical muscle stimulation over the VMO may reinforce awareness of the muscle contracting for patellar control.

**TABLE 21.6** Comparison of Forces and Muscle Action at the Knee During Dynamic Open-Chain and Closed-Chain Exercises<sup>67,304</sup>

Parameter	Open-Chain Exercise—Variable Resistance: Sitting, Knee Extension Machine	Closed-Chain Exercise—Variable Resistance: Squatting, Leg-Press Machine (Body Moving Away from Fixed Feet)
Rectus femoris development	More effective	Less effective
VMO development	Less effective	More effective for VMO (and VL)
Other muscle development	None	Effective for hamstrings
ACL tensile forces*	ACL under tension at < 25°	
PCL tensile forces*	PCL under tension from 25°–95° (peak at 1.0 × body weight)	PCL under tension throughout range (1.5–2.0 × body weight)
Patellofemoral compression	Peak stress at 60°, peak compression at 75°‡	Compression increases with knee flexion, peaking at 90°†
Tibiofemoral compression	Higher compression (more stability) < 30°	Higher compression (more stability) > 70°

\*The 0°–25° range should be excluded in open-chain exercises following ACL injury but may be included after PCL injury.

†Squat exercises: exercise only from 0°–50° with patellofemoral dysfunctions.

‡Open-chain exercise from 0°–30° and 75°–90° with patellofemoral dysfunctions. (Note: there is controversy in the literature regarding compressive forces in the patellofemoral joint from 0° to 30°.)

### Quadriceps Setting (Quad Sets)

**Patient position and procedure:** Supine, sitting in a chair (with the heel on the floor) or long-sitting with the knee extended (or flexed a few degrees) but not hyperextended. Have the patient contract the quadriceps isometrically, causing the patella to glide proximally; then hold for a count of 10, and repeat.

- Use verbal cues such as, “Try to push your knee back and tighten your thigh muscle” or “Try to tighten your thigh muscle and pull your kneecap up.” When the patient sets the muscle properly, offer verbal reinforcement immediately and then have the patient repeat the activity.
- Have the patient dorsiflex the ankle and then hold an isometric contraction of the quadriceps.<sup>7</sup>
- Monitor the gluteus maximus to make sure that the patient is not compensating with hip extension as a result of an inhibited quadriceps.

### Straight-Leg Raise

#### CLINICAL TIP

A supine SLR combines dynamic hip flexion with an isometric contraction of the quadriceps. The effective resistance of gravity (or any additional weight added at the ankle) decreases as the lower extremity elevates because of the decreasing moment arm of the resistance force. Consequently, the greatest resistance is encountered during the first few degrees of the SLR and resistance progressively decreases with greater hip flexion. The rectus femoris (which is also a hip flexor) is the primary muscle in the quadriceps group that is active during the SLR exercise.<sup>276</sup>

**Patient position and procedure:** Supine, with the knee extended. To stabilize the pelvis and low back, the opposite hip and knee are flexed, and the foot is placed flat on the exercise table. First, have the patient set the quadriceps muscle, and then lift the leg to about 45° of hip flexion while keeping the knee extended. Have the patient hold the leg in that position for a count of 10 and then lower it.

- To progress, have the patient lift to only 30° and then to only 15° of hip flexion, and hold the position.
- To increase resistance, place a cuff weight around the patient’s ankle.

### FOCUS ON EVIDENCE

It has been proposed that if an SLR in the supine position is coupled with external rotation or isometric adduction of the hip, the VMO or VM muscles are preferentially activated and strengthened.<sup>7,34,56,172</sup> The rationale for advocating these exercises is that many fibers of the VMO muscle originate from the adductor magnus tendon.<sup>7,135</sup> Although a number of authors<sup>6</sup>

have advocated these SLR adaptations to increase the medially directed forces on the patella, there is lack of evidence to substantiate the effect.

### Straight-Leg Lowering

**Patient position and procedure:** Supine. If the patient cannot perform an SLR because of a quadriceps lag or weakness, begin by passively placing the leg in 90° of SLR position (or as far as the flexibility of the hamstrings allows), and have the patient gradually lower the extremity while keeping the knee fully extended.

- Be prepared to control the descent of the leg with your hand under the heel as the torque created by gravity increases.
- If the knee begins to flex as the extremity is lowered, have the patient stop at that point, then raise the extremity upward to 90°.
- Have the patient repeat the motion and attempt to lower the extremity a little farther each time while keeping the knee extended.
- When the patient can keep the knee extended while lowering the leg through the full ROM, SLRs can be initiated.

### Multiple-Angle Isometric Exercises

- **Patient position and procedure:** Supine or long-sitting. Have the patient perform bent leg raises with the knee in multiple angles of flexion.
- **Patient position and procedure:** Seated at the edge of a treatment table. When tolerated, apply resistance just above the ankle to strengthen the quadriceps isometrically in varying degrees of knee flexion. Co-contraction of the quadriceps and hamstrings can be activated (except in the last 10° to 15° of knee extension) by having the patient push the thigh into the table while holding the knee in extension against resistance.<sup>103</sup>

### Short-Arc Terminal Knee Extension

#### CLINICAL TIP

Although in the past it was thought that the VMO was responsible for the terminal phase of knee extension, it is now well documented that all components of the quadriceps femoris muscle group are active throughout active knee extension and that the VMO primarily affects patellar alignment.<sup>276</sup>

**Patient position and procedure:** Supine or long-sitting. Place a rolled towel or bolster under the knee to support it in flexion (Fig. 21.23). The patient can also assume a short-sitting position at the edge of a table with the seat of a chair or a stool placed under the heel to stop knee flexion at the desired angle. Begin with the knee in a few degrees of flexion. Increase the degrees of flexion as tolerated by the patient or dictated by the condition.

- Initially, have the patient extend the knee only against the resistance of gravity. Later, add a cuff weight around the

**FIGURE 21.23** Short-arc terminal extension exercise to strengthen the quadriceps femoris muscle. When tolerated, resistance is added proximal to the ankle.

ankle to increase the resistance if the patient does not experience pain or crepitation.

- Combine short-arc terminal knee extension with an isometric hold and/or a SLR when the knee is in full extension.
- To reduce lateral shear forces at the knee, have the patient invert the foot as he or she extends the knee.<sup>7,101</sup>

**PRECAUTION:** When adding resistance to the distal leg, the amount of force generated by the quadriceps muscle increases significantly in the terminal ranges of knee extension. In this portion of the range, the quadriceps has a poor mechanical advantage and poor physiological length while having to contract against an external resistance force that has a long lever arm. The amount of muscle force generated causes an anterior translation force on the tibia, which is restrained by the ACL. This exercise is not appropriate for a patient during the early phase of postoperative rehabilitation when the reconstructed ligament is most vulnerable to imposed loads.

### Full-Arc Extension

**Patient position and procedure:** Sitting or supine. Have the patient extend the knee from 90° to full extension. Apply resistance to the motion as tolerated.

### CLINICAL TIP

Resistance applied from 90° to 60° in a nonweight-bearing position causes less anterior tibial translation than squatting (a closed-chain activity) in this range. Resistance applied in open-chain extension from 30° to 0°, however, increases anterior translation more than does performing minisquats in the same range.<sup>304</sup>

- Apply resistance through the full arc of motion only during the later phases of rehabilitation if the knee is pain free, stable, and asymptomatic. If there is pain, resistance should be applied only through those portions of the range with no symptoms.
- Various forms of resistance equipment discussed in Chapter 6 can be used to strengthen the knee extensors. Emphasize

high-repetition, low-resistance training with weight-training equipment and medium- to high-velocity training with isokinetic equipment to minimize compressive and shear forces on knee joint structures during exercise. When using equipment, the tibial pad against which the patient pushes while extending the knee can be placed proximally on the lower leg to decrease excessive stress on supporting structures of the knee.<sup>305</sup>

- If a cuff weight is applied to the tibia to provide resistance, it causes a distraction to the joint and stress on the ligaments when the patient sits or lies supine with the knee flexed to 90° and the tibia over the edge of the treatment table. To avoid this stress on ligaments, place a stool under the foot so it is supported when the leg is in the dependent position.<sup>37</sup>

## To Develop Control and Strength of Knee Flexion (Hamstrings)

### Hamstring Setting (Hamstring Sets)

**Patient position and procedure:** Supine or long-sitting, with the knee in extension or slight flexion with a towel roll under the knee. Have the patient isometrically contract the knee flexors by gently pushing the heel into the treatment table just enough to feel tension develop in the muscle group. Have the patient relax and then repeat the contraction.

### Multiple-Angle Isometric Exercises

**Patient position and procedure:** Supine or long-sitting. Apply either manual or mechanical resistance to a static hamstring muscle contraction with the knee flexed to several positions in the ROM.

- Place the tibia in internal or external rotation prior to resisting knee flexion to emphasize the medial or lateral hamstring muscles, respectively.
- Teach the patient to apply self-resistance at multiple points in the ROM by placing the opposite foot behind the ankle of the leg to be resisted.

### Hamstring Curls

- **Patient position and procedure:** Standing, holding onto a solid object for balance. Have the patient lift the foot and flex the knee (Fig. 21.24). Maximum resistance from gravity occurs when the knee is at 90° flexion. Apply resistance with ankle weights or a weighted boot. If the patient flexes the hip, stabilize it by having the patient place the anterior thigh against a wall or solid object.
- **Patient position and procedure:** Prone. Place a small folded towel or piece of foam rubber under the femur just proximal to the patella to avoid compression of the patella between the treatment table and the femur. With a cuff weight around the ankle, have the patient flex the knee to only 90°. Maximum resistance from gravity occurs when the knee first starts to flex at 0°. If hamstring curls are performed in the prone position using manual resistance, a weight-pulley system or isokinetic equipment resistance to the knee flexors can be applied throughout the full range of knee flexion.

**FIGURE 21.24** Hamstring curls; resistance exercises to the knee flexors with the patient standing. Maximal resistance occurs when the knee is at 90°.

**PRECAUTION:** Open-chain hamstring curls performed against resistance placed on the distal tibia cause posterior tibial translation. A patient with a PCL injury or reconstruction should avoid this exercise during the early stages of rehabilitation.

## Closed-Chain (Weight-Bearing) Exercises

Progressive closed-chain exercises are beneficial for activating and training the muscles of the lower extremity to respond to specific functional demands. As the quadriceps contract eccentrically to control knee flexion or concentrically to extend the knee, the hamstrings and soleus function to stabilize the tibia against the anterior translating force of the quadriceps at the knee joint. This synergy, along with the compressive loading on the joints, provides support to the cruciate ligaments.<sup>67,218</sup> In addition, because the hip extends and the ankle plantarflexes as the knee extends (and vice versa) during closed-chain activities, the two-joint hamstrings and gastrocnemius and the one-joint soleus are maintaining favorable length-tension relationships through action at the hip and ankle, respectively.

**Initiation of closed-chain exercises.** During rehabilitation, closed-chain exercises can be incorporated into an exercise regimen as soon as partial or full weight bearing is safe. In certain portions of the ROM, closed-chain strengthening exercises generate less shear force on the knee joint than open-chain quadriceps-strengthening activities. Therefore, resistance can be added to closed-chain activities sooner after injury or surgery than can be added to open-chain exercises while still protecting healing structures such as the ACL. Clinically, closed-chain exercises enable the patient to develop

strength, endurance, and stability of the lower extremity in functional patterns sooner after knee injury or surgery than do open-chain exercises. The progression of closed-chain exercises described in Chapter 20 is also appropriate for knee rehabilitation programs.

**Partial weight-bearing and support techniques.** If the patient does not tolerate or is not permitted to bear full weight on the involved extremity, begin exercises with upper extremity assistance, such as in the parallel bars or in a pool, to partially unload body weight and avoid excessive biomechanical stress. Also consider use of supportive taping techniques or bracing to ensure proper alignment during weight bearing. Begin exercises at a level tolerated by the patient and at which there is complete control and no exacerbation of symptoms.

### CLINICAL TIP

Because the knee is the intermediate link in the lower extremity chain, it is significantly influenced by hip and trunk function, as well as foot and ankle function, during weight bearing.<sup>113,234</sup> Therefore, exercises for these regions should be included in the rehabilitation of the knee if impairments are detected during the examination. Specifically, look for:

- Tightness of the TFL, gluteus maximus, rectus femoris, hamstrings, or gastrocnemius-soleus muscle group
- Weakness of the gluteus medius, external rotators, or gluteus maximus

## Closed-Chain Isometric Exercises

Closed-chain isometric exercises are done to facilitate co-contraction of the quadriceps and hamstrings.

### Setting Exercises for Co-Contraction

**Patient position and procedure:** Sitting on a chair, with the knee extended or slightly flexed and the heel on the floor. Have the patient press the heel against the floor and the thigh against the seat of the chair and concentrate on contracting the quadriceps and hamstrings simultaneously to facilitate co-contraction around the knee joint. Hold the muscle contraction, relax, and repeat. Use biofeedback to enhance learning of the co-contraction.

### Alternating Isometrics and Rhythmic Stabilization

**Patient position and procedure:** Standing, with weight equally distributed through both lower extremities. Apply manual resistance to the pelvis in alternating directions as the patient holds the position. This facilitates isometric contractions of muscles in the ankles, knees, and hips.

- Increase the speed of application of the resistive forces to train the muscles to respond to sudden shifts in forces.
- Progress the stabilization activity by applying the alternating resistance against the shoulders to develop trunk stabilization and then by having the patient bear weight only on the involved lower extremity while resistance is applied.

- Progress to weight bearing on unstable surfaces as balance and stability improve.

### Closed-Chain Isometrics Against Elastic Resistance

**Patient position and procedure:** Standing on the involved extremity, loop elastic resistance around the thigh of the opposite extremity and secure it to a stable object (see Fig. 20.26 in Chapter 20). Have the patient flex and extend the hip of the nonweight-bearing lower extremity at varying speeds to facilitate co-contraction of muscles and stability of the weight-bearing leg. This closed-chain exercise also facilitates proprioceptive input and balance on the weight-bearing (involved) lower extremity.

### Closed-Chain Dynamic Exercises

#### Scooting on a Wheeled Stool

**Patient position and procedure:** Sitting on a rolling stool or chair. Have the patient “walk” the feet forward to use the hamstrings or “walk” backward to use the quadriceps (Fig. 21.25). Be certain the knee is aligned vertically over the foot to avoid hip adduction, internal rotation, and subsequent valgus alignment of the lower leg.

- Increase the challenge of the exercise by having the patient steer around an obstacle course, roll the stool across carpeting, or pull against a resistance, such as pulling another person who is also on a rolling stool.

**FIGURE 21.25** Forward scooting on a wheeled stool to strengthen knee flexors and backward scooting to strengthen knee extensors.

**NOTE:** Patient position is standing in all of the following exercises.

#### Unilateral Closed-Chain Terminal Knee Extension

**Patient position and procedure:** Standing, elastic resistance looped around the distal thigh of the involved extremity and secured to a stationary structure (Fig. 21.26). Have the patient

**FIGURE 21.26** Unilateral closed-chain terminal knee extension.

actively perform terminal knee extension while bearing partial to full weight on the involved extremity.

#### Partial Squats, Minisquats, and Short-Arc Training

**Patient position and procedure:** Begin by having the patient flex both knees up to 30° to 45° and then return to full extension. Progress by holding elastic resistance that is secured under both feet (Fig. 21.27 A) or by holding weights in the hands. The patient should maintain the trunk upright, concentrate on maintaining a posterior weight shift, and lower the hips as though sitting down before moving the knees. The knees should maintain alignment with the toes to prevent valgus collapse and should not move forward beyond the toes to ensure gluteal activation and decreased patellofemoral joint forces.

- Progress squats to greater ranges of knee flexion during the advanced phases of treatment if necessary.
- Increase the difficulty of the exercise by performing unilateral resisted minisquats (Fig. 21.27 B) or squatting on unstable surfaces. Advanced activities are described and illustrated in Chapter 23.

#### Standing Wall Slides

**Patient position and procedure:** Standing, with back against the wall (see Fig. 20.29 A in Chapter 20). Flex the hips and knees and slide the back down and then up the wall, lowering and lifting the body weight.

- Apply elastic resistance around both thighs just proximal to the knees to provide added resistance to the hip abductors. This encourages the patient to maintain knee alignment over the toes to prevent or correct a valgus collapse.
- As control improves, have the patient move into greater knee flexion, up to a maximum of 60°. Knee flexion beyond 60° is not recommended to avoid excessive tibiofemoral joint shear forces and patellofemoral joint compressive forces.

**FIGURE 21.27** Resisted minisquats using elastic resistance; closed-chain short-arc training in (A) bilateral stance and (B) unilateral stance.

- Add isometric training by having the patient stay in the partial-squat position. If the patient is able, he or she maintains the partial squat and alternately extends one leg and then the other.
- Wall slides performed with a gym ball behind the back decrease stability and require greater control (see Fig. 20.29 B in Chapter 20).
- Increase the difficulty of the exercise by performing wall slides in unilateral stance (see Fig. 23.29 in Chapter 23).

### Forward, Backward, and Lateral Step-Ups and Step-Downs **VIDEO 21.1**

**Patient position and procedure:** Begin with a low step, 2 to 3 inches in height, and increase the height as the patient is able. Make sure the patient keeps the trunk upright and the knee aligned vertically over the foot to avoid valgus collapse.

- To reinforce proper lower extremity alignment and stimulate firing of the gluteus medius during forward step-ups, apply a graded manual resistive force to the lateral aspect of the forward thigh (Fig. 21.28 A).
- Emphasize control of body weight during concentric (step-up) and eccentric (step-down) quadriceps activities. To emphasize the quadriceps and minimize pushing off with the plantarflexors of the trailing extremity, teach the patient that the trailing heel must be the last to leave the floor and the first to return.
- Add resistance with a weight belt or handheld weights, or place elastic resistance (Fig. 21.28 B) or a belt attached to a pulley system around the patient's hips.
- Progress to stepping up to or down from higher surfaces, and add rotational movements.

### **FOCUS ON EVIDENCE**

An EMG study<sup>9</sup> of five weight-bearing exercises in single-leg stance demonstrated the following quadriceps recruitment from greatest activation to least (66% to 55% MVIC): wall squat (wall slide), forward step-up, minisquat, reverse step-up, and lateral step-up.

A kinematic study evaluating patellar joint forces and stress during forward step-up, lateral step-up and forward step-down activities showed the peak PF joint stress was greatest during the eccentric phase (by 7%) in the forward step-down due to a higher knee extensor moment when compared to the two step-up activities.<sup>42</sup>

### Partial and Full Lunges

Lunges may be performed by varying the length of the stride, by stepping into a lunge and bringing the trailing leg forward, or by stepping into a lunge and pushing back to the starting position. In addition, maintaining the lunge position and raising and lowering the body with the trunk erect will progress the exercise.

**Patient position and procedure:** Begin with the feet together, and then have the patient lunge forward with the involved extremity using a small stride and a small amount of knee flexion (see Fig. 20.32). Then return to the upright position by extending the knee and bringing the foot back beside the other foot. As the patient gains control, increase the stride length and knee flexion accordingly.

- Maintain the knee in alignment with the toes (to avoid hip adduction and internal rotation), and do not flex the forward leg beyond a vertical line coming up from the toes.<sup>68</sup>

**FIGURE 21.28 (A)** A forward step-up with manual pressure applied to the lateral thigh to reinforce proper lower extremity alignment and stimulate the gluteus medius. **(B)** Resisted step-ups against elastic resistance or a pulley to strengthen knee extensors.

- To increase the challenge, add weights around the trunk or in the patient's hands, and increase the speed of the activity as control improves.
- Progress by having the patient lunge forward in a diagonal direction, then out to the side, then diagonally backward, and then directly backward. (See Chapter 23 for descriptions and illustrations of advanced progressions.)

## Functional Progression for the Knee

To prepare for functional activities, it is important to develop adequate strength, stability, power, muscular and cardiopulmonary endurance, coordination and timing of movements, and the ability to control balance and to respond to expected or unexpected perturbations. Each of these elements is necessary for skill acquisition. The principle of specificity of training is applied to progress the patient's activities toward the desired functional outcomes. A brief summary of the key components of a functional progression for knee rehabilitation follows, with references to other chapters for additional information.

### Strength and Muscle Endurance Training

**Strength.** Advanced strengthening often involves high-load eccentric exercises or velocity-spectrum training. Resistance equipment, such as a leg press unit, a Total Gym® unit, or an isokinetic dynamometer, provide progressive loading of knee musculature beyond that of elastic resistance and cuff weights. During high-load, open-chain knee extension exercises, placing the tibial pad of the dynamometer close to the knee joint reduces anterior shear forces on the knee.<sup>305</sup>

**Muscular endurance.** To improve muscular endurance, exercises previously described in this chapter are progressed by

increasing the number of repetitions or the time spent at each resistance level. Equipment typically used for cardiopulmonary training, such as a treadmill, stationary bicycle, or stair-stepping unit, also can be used to develop lower extremity muscular endurance. Characteristics of exercise regimens designed to progressively develop strength and muscular endurance and features of various types of equipment are addressed in Chapters 6 and 7.

### Cardiopulmonary Endurance Training

A progression of aerobic activities, such as swimming, cycling, walking, running and using an upper extremity ergometer, elliptical trainer, stair-stepper, or cross-country ski machine are graded to the patient's tolerance and integrated into a rehabilitation program for cardiopulmonary endurance. These activities also increase muscular endurance in multiple muscle groups. If the patient is planning on returning to a sport activity, choose a conditioning activity that best replicates the muscle activity used. Refer to Chapter 7 for training guidelines.

### Balance and Proprioceptive Activities (Perturbation Training)

A progression of balance activities requiring trunk and lower extremity control is an essential component of a rehabilitation program to improve or restore a patient's functional capabilities.<sup>75,76,294,309</sup> As soon as partial to full weight bearing is permitted, balance training can progress from basic activities in bilateral stance on a stable surface to more challenging activities in unilateral stance on unstable surfaces. Examples include stabilization exercises against alternating resistive forces; maintaining balance during multidirectional arm movements; and controlled weight shifting, stepping, and

marching movements, to more challenging activities in unilateral stance on unstable surfaces. A sequence of activities for postural control and progressive balance training is described and illustrated in Chapters 8, 16, and 23.

### Plyometric Training and Agility Drills

**Plyometrics.** Plyometric training, also referred to as stretch-shortening drills, is designed to improve power and develop quick neuromuscular responses. This form of training is appropriate during the advanced phase of rehabilitation for selected patients intending to return to high-demand work- or sport-related activities. Training involves high-speed movements and quick changes of direction. Examples of lower extremity plyometric training include forward-backward and side-to-side shuffles, use of a Pro-Fitter<sup>®</sup>, and jumping on and off surfaces of varying heights and landing using proper mechanics to reduce the risk of injury. Refer to Chapter 23 for a progression of lower extremity plyometric activities.

**Agility.** Agility drills are designed to develop coordination, balance, and quick neuromuscular responses. Drills involve practicing activities that include directional changes at varying

speeds of movement. Activities include maneuvering around or stepping over obstacles in the environment first while walking and then while running, pivoting, cutting, or hopping. Examples of agility drills are in Chapter 23.

### Simulated Work-Related Activities and Sport-Specific Drills

A final component of an individualized rehabilitation program involves practicing activities that simulate the physical demands of a patient's work or desired recreational or sport activity. Simulated activities and drills enable a patient to practice under supervised conditions to receive feedback on correct mechanics. For example, the patient returning to a repetitive lifting job should practice activities that develop strength and endurance in the trunk stabilizers and hip and knee extensors while maintaining safe body mechanics.

Examples of early balance activities for the lower extremity are described in the exercise section of Chapter 20. A progression of lifting tasks and application of proper body mechanics are described in Chapters 8 and 16. Descriptions of sport-specific drills are beyond the scope of this textbook but can be found in a number of resources.

## Independent Learning Activities

### Critical Thinking and Discussion

- Consider each of these functional activities: Putting on socks and shoes, rising from a chair, climbing on to a city bus.
  - What ROM is needed in the knee joint for each activity?
  - If motion is restricted in either flexion or extension, what muscles may also have decreased mobility? What arthrokinematic motions may also be limited?
  - What muscles are functioning during the activities, and what level of strength is needed?
- Describe an intervention program to address loss of strength and/or ROM that is limiting these activities. What is the logical progression of the intervention?
- For all the two-joint muscles that cross the knee, describe their function at both the knee and the adjacent joint. How can each muscle function most efficiently at the knee in terms of its length-tension relationship?
- Describe the function of the knee during the gait cycle.
  - How much ROM is needed, and when during the gait cycle does the maximum degree of flexion and extension occur?
  - When during the gait cycle is each of the muscles active at the knee, and what are their functions?
  - What gait deviations occur when there is muscle shortening, muscle weakness, and joint pain? Explain why each deviation occurs.
- Two patients, both in their seventies, underwent TKA 10 days ago because of joint degeneration from OA of the right

knee and have been referred to you in your home health practice. One patient had a cemented TKA, and the other had a "hybrid" TKA. How does their postoperative management differ, or how is it similar?

- Describe the structures involved with a lateral retinacular release, a proximal realignment of the extensor mechanism, and a distal realignment procedure. How do these differences impact postoperative rehabilitation?
- What muscles could be weak or tight when a patient demonstrates pelvic drop and valgus collapse at the knee during a single-leg knee bend 6 months following ACL reconstruction? Describe interventions that can be used to correct these problems.

### Laboratory Practice

- Design, set up, and perform a circuit-training course to improve hamstring and quadriceps muscle activation, strengthening, and balance. Sequence the activities from basic to advanced. Observe the accuracy and safety with each exercise, and consider the stresses involved.
- Using mechanical resistance (pulleys, elastic resistance, and free weights), perform exercises to meet each of these objectives:
  - Strengthening the quadriceps with the greatest mechanical torque occurring when the knee is at 90°, at 45°, and at 25°.

- Strengthening the hamstrings with the greatest mechanical torque occurring when the knee is at 90°, at 45°, and at 0°.
3. Review the joint mobilization techniques for the knee; include basic glides, accessory motions, patellar mobilizations, and mobilization with movement techniques.
    - Identify and practice techniques that increase knee extension, beginning with the knee at 45° and progressing by 15° increments until full extension is reached.
    - Do the same for knee flexion, beginning at 25° and progressing by 15° increments until full range is achieved. What accessory motions are necessary?
    - What knee motions may be restricted if the patella does not glide distally?
    - What knee function may be lost if the patella does not glide proximally?
  4. Review and practice soft tissue and patellar mobilization techniques that are used to increase the mobility of the lateral retinaculum and IT band. How does mobilizing this tissue improve patellar tracking? What proximal muscles help to support normal patellar alignment during dynamic activities?
  5. Review and practice self-stretching techniques with and without equipment for all of the two-joint muscles at the knee.

## Case Studies

1. Mrs. James is a 49-year-old mother of three children. She is in good health but is recently experiencing considerable right knee pain, especially when standing after prolonged sitting, when descending stairs, and when on her feet for longer than 2 hours. She reports a right proximal tibial fracture 15 years ago that took approximately a year to return to normal mobility. On examination there is no obvious deformity or joint swelling. Knee flexion is 125° with a firm end feel and pain on overpressure; extension is 0° with firm end feel and pain on overpressure. There is a slight decrease in posterior glide accessory motion of the tibia and decreased mobility of the patella on the right compared to the left. Strength of the knee flexors and extensors is 4/5 bilaterally. She complains of pain in the right knee when squatting; pain begins at 45° flexion. She stops when the knees are at 75°, saying it hurts too much. She bends forward from the waist to pick up objects from the floor. She has difficulty lowering herself down to a low chair in a controlled manner.
  - List her impairments and functional limitations and state appropriate goals.
  - Develop an exercise program to meet the goals. Describe the exercises you will begin with and why they are appropriate. Explain how you will progress each exercise and the program.
  - List the possible manual techniques that would be beneficial to her and describe the rationale for each one.
  - Discuss the home exercises you would suggest and describe how you would teach them to her.
2. Mr. Ray, who is 25 years of age, was in a serious automobile accident and sustained femur and patella fractures of his left leg. His leg was immobilized in a long-leg cast for 3 months, followed by a short-leg cast for an additional month. He was allowed to perform partial weight bearing when in the short-leg cast. The cast was removed this morning, and he is to begin rehabilitation, although he will not be allowed full weight bearing for an additional month. He describes significant stiffness and discomfort when flexing his knee. Observation reveals significant atrophy in his left thigh and leg. There are no open sores or joint swelling. Range is limited to 25° flexion and 20° extension, with no joint play in the tibiofemoral or patellofemoral joints. He has the ability to do quadriceps and hamstring sets, but strength could not be tested.
  - Answer the same questions as in the previous case.
  - Even though patients in this and the previous case have restricted motion and demonstrate weakness, what are the differences in intervention strategies? Are there different precautions that you will follow during treatment? If so, what are they?
